A solution of 3.5*N*-nitric acid, with a platinum electrode, gives correct end-points with bromide-chloride mixtures, but at the final break the curve begins to rise sharply and then drops suddenly back, after which it tends to become horizontal. The system is rather insensitive and the potential readings are jerky and can be read only to the nearest 2 or 3 millivolts.

*N*/10-Nitric acid, with a silver electrode, gives correct end-points, and is very sensitive. For accurate work, involving a long titration time, it is conceivable that an error could be introduced owing to action of the acid on the silver electrode, but with ordinary titrations of a mixture of equivalent proportions, no error was observed. A platinum electrode is unsatisfactory with *N*/10-nitric acid.

It follows from the foregoing that although the presence of certain dyes is beneficial in the case of bromide-iodide mixtures, they are not of general value. On the other hand, barium, sodium, and ammonium nitrate, and sodium acetate in 5% solution give correct end-points with bromide-chloride and bromide-iodide mixtures for a wide variation in the proportions of the constituents of the mixtures. The presence of these salts curtails the titration time by increasing the sensitiveness of titration and lowering the time required for equilibrium potential in the region of the end-points; even for the titration of a single halide in solution their presence is beneficial. In absence of added salts, the silver halides formed in the titration remain in colloidal suspension until the final end-point is reached; if a salt is present, however, the silver halides begin to precipitate shortly after the first addition of silver nitrate.

The original object of this investigation was to study the applicability of electrometric methods to the examination of materials used in the manufacture of photographic emulsions, and to the analysis of emulsions themselves. In all the titrations made, this object was borne in mind. Consequently, in the examination of bromide-iodide mixtures, for example, low percentages of iodide in bromide were considered, rather than low percentages of bromide. A series of mixtures was studied in various circumstances to ascertain if it was easy to estimate a low percentage of one halide in the other. A limit of 0.2% of iodide in bromide and of chloride in bromide was set. The following table shows some results of measurements. The percentage composition refers to equivalents of one halide in another. The substances mentioned in the column

headed "Notes" were added to the electrolyte, 50 c.c. of a 5% solution being used in each case.

Mixture taken.	Vol. in c.c. of <i>N</i> /10-conc.	Found.	Notes.
100% Bromide.	5, 10	100% Bromide.	Same results in water, barium nitrate, sodium acetate, etc. Barium nitrate, etc., <i>must</i> be present.

0.2% " "	50	0.18% "	75 C.c. of 5% am- monium nitrate.

The table shows that it is possible to estimate 0.2% chloride in bromide or iodide, and 0.2% iodide in bromide, with a fair degree of accuracy. The bulk of the halide was precipitated with *N*/10-silver nitrate, but for the estimation of halide present in the proportion of 1% or less, *N*/100- or *N*/1000-silver nitrate was used, an *N*/10-solution being employed only for precipitating the bulk of the halide in excess. The accuracy of estimation of a small percentage of one halide obviously depends on its absolute amount. If the absolute amount is too small, it becomes impossible to estimate the chloride present in low ratio at all, because no distinction is observed between the two breaks in the curve. Using a mixture of *N*/10-strength, it is possible to estimate 0.2% chloride in iodide with 50 c.c., but in the case of 0.2% chloride in bromide, if 50 c.c. are used the breaks in the curve are not separated, and at least 100 c.c. must be taken.

The estimation of low percentages of chloride in iodide or bromide thus involves taking a big bulk of material; this makes the titration very long, and introduces a possible source of error in that some of the chloride solution may be occluded in the bulky silver bromide or silver iodide precipitate. Means were therefore sought by which

the bromide or iodide could be destroyed, at the same time leaving the chloride free in the solution, where it could be titrated.

Numerous methods have been devised for estimating mixtures of halides in which one halogen is removed by oxidation of its halide salt, leaving the other halide intact. Considering a chloride-bromide mixture, however, it is very probable that in the region of the point where practically all the bromide had been destroyed, some of the chloride would be attacked as well. A satisfactory method of operation would be to react with insufficient oxidiser to destroy all the bromide present, leaving, say, equal proportions of bromide and chloride, and then to titrate this mixture electrometrically in the usual way. In this manner, a big bulk of mixture, in which the absolute amount of chloride is high enough for the accuracy required, can be used without the disadvantages already mentioned. There seems theoretically to be no limit to the minuteness of the trace of chloride which could be estimated in this way.

Attempts to destroy all the bromide by means of ammonium persulphate (Engel. Compare Crookes's "Select Methods in Chemical Analysis," 1905, p. 558) or potassium permanganate (Winkler, *Z. angew. Chem.*, 1915, 28, 477, 494) were not successful. In the former case all the bromide could not be destroyed, even when many times the theoretical quantity of persulphate was used, whilst in the latter case some chlorine was always lost in getting rid of the last traces of bromide. For example, a mixture of 2.3800 g. of pure potassium bromide with 0.0050 g. of potassium chloride in 350 c.c. of water was analysed by Winkler's permanganate method, and 0.0038 g. of chloride was found instead of 0.0050 g.

Using just insufficient permanganate to react with all the bromide proved to be a very suitable and accurate means of determining low percentages of chloride in iodide and bromide. The procedure is best illustrated by an actual example, as follows: A mixture of 2.3800 g. of potassium bromide and 0.0050 g. of potassium chloride was dissolved in 350 c.c. of water, 25 c.c. of concentrated sulphuric acid were added, and the whole was boiled. A solution of  $N/2$ -chloride-free potassium permanganate was prepared. A blank test having shown that 43.5 c.c. of this solution were necessary to give a permanent pink colour with the halide mixture used, 43.0 c.c. of permanganate were added slowly to the boiling acidified halide solution, and boiling was continued until all the bromine was removed and the solution became colourless. Ammonium nitrate (10 g.) was dissolved in the solution, which was then cooled and titrated electrometrically with  $N/100$ -silver nitrate. The result was: chloride taken, 0.0050; found, 0.0051 g.

The presence of manganous salts in the titration beaker does not affect the titration adversely in any way. Owing to the presence of sulphuric acid in the solution, it is preferable to add ammonium nitrate or sodium acetate, rather than barium nitrate, for the titration. Although a titration carried out with barium sulphate present gave accurate results, its presence is best avoided if the possibility of occlusion is to be eliminated.

*Estimation of Low Percentages of Bromide in Chloride.*

Although percentages of chloride in bromide from 50% down to 0.2% have been shown capable of accurate estimation, very low percentages of bromide in chloride cannot be accurately determined by direct electrometric titration. It has been found quite impossible, by direct methods of electrometric titration, to determine bromide present to the extent of less than 5% in chloride.

The following observations were made with 5% bromide in chloride of *N*/10-strength: (a) with 20 c.c. of mixture + 150—200 c.c. of 5% ammonium nitrate titrated with *N*/100-silver nitrate, a curve was obtained, with no sign of a sharp break, but merely a slight increase of slope over a long range of c.c. silver nitrate added.

(b) (a) was repeated in presence of saturated ammonium nitrate solution with the same results.

The absence of a sharp break is peculiar. When a mixture of, say, equal proportions of chloride and bromide is titrated, the composition varies until it passes through a stage at which there is 5% bromide in chloride, and yet a sharp bromide end-point is obtained. The only difference between this and the cases (a) and (b) above is that there is a bulk of silver bromide present, owing to precipitation of the first 45% of bromide.

(c) In order to simulate these conditions, 20 c.c. of *N*/10-ammonium bromide were titrated to the end-point with *N*/10-silver nitrate. 20 C.c. of *N*/10-5% bromide in chloride were then added, and the titration was continued with *N*/100-silver nitrate. The same results were found as in (a) and (b). By plotting the curves of (a), (b), and (c) on a more closed scale, a fairly sharp increase of slope was observed in the neighbourhood of the theoretical end-point, but it was impossible to locate the end-point with any degree of certainty.

Titration with *N*/100-silver nitrate is thus useless for determining 5% of bromide in chloride. The only way of obtaining satisfaction seemed to be to work with a higher concentration of silver nitrate, and a bigger bulk of halides.

(d) 10 C.c. of 5% bromide in chloride + 50 c.c. of 5% barium nitrate, titrated with *N*/10-silver nitrate, gave a sharp break at

0.5 c.c. of silver nitrate, the theoretical value. The degree of accuracy to be expected with a titre of 0.5 c.c. is, however, low.

(e) (d) was therefore repeated with 100 c.c. of 5% bromide in chloride. Solid ammonium nitrate was dissolved in this, and it was titrated with  $N/10$ -silver nitrate. A definite break was obtained in the titration curve, and its inflexion point being taken as the bromide end-point, the theoretical bromide value was found. A quotation from Müller has already been cited, in which he states that bromide cannot be accurately determined in presence of chloride, unless the molar concentration of bromide exceeds that of chloride by five times.

As shown above, however, it is possible to estimate 5% bromide in chloride of  $N/10$ -strength by titration of 100 c.c. with  $N/10$ -silver nitrate. Percentages less than 5 cannot be so estimated with any degree of accuracy. The difficulty could probably be overcome by adding a known amount of bromide to adjust the ratio of  $\text{Br}^- : \text{Cl}^-$  to 1 : 1, titrating this mixture, and obtaining the original bromide by difference. The objection to this seems to be that any error in the titration of the total halide would be thrown on to the small percentage of bromide originally present.

Müller ("Elektrometrische Massanalyse," 2nd edn, 1923, p. 95), titrating 5% bromide in chloride directly, got accurate results\* in presence of barium nitrate, but a + 16% error in the bromide in absence of barium nitrate. With a 2.5% bromide in chloride he got an error of + 16% in presence of barium nitrate, and + 36% in absence of added salts. These results have been substantially confirmed in the experiments described here.

To estimate low proportions of bromide in chloride it thus appeared necessary to isolate the bromide as bromine either free from chlorine, or else with such an amount of chlorine as to give a preponderance of bromine, convert the bromine (and chlorine) into bromide (and chloride), and then titrate the bromide electrometrically. The presence of a small amount of chloride from chlorine carried over with the bromine will not be harmful, since, as has been shown, low ratios of chloride in bromide can be readily estimated.

Removal of bromine with bromate in acid solution was first tried. The method was satisfactory for 28.6% bromide in chloride, but for 1% bromide, it gave very variable results, and was therefore abandoned.

The use of permanganate proved to be satisfactory. The apparatus consists of a conical flask fitted with a stopper (preferably

\* This appears from Müller's table (p. 95) to be just a chance accuracy, and is contradictory to a statement by Müller quoted earlier in this paper.

of glass, ground in) carrying a graduated tap funnel for the permanganate, and a tube with a trap, leading to a vertical condenser dipping into ammonia in a receiving flask. The bromide-chloride mixture is put in the conical flask together with plenty of sulphuric acid and boiled. Permanganate is run in drop by drop until the pink colour persists for a short time, and then a further addition of about the same volume of permanganate is made, and the solution is boiled for some time, until it loses its colour. The ammonia in the receiver is acidified, ammonium nitrate added and the solution titrated as usual. The following figures show that this method is capable of a fair degree of accuracy :

Mixture examined.	Bromide in chloride.	
	Theoretical %.	% Found.
200 C.c. of 1% bromide in chloride ( <i>N</i> /10).	1	(1) 0.95
40 C.c. of 0.5% bromide in chloride ( <i>N</i> /10).	0.5	(2) 0.9 0.49

A further attempt to estimate bromide in chloride was made using the method of Willard and Fenwick (*J. Amer. Chem. Soc.*, 1923, 45, 623), in which the halides are mixed with potassium cyanide solution and sulphuric acid and titrated electrometrically to the CNBr end-point with permanganate solution. The method was tried with a platinum electrode and calomel cell, but the potential readings were very inconsistent and jerky, and the rate of attainment of equilibrium of potential was very variable. The method of Willard and Fenwick depends on the same reaction as that employed by Müller and Schuch (*Z. Elektrochem.*, 1925, 31, 332) for estimating halogens in solution by electrometric titration with cyanide. Various modifications of this method were tried without success.

The ingenious method of "differential titration" due to Cox, already mentioned, was investigated for the titration of bromide with silver nitrate, and good results were obtained. An example of the method used is as follows : 10 c.c. of *N*/10-bromide + 200 c.c. of water were put into each of two beakers. The solutions were united by a bridge of saturated ammonium nitrate solution, and silver electrodes were immersed one in each solution and connected to the potentiometer. The two solutions were titrated simultaneously with *N*/10-silver nitrate from two burettes, one being kept 0.2 c.c. ahead of the other, the *E.M.F.* being measured after each addition of silver nitrate as usual. A very sharp maximum was obtained, and equilibrium was practically instantaneous. Bromide found = 20.1 c.c.; theoretical = 20.14 c.c. of *N*/10-Ag. The method is thus satisfactory for plain bromide solution. Its advantages are that it eliminates the use of the calomel cell, and

equilibrium is instantaneous at the end-point. Its disadvantage is that manipulation of two burettes is necessary. On the whole, however, it appears to possess no ultimate advantage over the ordinary method.

The differential method was tried for the estimation of 1% bromide in chloride, but without success. At the bromide end-point the curve certainly tended to a maximum, but this could not be definitely located.

#### *Estimation of a Mixture of Three Halides.*

Since a pair of soluble halides can be estimated accurately under certain conditions, it is to be expected that a mixture of three halides could just as accurately be determined under similar conditions.

A mixture containing 3% iodide and 1% chloride in  $N/10$  bromide was examined. This ratio represents possible proportions of halide in a photographic preparation. 20 C.c. of the mixture + 200 c.c. of 5% barium nitrate solution were taken; the bulk was titrated with  $N/10$ -silver nitrate and the end-points were determined with  $N/100$ -silver nitrate. Taken: bromide, 19.48; chloride, 0.23; iodide, 0.59. Found: bromide, 19.48; chloride, 0.22; iodide, 0.59 (the figures denote equivalents of  $N/10$ -silver nitrate).

#### *Analysis of Silver Halides.*

In the analysis of silver halides by electrometric methods, two methods of procedure are possible. The first is to dissolve the silver halides in a suitable solvent and titrate directly the solution obtained. The second method is to set free the halogen from the silver halides in the form of soluble halides, which can be readily titrated by the normal methods.

The only method of the first type known to the author is that due to Müller (*Phot. Ind.*, 1924, 305, 332). The silver halides are dissolved in a slight excess of potassium cyanide solution, and the resulting solution is titrated electrometrically with silver nitrate. The theory of the titration and the method of deducing the results are lucidly described in Müller's original paper. Müller claims satisfactory results in the titration of a single silver halide, and with mixtures of silver iodide with silver bromide or silver chloride. Numerous measurements made to check the accuracy of the method have fully substantiated Müller's claims. The method suffers, however, from a serious limitation in that it does not distinguish between silver bromide and silver chloride. In the analysis of many photographic materials this should be of no account, since the majority of fast plates should consist entirely of silver bromide

and silver iodide mixtures. In the case of some plates, however, chloride is added in addition to the other two halides, and in most cases chloride is present unintentionally because the soluble iodide and bromide used in making the emulsions are rarely, if ever, free from chloride. For the analysis of chloro-bromide emulsions, Müller's method would obviously be unsuitable.

Owing to the limitations of Müller's method, the second type of method, in which the silver halides are converted into soluble halides, was investigated. Samples of pure silver halides were first prepared in the following manner. The preparations were carried out in red light, and the products were stored in dark brown glass bottles.

*Silver chloride* was prepared by adding silver nitrate drop by drop to a vigorously stirred solution of pure potassium chloride until the slightest excess of chloride remained. The precipitate was washed many times with water, and drained by suction. One sample of chloride was dried in a desiccator, but formed such hard lumps that it could not readily be dissolved in cyanide solution. The moist preparation was therefore used.

*Silver bromide* was prepared from a sample of commercial potassium bromide containing about 1% of chloride. It was dissolved in 5% ammonium nitrate solution, and silver nitrate, also in 5% ammonium nitrate solution, was run in drop by drop, the whole being vigorously stirred. Silver nitrate equivalent to 14/17 of the bromide was added during 3 hours. The precipitate was washed five times by decantation, collected, and dried in a desiccator.

*Silver iodide.* Part of the damp sample made for the preparation of pure soluble iodide, as described earlier, was dried in an electric oven at 105°.

### *Conversion of the Silver Halides into Soluble Halides.*

Two methods of reduction of the silver halides to give the halogen in the form of soluble halides were investigated: (a) Direct reduction of the solid silver halide. (b) Reduction of the silver halide in solution.

*Method (a).*—The simplest method of getting the halide in the soluble form is direct reduction of the solid silver salt by a substance such as hydroxylamine. For electrometric titration it is necessary that the excess of the reducing agent be rendered harmless in some simple way which does not involve any loss of halogen.

Destruction of any excess of hydroxylamine could be satisfactorily carried out by gentle ignition with excess of alkali at about 200°. Oxidising agents, which would probably cause loss of halogen, should not be used.

Formic acid was unsuitable as a reducing agent, even on prolonged boiling with the silver salts. Reduction was far from complete, and chocolate-brown products resembling the synthetic photo-halides were formed. Hydroxylamine sulphate in alkaline solution was very efficient, but the reduction of solid silver halides by its means, even on very prolonged stirring, was incomplete in the majority of cases. The spongy silver mass obtained invariably contained traces of unreduced silver halide, which could be detected by dissolving the silver in nitric acid. Attempts were made to peptise the silver halides before reduction and thus render the reduction quantitative. Octyl alcohol was useless for this purpose. Addition of a known excess of potassium iodide gave a finely-divided suspension in the case of silver iodide, but the excess of halogen ions slowed down the rate of reduction so much as to render its use impracticable.

Boiling a suspension of silver iodide in water with zinc and dilute acetic acid gave incomplete reduction.

*Method (b).*—Reduction of the solid halide having proved useless for obtaining quantitative conversion to soluble halide, the reduction of the solution of the silver halides in potassium cyanide solution was investigated. A solution of silver iodide in cyanide was treated with (a) alkaline hydroxylamine, (b) alkaline hydrazine hydrate, (c) sodium hydrosulphite [hyposulphite], and (d) diaminophenol (amidol). With (a) there was no reduction in 18 hours, and with (b) in the same time, only a trace of action. Hydrosulphite reduced the solution directly to silver; and amidol caused reduction on long standing, but there was simultaneous formation of undesirable oxidation products.

When hydrosulphite is added to a solution of silver iodide in cyanide, precipitation of the silver iodide first occurs, and this is followed rapidly by its reduction. If the solutions are too concentrated, coagulation of the silver iodide occurs before it is reduced, and results in a part of the silver halide inside the curds remaining unreduced. Complete reduction of the silver halide can be effected by working in dilute solution, and adding the hydrosulphite solution a little at a time. On each addition a yellow colloidal solution of silver iodide forms. The next addition of hydrosulphite should not be made until reduction of the colloidal suspension due to the previous addition begins.

Attempts were made to prevent coagulation of the silver iodide by adding colloids before reduction. Gelatin and gum arabic effectively prevented coagulation, but their use resulted in the formation of a protected colloidal silver sol on reduction, and this could not be removed by filtration, even after prolonged boiling

with electrolytes. More satisfactory results were obtained with dextrin; the silver formed on reduction with hydrosulphite readily coagulated on boiling, and could be filtered off.

The excess hydrosulphite can be destroyed by boiling with acid, which also removes all the cyanide ions, and the solution of soluble halides is then ready for titration, after addition of barium nitrate or other salt.

Almost all commercial samples of sodium hydrosulphite contain appreciable quantities of chloride. This makes the hydrosulphite method dependent on the ability to obtain the chloride-free product, the application of a correction for chloride being undesirable. Attempts made to prepare pure hydrosulphite as required, *e.g.*, by passing sulphur dioxide gas into water containing metallic zinc, or into a solution of sodium sulphite containing zinc were not satisfactory. Combination of the two operations of preparing hydrosulphite and reducing the silver complex by passing sulphur dioxide into a cyanide solution of silver iodide containing sodium sulphite and metallic zinc did not give very satisfactory results.

*Reduction with Zinc.*—Although hydrosulphite is very satisfactory for reducing the cyanide solution, the difficulty of getting samples free from chloride led to trials with other reducing agents, of which zinc dust or granulated zinc, with acetic acid, proved very satisfactory.

Boiling the solution with granulated zinc and acetic acid gives complete reduction. On adding the acetic acid there is a tendency to form colloidal silver halide, but although in certain cases coagulation sets in, it is not of such a nature as to prevent complete reduction to silver. Addition of sodium acetate to the acetic acid, lowering the acidity to  $p_H$  4.8, did not prevent some silver salt being thrown out of solution.

Results as satisfactory as those obtained with granulated zinc and acetic acid are obtained by boiling with granulated zinc or zinc dust without acid, and no precipitation of silver halide occurs in these cases. It is necessary, however, to add acetic acid after the reduction is over in order to remove the excess of cyanide. The disadvantage in the case of zinc dust is that many samples contain chloride, whereas granulated zinc can be readily obtained very pure.

The conditions for titration of the reduced solution are as follows :

- (1) No free cyanide must be present. This is ensured by boiling with acetic acid.

- (2) Presence of free acetic acid has no adverse effect on the titration of mixed halides. In fact, sodium acetate has been shown to be advantageous.

(3) Undissolved zinc must be filtered off, otherwise further reduction will occur during the titration with silver nitrate.

(4) Zinc ions present in the titration must have no adverse effect. That they do not affect the titration was shown by control titrations to which zinc sulphate had been added.

(5) Boiling a solution of soluble halide with zinc and acetic acid must not result in loss of halogen. Blank experiments showed that no such loss occurred.

The method was then tested quantitatively, with known amounts of standard solutions of silver halides in potassium cyanide. Müller's titration method (*vide supra*) was employed for standardising these solutions. Use of this method for estimating known weights of silver halide in cyanide solution gave very accurate results, and justified its use for the standardisation of solutions. 20 C.c. of the standard solutions of silver iodide, bromide, and chloride were equivalent to 17·20, 27·10, and 7·65 c.c., respectively, of *N*/10-silver nitrate.

Both granulated zinc and zinc dust reduction gave accurate results with all three halides. The method finally used in all cases is illustrated by the following example :

Stock silver iodide-potassium cyanide solution (20 c.c.) was diluted to about 100 c.c. with water and heated, 1—2 g. of granulated zinc in small pieces were added, the solution was boiled vigorously for 10—15 minutes, 50 c.c. of acetic acid (100 c.c. of glacial acid diluted to 1 litre with water) were added, and boiling was continued vigorously until all smell of cyanide had disappeared. The solution was then cooled and decanted through a filter, the metallic residue being carefully washed several times. Ammonium nitrate was added to the combined filtrate and washings to make about 5% concentration, and titration was carried out electrometrically in the manner already described.

The quantities taken and found, expressed as c.c. of *N*/10-silver nitrate, were : silver iodide, 17·20 and 17·20; silver bromide, 27·10 and 27·10, 27·05; silver chloride, 7·65 and 7·65. The conversion of silver halide into soluble halide is thus quantitative. There should therefore be no more difficulty attending the estimation of mixed silver halides than was the case with mixtures of soluble halides already described. For this reason, exhaustive investigation of mixed silver halides was not made. For two mixtures of silver iodide and silver bromide, reduced with zinc and acetic acid, the values, in c.c. of *N*/10-silver nitrate, were : (1) Bromide : taken, 27·10; found, 27·05. Iodide : taken, 4·30; found, 4·30; (2) Bromide : taken, 27·10 found, 27·09. Iodide : taken, 0·43; found, 0·41.

*Analysis of Photographic Emulsions.*

The method described above was applied to the analysis of photographic emulsions.

Preliminary experiments were made to ascertain whether the reduction of silver halides could be satisfactorily carried out in presence of gelatin. A mixture of standard potassium cyanide-silver iodide solution, 100 c.c. of water, and 25 c.c. of 1% gelatin was heated to boiling, granulated zinc and 50 c.c. of 10% acetic acid were added, and the boiling was continued. In  $\frac{1}{2}$  hour very little reduction had occurred, and the silver halide which had been thrown out of solution was carried away from the sphere of reduction by the frothing gelatin. Several hours' boiling had not resulted in complete reduction.

In another case, the emulsion was scraped off a soaked photographic plate into water, which was heated to disperse the gelatin. Cyanide was added to dissolve the silver salts, and the whole was boiled with zinc and acetic acid. After several hours, reduction was again incomplete.

It was obvious that the presence of gelatin was to be avoided. If the emulsion is boiled with nitric acid to destroy the gelatin there is an element of risk involved, in view of the known action of nitric acid in freeing halogen from silver halides. Lehmann and Bolmer (*Phot. Ind.*, 1922, 467, 491) found that cold nitric acid above a concentration of 47%, and hot nitric acid above 5%, converts silver iodide into silver nitrate and iodine. If, however, 5% nitric acid is used for destroying the gelatin, the halide remains in suspension and cannot be filtered. The workers mentioned recommended a mixture of 4% nitric acid in 20% acetic acid for isolating the silver halide. Valenta (*Phot. Korrr.*, 1914, 51, 122; "Photographische Chemie und Chemikalienkunde," I, 2nd edn, 1921, p. 151) used 20% nitric acid for destroying the gelatin. This practice is criticised by Lehmann and Bolmer, and is shown to lead to errors.

It appeared preferable to avoid the use of oxidising acids for the destruction of the gelatin, in the case of plates, at any rate. The method of fixing out the silver halides with cyanide was therefore tried, with success; this has the advantage of eliminating the need for stripping the emulsion.\*

Numerous commercial plates were investigated, to ascertain the best conditions for analysis. With plates of fast, or special rapid

\* If stripping is considered desirable, it can readily be carried out by means of alkaline sodium benzoate, prepared by dissolving benzoic acid in excess of caustic soda solution.

type, one half-plate provides a suitable quantity of material for investigation, but in the case of thinly-coated plates of the process type, two half-plates should be used.

The method of analysis finally adopted for a half-plate is as follows:

The plate is fixed out in a dish with 100 c.c. of *N*/10-potassium cyanide, and washed by soaking (5 minutes) in three changes of 100 c.c. of water. No silver salts can, in general, now be detected in the gelatin film. As a precaution, however, after washing, the plate is spotted with sodium sulphide; the absence of a brown stain indicates freedom from silver salts. The washings and fixing solution are combined, reduced with zinc and acetic acid, and treated as described for the examination of mixed silver salts. *N*/100- or *N*/10-Silver nitrate is used for titration, according to the amount of the particular halide being analysed. Owing to a slight action of the cyanide solution on the gelatin of the plate, a little gelatin sometimes goes into solution, but it only results in a somewhat slower attainment of equilibrium of potential when dilute silver nitrate is used. With *N*/10-silver nitrate, equilibrium is attained at the normal rate.

The following table shows the results obtained in the analysis of a few commercial plates. These plates were of *unknown* composition, and so no check on the results was available.

Plate.	Size.	AgI.	AgBr.	Total halide.	% AgI.
A. Special rapid.	$\frac{1}{4}$	0.41	6.74	7.15	5.73
B. " "	$\frac{1}{4}$	0.47	8.18	8.65	5.44
C. " "	$\frac{1}{2}$	0.52	13.88	14.40	3.61
D. " "	$\frac{1}{2}$	0.55	13.61	14.16	3.88
E. Process.	$\frac{1}{2}$	0.11	9.30	9.41	1.17

Plates A and B were of one brand. It does not follow from this that they are of identical composition, since variations often occur among plates of the same manufacture. Also it is improbable that the total amount of silver halide is identical on both plates. Similar remarks apply to C and D. The values in columns 3, 4, and 5 refer to c.c. of *N*/10-silver nitrate equivalent to the halides.

At the time when these measurements were made, only one emulsion of accurately known composition was available. Duplicate analyses were made of half-plates hand-coated with this emulsion, with the following results:

	AgI.	AgBr.	Total halide.	% AgI.	
				Found.	Theor.
Plate 1 .....	0.81	19.83	20.64	3.92	3.95
Plate 2 .....	0.80	19.57	20.37	3.92	3.95

The method thus appears capable of giving accurate results. It possesses the great advantage of ease and comparative rapidity.

The author wishes to express his gratitude to Dr. T. Slater Price, F.R.S., Director of Research to the British Photographic Research Association, for the interest he has taken in this work, and for the valuable criticism and advice he has given.

## CV.—*The Absorption Spectra of Various Derivatives of Salicylic Acid.*

By JOHN EDWARD PURVIS.

THE author described (J., 1925, 127, 2771) the absorption spectra of various compounds derived from salicylic acid in order to compare the influence of different types of nuclei. The investigation has been continued with the following coloured and colourless salts and other compounds of the acid. The substances were examined in the first instance in  $M/200$ -solutions, with the exceptions of 3-nitrosalicylic acid and 5-aminosulphosalicylic acid, which were not so soluble. These were examined in  $M/2000$ - and  $M/20,000$ -solutions.

*Lithium, calcium, and zinc salicylates.* The curves (Fig. 1, upper curves) show in the lithium compound a band at  $1/\lambda$  3350 ( $\lambda$  2984) comparable with that of salicylic acid (*loc. cit.*), but the more refrangible band between  $1/\lambda$  4120 ( $\lambda$  2425) and  $1/\lambda$  4300 ( $\lambda$  2320) is not so well marked as that in salicylic acid. In the calcium and zinc salts, somewhat similar phenomena were noticed; and there are differences in the positions of the bands dependent on the respective molecular weight. The less refrangible band of the monobasic lithium salt is not, of course, so strong as that of the calcium and zinc salts.

*Lithium o-acetoxybenzoate* (Fig. 1, upper curves). The replacement of the hydroxyl hydrogen atom by the acetyl group has produced a similar change to that in salicylic acid and *o*-acetoxybenzoic acid, and in theobromine salicylate and theobromine *o*-acetoxybenzoate (*loc. cit.*). The less refrangible band at  $1/\lambda$  3740 ( $\lambda$  2672) is very weak and is shifted towards the more refrangible regions; and the more refrangible band is represented by a more rapid extension of the rays from about  $1/\lambda$  4020 ( $\lambda$  2486). As the author has previously pointed out in the case of *o*-acetoxybenzoic acid, this has produced an absorption comparable with that of benzoic acid.

*Copper salicylate* (bluish-green). The curve (Fig. 1, lower curves)

shows the less refrangible band of salicylic acid well developed, and the more refrangible one is nearly obliterated. There is a rapid absorption of the rays between about  $1/\lambda$  2850 ( $\lambda$  3506) and  $1/\lambda$  2550 ( $\lambda$  3919), extending well into the visible region.

*Uranyl salicylate* (reddish-brown). The curve (Fig. 1, lower curves) has a somewhat similar form to that of copper salicylate,

but the band between  $1/\lambda$  2940 ( $\lambda$  3400) and  $1/\lambda$  2520 ( $\lambda$  3967) is better marked, and there is another band on the less refrangible visible parts at about  $1/\lambda$  2200 ( $\lambda$  4544). The band at  $1/\lambda$  3400 ( $\lambda$  2940) is wider than the corresponding band of the copper salt.

*3-Nitrosalicylic acid* (yellow), *3:5-dinitrosalicylic acid* (yellow). In each of these substances there is a large band extending into the visible region (Fig. 2, upper curves), and it is much wider than

the corresponding bands of the substances described above. The more refrangible band is merely indicated by the more rapid extension of the rays from  $1/\lambda$  4000 ( $\lambda$  2498) to  $1/\lambda$  4400 ( $\lambda$  2271) in the nitro-compound, and from  $1/\lambda$  3920 ( $\lambda$  2550) to  $1/\lambda$  4350 ( $\lambda$  2298) in the dinitro-compound. These results are not unlike those described by the author (J., 1915, 107, 966) in the case of some nitro-compounds of benzoic and cinnamic acids.

FIG. 2.

5-Sulphosalicylic acid, 5-aminosulphosalicylic acid. These two substances show (Fig. 2, lower curves) that the more refrangible band of salicylic acid is not so definite, but in each case the less refrangible one is well marked. In the amino-compound this band is not quite so strong as it is in the sulpho-compound, and there are differences in the persistency.

5-Nitrosulphosalicylic acid (yellow). There is a wide band

(Fig. 2, lower curves) at  $1/\lambda$  3000 ( $\lambda$  3344) not unlike that of the other nitro-compounds, and extending into the visible region. The more refrangible one almost disappears.

*Sodium 3-nitro-5-aminosalicylate* (reddish-brown). This substance (Fig. 2, lower curves) exhibits a large band at  $1/\lambda$  2750 ( $\lambda$  3633) which extends rapidly into the visible regions. This band may be compared with that of the other nitro-compounds. There is also a shallow band from about  $1/\lambda$  3400 ( $\lambda$  2939) to  $1/\lambda$  3930 ( $\lambda$  2543).

*Hexamethylenetetramine*, *Hexamethylenetetramine salicylate*. Through 56 mm. thickness of a  $M/200$ -solution hexamethylenetetramine exhibited no band; and the rays were transmitted to  $\lambda$  2150. Its salicylate, on the other hand, exhibited an absorption band comparable with that of salicylic acid. Paraldehyde shows no specific absorption (J., 1925, 127, 9); and it is suggested that, like paraldehyde, the condensation of formaldehyde with ammonia in the production of hexamethylenetetramine neutralises the free valencies of the aldehydic oxygen which produce a band in formaldehyde itself.

*Results.*—Considering these results with those of salicylic acid and its various salts (*loc. cit.*), it appears that the specific absorption of the substances depends on the nature of the basic and of the acid radicals. Changes in the nature of the one or the other produce changes in the position and intensity of the bands characteristic of each. The author has already shown, in a study of the absorption spectra of some organic and inorganic salts of didymium (*Proc. Camb. Phil. Soc.*, 1923, 21, 781), that the bands of didymium in the visible regions were modified in intensity according to the type of the negative radical united with this base.

As regards the other derivatives of salicylic acid, the influence of the nitro-group in the benzene radical powerfully intensifies and shifts the less refrangible band of the acid, but appears to lessen that of the more refrangible one. Also the replacement of the hydrogen atom of the hydroxyl group by a radical, as in lithium salicylate and lithium *o*-acetoxybenzoate, changes the absorption capacity of the other parts of the molecule; and this is comparable with the phenomena of *o*-acetoxybenzoic acid, and of the *o*-acetoxybenzoates of theobromine and quinine.

CVI.—*Elimination of the Amino-group of Tertiary Amino-alcohols. Part III. A New Method for the Preparation of Optically Active Ketones.*

By ALEX. MCKENZIE, ROBERT ROGER, and GEORGE OGILVIE WILLS.

PREVIOUS research (McKenzie and Richardson, J., 1923, **123**, 79; McKenzie and Roger, J., 1924, **125**, 844; McKenzie and Dennler, J., 1924, **125**, 2105; McKenzie and Wills, J., 1925, **127**, 283) carried out in this laboratory on the behaviour of certain tertiary amino-alcohols towards nitrous acid has demonstrated that in no case was the glycol corresponding with the amino-alcohol isolated, although such glycols are readily enough accessible in other ways. The action is thus an abnormal one, the product invariably being a ketone (a dehydration product of the glycol). At once the simplest and the most obvious interpretation would be based on the assumption that the glycol is formed as an intermediate phase and then undergoes dehydration. This is an assumption which is, however, untenable, and the experimental evidence is conclusive in proving that a hydrocarbon residue migrates from one carbon atom to another adjacent to it. A process, such as this, for effecting the migration of groups was designated by McKenzie and Roger as "semipinacolinic deamination" from its analogy with the semipinacolinic changes which have come under the observation of Tiffeneau, Orékhov, and their colleagues.

The latter chemists, as well as Meerwein, have studied the dehydration of glycols where the two hydroxyl groups are bound to contiguous carbon atoms by gripping forces which vary in intensity. Wherever the variation of this gripping force is very great, that is to say, when the one hydroxyl group is very firmly and the other very loosely bound, the investigation of the dehydration of a glycol does occasionally provide a good indication of the migrational aptitude of groups. But, especially in other cases, semipinacolinic deamination is proving of service where the evidence deduced from the dehydration of glycols as to migrational aptitude is rather inconclusive. In fact, the method possesses the advantage of being a general one for testing the migrational aptitude of groups, as the elimination of the amino-group necessarily involves group transposition :

An extension of the method has lately been published by Orékhov

and Roger (*Compt. rend.*, 1925, **180**, 70) to embrace tertiary amino-alcohols where the amino-group is attached to a secondary carbon atom. Thus, the action of nitrous acid on  $\beta$ -hydroxy- $\beta\beta$ -diphenylethylamine leads to the formation of deoxybenzoin and not of *as*-diphenylethylene oxide, whilst the interpretation advanced by us agrees with that of Orékhov and Roger. Again, the superiority of the migrational aptitude of the *p*-anisyl as compared with the phenyl group is shown by the formation of *p*-methoxydeoxybenzoin from  $\beta$ -hydroxy- $\beta$ -phenyl- $\beta$ -anisylethylamine:

Further, when  $\beta$ -phenyl- $\beta$ -( $\alpha$ )-naphthylethylamine is deaminated (Luce, *Compt. rend.*, 1925, **180**, 145), the naphthyl group wanders more readily than does the phenyl group, since  $\omega$ - $\alpha$ -naphthyl-acetophenone is formed:

In the present paper, an application of our method to optically active amino-alcohols is described. The products are ketones, and it is remarkable that *optical activity is preserved in spite of the molecular rearrangement which is involved*.

It may be recalled that in the formation of diphenylacetone from  $\beta$ -hydroxy- $\alpha\beta$ -diphenylpropylamine a phenyl group migrates from a carbon atom to the adjacent one to which a phenyl group is already attached, and it would not therefore be anticipated (since diphenylacetone does not possess an asymmetric carbon atom) that the resulting ketone would be optically active if the starting point were the optically active amino-alcohol. The action of concentrated sulphuric acid on methylhydrobenzoin, the glycol corresponding with the above amino-alcohol, forms a striking contrast to the above, inasmuch as there is no group wandering, the change being what Tiffeneau calls "vinyl dehydration":

Now when the dextrorotatory methylhydrobenzoin, obtained by acting on *l*-benzoin with magnesium methyl iodide, is dehydrated with concentrated sulphuric acid, the resulting methyldeoxybenzoin is optically inactive, as it would necessarily be if the mechanism of

the action were that of vinyl dehydration. But McKenzie and Roger (J., 1924, 125, 2148) have shown that, when the dehydrating agent is dilute sulphuric acid, the optical activity does not disappear; the product is not, however, an optically active methyldeoxybenzoin, but the lævorotatory diethylenic oxide,  $\left(\text{CPhMe}\cdot\text{CHPh}\right)_2$ . It is possible that the *r*-methyldeoxybenzoin, which is formed when concentrated sulphuric acid is employed, is produced from the lævorotatory diethylenic oxide formed as an intermediate phase, whilst racemisation accompanies the transformation of the oxide into the *r*-ketone.

In the experimental section, the preparation of *d*-methyldeoxybenzoin is described. *d*-Alanine was converted into its ethyl ester hydrochloride, from which 1-β-amino-α-diphenyl-*n*-propyl alcohol was obtained by the action of magnesium phenyl bromide.\* When the amino-alcohol, with  $[\alpha]_D - 82^\circ$  in chloroform, is acted on by nitrous acid, it gives the *d*-ketone with  $[\alpha]_D + 207^\circ$  in the same solvent. On the interpretation of semipinacolic deamination, the following mechanism is suggested:

In a discussion of the Walden inversion, Büllmann (*Annalen*, 1912, 388, 330) depicts the action of silver nitrate on α-bromopropionic acid as taking place between the silver ion and the acid ion on the lines:

The resulting "Zwitterion" then combines with the hydroxyl ion from water:

\* The designations *d*- and *l*- throughout this paper mean dextrorotatory and lævorotatory, respectively, and do not refer to configurative relationships. The dextrorotatory alanine is converted in the above case into a lævorotatory amino-alcohol which is, however, configuratively related to the parent amino-acid.

Biilmann advanced this idea as a basis of some generalisations which are untenable, as they were framed on an imperfect recognition of the literature and were not in accordance with the experimental facts. McKenzie and Clough (J., 1913, **103**, 687), in their criticism of Biilmann's paper, pointed out that since a "Zwitterion" is supposed to be electrically neutral, it cannot even be urged that a free electric charge plays the part of the fourth grouping which is necessary for the retention of asymmetry. At the same time, the conclusion was drawn that if Biilmann's idea were accepted, the formation of an optically active structure containing a tervalent carbon atom must be admitted, a view for which there was not the slightest experimental evidence.

It might be submitted that such evidence is now forthcoming in the retention of asymmetry during the formation of *d*-methyldeoxybenzoin (IV) from *l*- $\beta$ -amino- $\alpha\alpha$ -diphenyl-*n*-propyl alcohol (I). Various interpretations could be advanced, and of these the one which we favour as being the least unsatisfactory is the following. After the elimination of the nitrogen from (II), the carbon atom (*a*), from which the nitrogen has been detached, retains an electric charge *K*; the oxygen atom attached to the contiguous carbon atom (*b*) also retains an electric charge *K'*, so that (III) would be written thus (A) :

Were those charges of opposite kinds, positive and negative, the formation of diphenylpropylene oxide (B) would have been anticipated instead of that of the isomeric methyldeoxybenzoin. Now diphenylpropylene oxide (Stoermer, *Ber.*, 1906, **39**, 2288) is a stable compound, which under the experimental conditions adopted would have been isolated if it had been formed. Since it is not formed, the assumption—a very problematical one—is made that the electric charges as pictured above are of the same sign, and repel one another. During the transposition of a phenyl group to carbon atom (*a*), we are dealing with a reaction of substitution, the charge *K* playing the part of a group and being displaced by a phenyl group which may or may not occupy the position vacated by the amino-group, so that on this picture a *Walden inversion* is possible within the molecule itself.

There is no evidence available as to whether *d*-methyldeoxybenzoin has the same configuration as the *d*-alanine from which it is prepared; so far as is known, it may equally well have the

opposite configuration. Now one of us in the course of work on the Walden inversion has shown that displacement racemisation very frequently accompanies the displacement of groups in optically active compounds, especially in such as have a phenyl group attached to the asymmetric carbon atom, and it is thus rather significant that the crude product from the deamination of the *l*-amino-alcohol gave a value for its specific rotation which is considerably below that of the optically pure ketone (see experimental part). In this product we probably had to deal with a mixture of the *r*- and *d*-ketones, from which the latter was easily isolated by repeated crystallisation.

There are several examples on record where an electric charge is put forward as playing the part of a group in retaining asymmetry. For example, Marvel and Noyes (*J. Amer. Chem. Soc.*, 1920, **42**, 2259) point out that the electronic formula for an aliphatic diazo-compound suggests the possibility of such a compound exhibiting optical activity, although this is not apparent from the formulæ either of Curtius or of Angeli and Thiele. Chiles and Noyes (*J. Amer. Chem. Soc.*, 1922, **44**, 1798) claim to have obtained several optically active aliphatic diazo-compounds which do not contain an asymmetric atom in the old sense of the term, thus diethyl diazoglutarate is formulated as (C) on the basis of the Angeli-Thiele scheme,

which is in better agreement with the modern views of Lewis and Langmuir than is (D) on the Curtius scheme. Further observations by Levene and Mikeska (*J. Biol. Chem.*, 1922, **52**, 485; 1923, **55**, 795) on diethyl diazosuccinate indicate that a compound of the type  $\text{N}_2 = \text{C} \begin{array}{l} \text{R}_1 \\ \text{R}_2 \end{array}$  can exhibit optical activity, whilst Phillips (*J.*, 1925, **127**, 2552) has described an optically active form of ethyl *p*-toluenesulphinate,  $\text{EtO} \cdot \text{S}^+(\bar{\text{O}}) \cdot \text{C}_6\text{H}_4$ . In a recent historical survey (*Die Naturwissenschaften*, 1925, 331) Walden has also directed attention to the asymmetry of the sulphur, selenium, and tin compounds prepared by Pope, and suggests that the sulphur atom in the optically active methylethylthetine ion,  $\text{CH}_3 > \text{S} \begin{array}{l} \text{CH}_2 \cdot \text{CO}_2\text{H} \\ \text{C}_2\text{H}_5 \end{array}$ ,

for example, has an electric charge which plays the part of a group.

Other examples of the application of semipinacolinic deamination for the preparation of optically active ketones are now described. Whereas *d*-alanine gives, by the action of magnesium phenyl bromide on its ester hydrochloride, an amino-alcohol of the opposite

sign of rotation, the amino-alcohol obtained from *d*-phenylalanine by the same method has the same sign of rotation as that of the parent amino-acid, namely, dextrorotatory, and it has the same configuration. The deamination, however, caused a change of sign, *d*- $\beta$ -amino- $\alpha$ -diphenyl- $\beta$ -benzylethyl alcohol giving *l*-benzyldeoxybenzoin:

Thus, whilst dextrorotatory alanine gives dextrorotatory methyldeoxybenzoin, the ketone derived from dextrorotatory phenylalanine is laevorotatory. In a similar manner, *l*-phenylalanine was converted into a laevorotatory amino-alcohol which gave *d*-benzyldeoxybenzoin. The configuration of the *d*- and *l*-benzyldeoxybenzoins in relationship to the parent amino-acids is unknown owing to the possibility of an intramolecular Walden inversion during the deamination of the amino-alcohol.

The optically active ketones described are very readily racemised at the ordinary temperature when a few drops of alcoholic potash are added to their alcoholic solutions. For comparison, the effect of the catalyst on *l*-benzoin is described. The catalytic racemisation of *l*-benzoin was first interpreted by Wren (J., 1909, 95, 1593) on the basis of a desmotropic change caused by the migration of a hydrogen atom, and on this assumption *d*-methyldeoxybenzoin undergoes racemisation through an enolic complex:

Subsequent work by McKenzie and Wren on the hydrolysis of optically active esters by alcoholic potash (compare McKenzie and Smith, *Ber.*, 1925, 58, 894) and by McKenzie and Smith on the catalytic racemisation of optically active acid amides (J., 1922, 121, 1348) has provided evidence that the catalyst is potassium ethoxide, and it is suggested that the hypothetical enolic isomeride is formed only after the catalyst has combined with the ester or amide. A similar interpretation can be advanced with regard to ketones like methyldeoxybenzoin which contain (a) a phenyl group attached to the asymmetric carbon atom, and also (b) a hydrogen

atom attached to the asymmetric carbon atom which in turn is attached directly to a carbonyl group. The point is emphasised that the latter hydrogen atom has no migrational tendency in the ketone itself, and does not become mobile until an additive complex with potassium ethoxide has first been formed.

We are continuing our work on semipinacolinic deamination, more particularly with reference to the preparation of optically active ketones derived from phenylaminoacetic acid, phenylalanine and alanine. A few additional observations on the action of magnesium benzyl chloride on *d*-benzyldeoxybenzoin, ethyl *r*-alanine hydrochloride, and ethyl *r*-phenylaminoacetate hydrochloride, respectively, and on the deamination of *r*- $\beta$ -amino- $\beta$ -phenyl- $\alpha$ -dibenzylethyl alcohol are recorded at the end of the experimental section.

## EXPERIMENTAL.

### *Optically Active Methyldeoxybenzoin.*

*Action of Magnesium Phenyl Bromide on Ethyl d-Alanine Hydrochloride.*—The final purification of the *d*-alanine employed was effected by dissolving the amino-acid in hot water, and then adding rectified spirit until crystallisation started. The amino-acid separated in long, silky needles, and, for comparison with the value of the specific rotation quoted by Fischer (*Ber.*, 1906, **39**, 464), 0.8000 g. was made up to 10 c.c. with *N*-hydrochloric acid; this solution gave  $\alpha_D + 1.17^\circ$  in a 1-dm. tube, whence  $[\alpha]_D + 10.4^\circ$  for the hydrochloride ( $c = 11.276$ ), a value identical with Fischer's.

*d*-Alanine ethyl ester hydrochloride (15 g., 1 mol.) was added in instalments to an ethereal solution of magnesium phenyl bromide prepared from bromobenzene (150 g., 10 mols.), and the mixture was heated for 5 hours. The additive complex underwent slow decomposition when ice, ammonium chloride, and ammonia were added. When the decomposition was completed, the mixture was extracted several times with ether, the ethereal solution was dried with anhydrous sodium sulphate, the ether was expelled, and the resulting oil recrystallised from light petroleum. The crystals obtained were washed with light petroleum, and then consisted of the optically pure amino-alcohol (5.8 g.). The light petroleum was evaporated from the filtrates, the diphenyl was removed by distillation in steam, and the residual oil was extracted with ether. The oil resulting from the ethereal solution was dissolved in hot aqueous alcohol, and a mixture of oil and crystals separated on cooling. The oil was separated from the crystals by means of light petroleum, and in this manner an additional 5.2 g. of the amino-alcohol were obtained. Total yield = 11 g.

In another preparation the procedure was varied as follows. *d*-Alanine ethyl ester hydrochloride (8 g.) was added gradually to the Grignard reagent prepared from bromobenzene (98 g.), and the mixture after 3 hours' heating was decomposed by ice and dilute hydrochloric acid. In this case the diphenyl remained in the ethereal layer, which was separated from the aqueous layer containing the solution of the hydrochloride of the amino-alcohol. The latter solution was then decomposed by ammonia, but the precipitate which formed contained, not only the free amino-alcohol, but also some of its hydrochloride; the latter was removed by treatment with hot water. Yield of pure amino-alcohol = 4 g. The homogeneity of the amino-alcohol from this and from the preceding preparation was established by repeatedly crystallising from aqueous alcohol and examining the crystals polarimetrically. The amino-alcohol prepared from *d*-alanine is laevorotatory in chloroform, or in ethyl alcohol.

1- $\beta$ -Amino- $\alpha$ -diphenyl-*n*-propyl alcohol,  $\text{CH}_3\cdot\text{CH}(\text{NH}_2)\cdot\text{CPh}_2\cdot\text{OH}$ , separates from aqueous alcohol in needles, m. p. 101.5–102.5°. The *r*-isomeride (McKenzie and Wills, *loc. cit.*) also melts at 101.5–102.5°. The *l*-amino-alcohol is very sparingly soluble in water or in light petroleum, and readily soluble in ethyl alcohol, chloroform, benzene, toluene, or acetone (Found: C, 79.1; H, 7.7.  $\text{C}_{15}\text{H}_{17}\text{ON}$  requires C, 79.3; H, 7.5%). Its colour reaction with concentrated sulphuric acid is similar to that exhibited by the *r*-isomeride. Its specific rotation was determined in chloroform:  $l = 2$ ,  $c = 1.6776$ ,  $\alpha_D^{15^\circ} = -2.76^\circ$ ,  $[\alpha]_D^{15^\circ} = -82.3^\circ$ ;  $\alpha_D^{15^\circ} = -3.32^\circ$ ,  $[\alpha]_D^{15^\circ} = -99.0^\circ$ . In ethyl alcohol:  $l = 2$ ,  $c = 1.6628$ ,  $\alpha_D^{15^\circ} = -2.11^\circ$ ,  $[\alpha]_D^{15^\circ} = -63.4^\circ$ ;  $\alpha_D^{15^\circ} = -2.51^\circ$ ,  $[\alpha]_D^{15^\circ} = -75.5^\circ$ .

*The Action of Nitrous Acid on 1- $\beta$ -Amino- $\alpha$ -diphenyl-*n*-propyl Alcohol.*—A solution of sodium nitrite (2 g.) in water (10 c.c.) was added drop by drop in the course of  $\frac{3}{4}$  hour to 2.2 g. of the amino-alcohol dissolved in 75 c.c. of 25% acetic acid, the temperature being kept at 0° during the addition. The whole was kept at 0° for 5 hours. The oil, which at first separated, crystallised slowly in needles, which were collected, washed with water, and as usual dried in a vacuum over sulphuric acid before a polarimetric determination was made. Yield: 1.9 g. In chloroform:  $l = 2$ ,  $c = 2.0092$ ,  $\alpha_D^{15^\circ} + 6.33^\circ$ ,  $[\alpha]_D^{15^\circ} + 158^\circ$ . Thus the laevorotatory amino-alcohol gave a dextrorotatory ketone. After one crystallisation of the product from aqueous alcohol, fine, silky needles were obtained giving the following value in chloroform:  $l = 2$ ,  $c = 2.0096$ ,  $\alpha_D^{15^\circ} + 7.15^\circ$ ,  $[\alpha]_D^{15^\circ} + 178^\circ$ . As the substance, however, was not yet optically pure, the deamination of the amino-alcohol was conducted in three additional experiments with 2.5 g., 4.3 g.,

and 5.2 g., respectively. The 9 g. of crude ketone thus obtained were crystallised repeatedly from aqueous alcohol until determinations of the rotatory power showed that the ketone had been obtained pure. Five crystallisations were necessary. Yield = 4 g.

*d*-Methyldeoxybenzoin,  $C_6H_5 \cdot CH(CH_3) \cdot CO \cdot C_6H_5$ , crystallises from aqueous alcohol in glistening, silky plates or needles, m. p. 34–35° (Found: C, 85.5; H, 6.7.  $C_{15}H_{14}O$  requires C, 85.7; H, 6.7%). It is readily soluble in the commoner organic solvents. It gives a pale yellowish-green coloration when a trace is dissolved in cold concentrated sulphuric acid. Determinations of its specific rotation gave the following results. In chloroform for  $c = 1.0715$  ( $l = 2$ ):

$\lambda$ .....	6563	5893	5461	4861	4358
$\alpha_D^{17}$ .....	+3.39°	+4.44°	+5.57°	+7.99°	+11.86°
$[\alpha]_D^{17}$ .....	+158°	+207°	+260°	+373°	+553°

In ethyl alcohol:

$$l = 2, c = 2.2320, \alpha_D^{18} + 9.41^\circ, [\alpha]_D^{18} + 210.8^\circ.$$

After 1 day at the ordinary temperature, the solutions exhibited no autoracemisation.

#### *Optically Active Benzyldeoxybenzoins.*

*Resolution of r-Phenylalanine.*—The method of Fischer and Schoeller (*Annalen*, 1907, 357, 1) was employed. Formyl-*r*-phenylalanine was resolved by brucine in methyl-alcoholic solution, and the resulting *d*- and *l*-formyl-acids were hydrolysed by hydrobromic acid. The *d*-phenylalanine obtained gave in aqueous solution:  $l = 2, c = 2.043, \alpha_D^{16} + 1.43^\circ, [\alpha]_D^{16} + 35.0^\circ$ , whilst the *l*-amino-acid gave in the same solvent:  $l = 2, c = 2.043, \alpha_D - 1.42^\circ, [\alpha]_D - 34.8^\circ$ . The values quoted by Fischer and Schoeller are: for the *d*-acid,  $[\alpha]_D^{20} + 35.14^\circ$ , and for the *l*-acid,  $[\alpha]_D - 35.09^\circ$ .

For the preparation of the optically active phenylaminoacetic acids, the resolution of the *r*-acid by Reyhler's *d*-camphorsulphonic acid\* was in our experience (McKenzie and Wills, *loc. cit.*) more practicable than that described by Fischer and Weichhold (*Ber.*, 1908, 41, 1286) through the agency of the formyl-*r*-acid. Accordingly, attempts were made to prepare the optically active phenylalanines on similar lines. The homogeneous *dAdB* salt was obtained by combining the *r*-amino-acid with an equimolecular quantity of *d*-camphorsulphonic acid, and then crystallising the salt several times until the rotation was constant in value.

*d*-Phenylalanine *d*-camphorsulphonate separates from water in

\* Recent work on the constitution of Reyhler's acid indicates that the sulphonic group occupies the 10-position in the camphor molecule with sulphonation of the methyl group (Wedekind, Schenk, and Stüsser, *Ber.*, 1923, 56, 633).

needles. In aqueous solution:  $l = 2$ ,  $c = 2.0200$ ,  $\alpha_D^{25} + 0.74^\circ$ ,  $[\alpha]_D^{25} + 18.3^\circ$ . We did not, however, find that this was a convenient method for effecting the resolution. Crystallisation took place too sluggishly, whether effected from water, benzene, aqueous alcohol or aqueous acetone, and the yield of the pure salt was small.

The enantiomorphous salt was prepared by combining *l*-phenylalanine with *l*-camphorsulphonic acid in methyl-alcoholic solution.

*l*-Phenylalanine *l*-camphorsulphonate separates from methyl alcohol in plates, m. p. 109—110°. In aqueous solution:  $l = 2$ ,  $c = 2.0208$ ,  $\alpha_D^{25} - 0.74^\circ$ ,  $[\alpha]_D^{25} - 18.3^\circ$ .

*The Action of Nitrous Acid on l-β-Amino-α-diphenyl-β-benzyl-ethyl Alcohol.*—The *l*-amino-alcohol was prepared by the action of magnesium phenyl bromide on *l*-phenylalanine (compare the preparation of the *d*-amino-alcohol, McKenzie and Wills, *loc. cit.*). The mixture of 1.9 g. of the *l*-amino-alcohol and 40 c.c. of 25% acetic acid was warmed until most of the solid had dissolved, and was then cooled to 0°. The gradual addition of a solution of sodium nitrite (1.3 g. in 10 c.c. of water) during 30 minutes caused the separation of a voluminous solid, which was kept for 4 hours at 0° in contact with the solution. This solid (1.25 g.) was strongly *dextrorotatory*, giving in chloroform solution  $[\alpha]_D + 233^\circ$  for  $c = 1.346$  ( $l = 2$ ). It consisted of the almost pure ketone, and was recrystallised twice from ethyl alcohol.

*d*-Benzyldeoxybenzoin,  $\text{CH}_2\text{Ph}\cdot\text{CHPh}\cdot\text{CO}\cdot\text{Ph}$ , is sparingly soluble in ethyl alcohol, from which it separates in silky needles, m. p. 121—121.5° (Found: C, 88.3; H, 6.5.  $\text{C}_{21}\text{H}_{18}\text{O}$  requires C, 88.1; H, 6.3%). It is readily soluble in chloroform, ether, or acetone. Its specific rotation was determined in chloroform:  $l = 2$ ,  $c = 1.348$ ,  $\alpha_D^{25} + 6.50^\circ$ ,  $[\alpha]_D^{25} + 241^\circ$ . In ethyl alcohol:  $l = 2$ ,  $c = 0.392$ ,  $\alpha_D^{25} + 1.90^\circ$ .

*The Action of Nitrous Acid on d-β-Amino-α-diphenyl-β-benzyl-ethyl Alcohol.*—The deamination was conducted as in the preceding case. The crude product (0.8 g.) obtained from the *d*-amino-alcohol (0.9 g.) was strongly *levorotatory* in chloroform solution, giving  $[\alpha]_D - 195^\circ$  for  $c = 1.5984$  ( $l = 2$ ). It was crystallised thrice from ethyl alcohol until the optically pure ketone was obtained.

*l*-Benzyldeoxybenzoin crystallises from ethyl alcohol in silky needles, m. p. 121—121.5°. With concentrated sulphuric acid, a trace of the compound gives a faint greenish-yellow coloration. The following determinations of the specific rotation were made. In chloroform:  $l = 1$ ,  $c = 1.258$ ,  $\alpha_D^{25} - 3.04^\circ$ ,  $[\alpha]_D^{25} - 242^\circ$ . In acetone:  $l = 1$ ,  $c = 1.118$ ,  $\alpha_D^{25} - 2.45^\circ$ ,  $[\alpha]_D^{25} - 219^\circ$ ;  $\alpha_{461}^{17} - 3.00^\circ$ ,  $[\alpha]_{461}^{17} - 268^\circ$ .

It is very unusual to find an optically active compound and

its inactive isomeride melting at practically the same temperature. Several such cases have been noted in the course of the present research; thus, *r*- $\beta$ -amino- $\alpha\alpha$ -diphenyl- $\beta$ -benzylethyl alcohol melts at 144.5—145.5° (McKenzie and Richardson, J., 1923, **123**, 91), whereas the *d*-isomeride melts at 143—144° (McKenzie and Wills, *loc. cit.*, p. 293). *r*-Benzyldeoxybenzoin melts at 121.5—122° (McKenzie and Richardson, *loc. cit.*; McKenzie and Roger, J., 1924, **125**, 849), whereas the optically active isomerides melt at 121—121.5°, and reference has been already made to *l*- and *r*- $\beta$ -amino- $\alpha\alpha$ -diphenyl-*n*-propyl alcohols, which melt at 101.5—102.5°.

*Catalytic Racemisation of Optically Active Ketones.*

*l*-Benzoin.—This ketone was prepared by the action of magnesium phenyl bromide on *l*-mandelamide (McKenzie and Wren, J., 1908, **93**, 309). A determination was made of its specific rotation in ethyl-alcoholic solution:  $l = 2$ ,  $c = 1.1550$ ,  $\alpha_D^{18} - 3.06^\circ$ ,  $[\alpha]_D^{18} - 132.5^\circ$ . To this solution in a 2-dcm. tube, four drops of ethyl-alcoholic potash (0.4487*N*) were added, and quickly mixed. Polarimetric readings were taken at intervals, and after 1 hour three additional drops of the alcoholic alkali were added. The initial reading immediately after the addition of the alkali was  $\alpha_D - 3.05^\circ$ ;  $t$  = interval (minutes) after addition of the catalyst, and  $\theta^\circ$  = observed angle:

$t$ .....	15	30	45	60	65	80	100	120	140
$\theta^\circ$ ...	-2.77	-2.68	-2.61	-2.61	-2.49	-2.26	-2.00	-1.82	-1.72
$t$ .....	180	220	250	280	340	400	23 hrs.	31 hrs.	5 days
$\theta^\circ$ ...	-1.48	-1.22	-1.06	-0.91	-0.70	-0.55	-0.24	-0.22	-0.22

*d*-Methyldeoxybenzoin.—An ethyl-alcoholic solution of the ketone ( $c = 0.8095$ ) gave  $\alpha_D^{18} + 3.37^\circ$  in a 2-dcm. tube. Four drops of ethyl-alcoholic potash (0.4487*N*) were mixed with the solution, and the fall in rotation was noted as below:

$t$ (mins.) .....	1	10	20	30	40	50	60	90
$\theta^\circ$ .....	+3.36	+3.25	+3.13	+3.04	+2.94	+2.83	+2.74	+2.54
$t$ (hours) .....	2	3	4	5	6	7	7½	23½
$\theta^\circ$ .....	+2.32	+2.00	+1.70	+1.49	+1.25	+1.04	+0.94	+0.10
								+0.07
								+0.00

The alcohol was evaporated from the solution, and the solid was crystallised from ethyl alcohol; silky needles of *r*-methyldeoxybenzoin, m. p. 49.5—50.5°, separated.

*d*-Benzyldeoxybenzoin.—An ethyl-alcoholic solution of the ketone ( $c = 0.392$ ) gave  $\alpha_D^{18} + 1.90^\circ$  in a 2-dcm. tube, and this value was unchanged after 1 day at the ordinary temperature. Three drops (0.05 c.c.) of ethyl-alcoholic potash (0.4487*N*) were then mixed with the solution and the fall in rotation was noted as below:

<i>t.</i>	$\theta.$	<i>t.</i>	$\theta.$	<i>t</i>	$\theta.$
1 min.	+1.87°	4 hours	+1.26°	24 hours	+0.31°
10 "	1.82	5 "	1.15	26 "	0.25
20 "	1.78	6 "	1.05	32 "	0.16
30 "	1.74	7 "	0.96	48 "	0.06
1 hour	1.63	8 "	0.88	54 "	0.05
2 hours	1.49	11 "	0.74	73 "	0.02
3 "	1.37	12 "	0.69		

*Action of Magnesium Benzyl Chloride on d-Benzyldeoxybenzoin.*  
 —The mixture of the ketone (0.6 g.) and the Grignard reagent prepared from benzyl chloride (2 g.) was boiled for 6 hours and then decomposed by ice and dilute sulphuric acid. The ethereal layer was dried, the ether expelled, and the oil triturated with hot light petroleum. The resulting solid was crystallised from light petroleum (b. p. 80–100°), *d*- $\alpha\beta$ -diphenyl- $\alpha\beta$ -dibenzylethyl alcohol,  $\text{CH}_2\text{Ph}\cdot\text{CHPh}\cdot\text{CPh}(\text{OH})\cdot\text{CH}_2\text{Ph}$ , separating in rosettes of needles, m. p. 167–168° (Found: C, 88.6; H, 7.0.  $\text{C}_{28}\text{H}_{26}\text{O}$  requires C, 88.8; H, 6.9%). In chloroform:  $l = 1$ ,  $c = 1.306$ ,  $\alpha_D^{20} + 2.02^\circ$ ,  $[\alpha]_D^{25} + 155^\circ$ .

We are indebted to Mr. Arthur Kelman Mills for the following observations.

*Action of Magnesium Benzyl Chloride on Ethyl  $\alpha$ -Alanine Hydrochloride.*—The ester hydrochloride (1 mol.) was heated for several hours with the Grignard reagent prepared from benzyl chloride (9 mols.). The mixture was decomposed by ice and ammonium chloride, the ether layer separated, the ether expelled, and the dibenzyl removed by steam distillation. The product was purified by crystallising first from light petroleum and then from rectified spirit.

*$\alpha$ -Amino- $\alpha\alpha$ -dibenzyl- $n$ -propyl alcohol,*

is moderately soluble in rectified spirit, from which it crystallises in plates, m. p. 93.5–94.5° (Found: C, 80.1; H, 8.4.  $\text{C}_{17}\text{H}_{21}\text{ON}$  requires C, 80.0; H, 8.3%).

*Action of Magnesium Benzyl Chloride on Ethyl  $\alpha$ -Phenylaminoacetate Hydrochloride.*—The ester hydrochloride (10 g., 1 mol.) was added to the Grignard reagent prepared from benzyl chloride (52.5 g., 9 mols.) and boiled for 3 hours. After decomposition with ice and ammonium chloride, the ethereal layer was separated and dried and from it an oil was obtained which was dissolved in hot light petroleum (b. p. 60–80°). 6.9 G. of solid crude amino-alcohol separated. This was recrystallised from rectified spirit; 6.0 g. of  $\beta$ -amino- $\alpha\alpha$ -dibenzyl- $\beta$ -phenylethyl alcohol, m. p. 125–126°, were then obtained. This compound has already been described by Thomas and Bettzieche (*Z. physiol. Chem.*, 1924, 140, 244), who used somewhat different experimental conditions from the above.

*Deamination of r-β-Amino-β-phenyl-α-dibenzylethyl Alcohol.*—To the solution of the amino-alcohol (4 g.) in 25% acetic acid (120 c.c.) an aqueous solution of sodium nitrite (3 g.) was added while the whole was maintained at 0°. The white solid which at first separated soon became viscous, and was extracted with ether. The product from the ethereal solution was dissolved in alcohol, and the solid which separated was crystallised twice from light petroleum (b. p. 40–60°). The resulting rosettes of needles consisted of benzyl αβ-diphenylethyl ketone,  $\text{CH}_2\text{Ph}\cdot\text{CHPh}\cdot\text{CO}\cdot\text{CH}_2\text{Ph}$ , m. p. 74–75°. For comparison, α-phenyl-ββ-dibenzylethylene glycol was prepared from ethyl *dl*-mandelate by the action of magnesium benzyl chloride, and dehydrated with concentrated sulphuric acid according to Orékhov (*Bull. Soc. chim.*, 1919, **25**, 111). When prepared in the latter manner, the ketone had m. p. 74–75° (Orékhov gives 75–76°), and there was no depression of the melting point when it was mixed with the product of the deamination.

The Carnegie Trust for the Universities of Scotland afforded facilities for the prosecution of this work, and we desire to express our thanks both to them and to the Government Grant Committee of the Royal Society.

## CVII.—*Experiments on the Variation of the Angles of Crystals during Growth.*

By ERNEST SYDNEY HEDGES.

THE slight deviations from the theoretical angle which are to be observed in almost every crystal and the replacement of a theoretical face by a series of faces inclined to each other at minute angles are familiar to everyone who has carried out accurate measurements with a goniometer. In the practical measurement of these crystals it is customary to take the mean of such a set of readings, and in the majority of cases the method produces good results from a theoretical point of view. These vicinal faces are generally ignored, therefore, in determining the symmetry of the crystal. A study of the actual process of crystallisation, however, is incomplete if these forms are left neglected; in fact, regarded from a purely physical point of view, the existence of such faces may be a matter of some importance, and one which may help towards the elucidation of the process of crystallisation.

Several investigators have been interested in these variations and

have made exhaustive measurements on crystals which have been removed from the mother-liquor. Pfaff (*Sitzungsber. Physik. Med. Erlangen*, 1878, 10, 59), from a study of cubic crystals, concluded that the variations were exhibited by birefringent specimens, indicating a state of strain. Brauns (*Neues Jahrbuch*, 1887, 1, 136) could not confirm this opinion, and experiments with lead nitrate led him to suggest that the vicinal faces are really faces of low indices which have been distorted under the influence of gravity. Wulff (*Z. Kryst. Min.*, 1901, 34, 449) supposed the variations to be due to concentration currents playing over the crystal during its growth.

In order to study this problem more fully, a special type of goniometer was devised by Miers (*Phil. Trans.*, 1903, A, 202, 459), which permitted of the measurement of a crystal *during its growth*. The observations were concerned mainly with potassium alum and ammonium alum, and it was shown that the octahedral planes are invariably replaced by vicinal faces belonging to triakis octahedra which are subject to continual variations during the growth of the crystal.

The experiments described in the present paper are a continuation of this work, which the author has undertaken at the suggestion of Sir Henry Miers, using the same goniometer. The observations have been made over the course of the last three years and the work had to be discontinued abruptly. It is thought that the results so far achieved, although incomplete, may prove of interest and value.

#### EXPERIMENTAL.

*Orthorhombic System.*—For the purpose of studying the variations of angle exhibited by the vicinal faces during crystallisation, the crystal was immersed in a slightly supersaturated solution made up at a few degrees above room temperature and readings were taken at various time intervals for several hours. As a rule, immediately after immersion the images yielded by the vicinal faces became poor owing to a slight dissolution of the crystal. Crystallisation began quickly at first and subsequently became slower as the temperature of the solution approximated to that of the room. The substances used were sodium potassium tartrate and magnesium sulphate.

Two important results were derived from these experiments. (1) During the growth of a crystal the number of vicinal faces increases at first, generally reaching a maximum about one hour after immersion, after which the number of images steadily diminishes.

This process runs parallel with the rate of crystallisation, which increases to a maximum during the initial cooling and then slows

down as the crystallising temperature reaches that of the room. The following series of measurements, giving the readings for images from the vicinal faces occurring in a fixed portion of the prism zone of sodium potassium tartrate, illustrates this point. All columns of figures are to be read vertically.

TABLE I.

2.30 p.m.	2.45 p.m.	3.00 p.m.	3.15 p.m.	4.25 p.m.
269° 42½'	270° 10'	269° 55½'	270° 0'	272° 26½'
270 10	271 4½	270 5½	270 7½ (A)	271° 2'
272 35	271 14	271 8	270 15	272 31
	271 22	271 23½	270 57	272 40
	272 10	271 59	271 24	272 24
		272 27	272 0	272 47
		272 35	272 17	

This series of results is representative of the behaviour observed with nine crystals of sodium potassium tartrate. Similarly, Table II shows the total number of faces in the prism zone of magnesium sulphate yielding definite images at various times during the growth of a crystal, and is characteristic of the general results obtained with numerous other crystals.

TABLE II.

Time .....	1.25 p.m.	1.45 p.m.	2.10 p.m.	2.45 p.m.
No. of faces .....	9	13	16	11

(2) During the process of growth, the positions of the faces undergo rapid variations of considerable magnitude.

A rather extreme case was observed with the face marked A in Table I—an image chosen on account of its peculiar brightness. The image was kept under continuous observation for an hour and its position was read every minute. The readings vary in a very irregular fashion, the highest being 270° 10' and the lowest 269° 50'. The variation here is unusually large for an individual image, and this may correspond with the very rapid growth of the crystal which was observed in this particular experiment. The next series of readings, taken at five-minute intervals on a different crystal, is more characteristic of a general case: 205° 22', 205° 20', 205° 20½', 205° 19½', 205° 20', 205° 20½', 205° 20'.

An idea of the individual variations in the positions of the faces in the case of magnesium sulphate is gained from the following values for two bright images taken during growth. This example has been selected from series of readings taken with eleven different crystals of magnesium sulphate at various times.

4.40 p.m.	5.35 p.m.	6.15 p.m.
264° 7½'	264° 11½'	264° 14'
264 16	264 13½	264 16½

*Tetragonal System.*—A few experiments carried out with diammonium hydrogen phosphate confirmed the same general results. The faces on these crystals belong to two forms—prism and pyramid—and according to Groth no other forms have been observed. Both forms were found to be replaced by vicinal faces and the measurements of the prism zone given in Table III show that there is a maximum deviation of 20' from the right angle.

TABLE III.

2.40 p.m.			3.10 p.m.			3.35 p.m.		
118° 38'	298° 36'	}	118° 37½'	298° 41'	}	118° 36'	298° 34'	
	298 33			298 35				
208 37	28 34		208 35	28 34		208 33	28 34	
				28 20			28 20	

*Cubic System.*—More detailed experiments were conducted with sodium chlorate. Initially, the method was the same as in the foregoing case, i.e., the measurements were taken over the course of a few hours during the slow cooling of a solution. Under such conditions, the crystal is never in equilibrium with the mother-liquor. It is necessary to reproduce only one set of readings to represent the general results observed with nineteen crystals which have been examined.

Table IV records the complex images replacing the cube faces of a dextrorotatory sodium chlorate crystal. In addition to the exact position in the horizontal plane, the direction of those images which are out of the horizontal zone is indicated, although for the present purpose the distance above or below the zone was not measured.

TABLE IV.

1.45 p.m.		2.15 p.m.		2.45 p.m.		3.20 p.m.	
192° 27'		192° 27' Below.		192° 28' Below.		192° 28' Below.

		282 54 V. bright.					
		282 56					
12 31		12 30		13 30		12 29	
12 37		12 36		13 0 Bright. Sl.		12 35	
12 57		12 56				12 58 Above, v.	
13 1	} V. bright.	13 0 Sl. above and v.		13 1½ above.		bright.	
13 3		13 2 bright.					
13 5							
102 40 Above.		102 36 Above.		102 43 Above.		102 43 Above.	
102 43 Three vert.		102 39 "		102 47 "		102 47 "	
102 46 Above.		102 43 "		102 52 On.		102 51 On.	
102 55 Two vert.		102 46 "		102 54 Below.		102 53 Below.	
		102 53 On.					
		102 57 Above.					

In this case, the mean of the vicinal faces *in the horizontal zone* replacing the cube face is calculated, and Table V, where these values are grouped, indicates that it is impossible to ascertain the true position of the cube faces by taking the mean of such readings.

TABLE V.

Mean Positions.						
Time.	A.	B.	C.	D.		
1.45 p.m.	192° 45½'	282° 45½'	12° 52'	102° 49'

2.45 "	193 0½'	282 57	12 46	102 52		
3.20 "	192 57	282 44½	12 32	102 51		
Suggested Cube Faces.						
1.45 "	193 1½'	282 54	13 1	102 55		
2.15 "	193 1½'	282 54	13 1	102 53		
2.45 "	193 0	282 52½	13 0	102 52		
3.20 "	192 59	282 51	12 58	102 51		

The table also gives the readings which would correspond to the cube faces on the assumption that the vicinal faces in accordance with the symmetry of the crystal belong to forms  $\{hko\}$  in a horizontal zone on one face and  $\{okl\}$  in a vertical zone on the adjacent face. The suggested cube face is the point of intersection of a vertical zone with a horizontal zone. The validity of the assumption is shown later. For example, at 2.15 p.m., the reading 193° 1½' represents an image in the horizontal plane which is duplicated in the vertical plane, and an examination of the tables shows that this face is prominent throughout the growth. Parallel to this face there occur the readings 13° 0' and 13° 2' arranged symmetrically about the suggested cube face, and inspection shows these faces to be prominent throughout. On the other hand, at right angles to these faces there is nothing to correspond. If the probable positions of the other pair of cube faces are worked out by the same method, they have a mean value of 282° 53' and 192° 53'.

*The Vicinal Faces in Relation to the Symmetry.*—The symmetry of sodium chlorate is the lowest type of the cubic system. There are no planes of symmetry, but there is a threefold axis passing through each solid angle of the cube and a two-fold axis normal to each cube face. If, therefore, the vicinal faces belong to the form  $\{hko\}$  and are consistent with the symmetry of the crystal, one would expect the vicinal faces replacing each pair of opposite cube planes to be disposed alike and to differ from the other pair in a perpendicular sense. This has been found to occur without exception in every crystal of sodium chlorate examined. In the cube faces A and C, the images are arranged mainly in the horizontal zone and in faces B and D they occur for the most part in a vertical zone.

Additional evidence on this point is observed when the crystal

is first immersed or during the incipient stages of dissolution when the temperature of the room rises. Under such conditions, a narrow band or haze of light appears in the field which represents either a rounded surface or a continuous series of facets etched on the crystal by the solvent. On one pair of parallel faces this band lies in the horizontal plane and on the other pair it is vertical. Conditions are often realised when such a vertical band is present simultaneously with well-developed images occurring either in the band or in the horizontal zone. This condition permits of a more certain way of determining the positions of the true cube faces, which is applicable even when the cube faces are themselves absent. Accurate measurements of sharp images appearing in the horizontal and vertical bands can be made and the point of intersection of the zones may be taken as the theoretical position of the cube face.

FIG. 1.

FIG. 2.

Thus, in one crystal, the positions of the vertical bands yielded by the faces B and D were measured as  $104^{\circ} 10'$  and  $284^{\circ} 10'$ , respectively. The true cube faces may be taken, therefore, as  $14^{\circ} 10'$ ,  $104^{\circ} 10'$ ,  $194^{\circ} 10'$ ,  $284^{\circ} 10'$ . The images actually yielded by the faces A and C were: A =  $13^{\circ} 54'$ ,  $14^{\circ} 4'$ ,  $14^{\circ} 20'$ ; C =  $194^{\circ} 0'$ ,  $194^{\circ} 20'$ . Although the cube faces are here not present, they are replaced by faces inclined symmetrically on either side.

The images, however, are not confined solely to the horizontal plane or to the vertical plane, and several occur which do not belong to either zone. Fig. 1 represents the appearance of the field in viewing the horizontally disposed face of a dextrorotatory crystal of sodium chlorate and may be compared with Fig. 2, which represents a similar state in a levorotatory crystal.

Attention may be directed to the upward trend from left to right in the faces A and C of the right-handed crystal and the downward trend from left to right in the corresponding faces of the left-handed crystal. Similarly, the trend of faces B and D was in the opposite direction in the two enantiomorphs. The angles XOY and PQR

were measured as  $16^\circ$  and  $17^\circ$ , respectively. This effect was noticed in two other specimens (right- and left-handed, respectively) which originated in the same batch of crystals. In later experiments, however, such a differentiation between the optical isomerides was not observed. No cases have appeared where the disposition is in an opposite sense to this, but those images which do not belong to either zone have been arranged in an apparently haphazard way.

Thus, although it is not possible to deduce the direction of optical rotation from the disposition of the vicinal faces, there is a tendency for these to be arranged in accordance with the optical properties of the crystal.

*Experiments on Slow Growth.*—With the object of studying the forms produced when the crystal is in true equilibrium with the solution, a crystal of sodium chlorate was induced to grow very slowly over a period of several weeks and readings were taken every morning about 9.30 a.m. before the room had warmed up. To realise favourable conditions for such experiments was a matter of considerable difficulty and in the damp Manchester atmosphere it was only found possible during the summer months; at other times of the year, the saturated solution tended to gain water often. When the necessary climatic conditions prevailed, the method adopted was to place a glass cover over the whole instrument during the night, when the crystal grew mainly by cooling, and to remove it during the day, when the crystal grew mainly by evaporation. In this way, crystallisation was always slow and a crystal did not increase in breadth by more than a quarter of an inch in a month.

The arrangement of the images during the first stages of slow growth was precisely similar to that already described, during the rapid growth of sodium chlorate crystals, the complex faces A and C differing in a perpendicular sense from the faces B and D. Again, the total number of images present underwent a progressive decrease with time. In addition to this, however, there was observed a most marked flattening of the forms during the process—that is to say, the images gradually approached one another until finally what appeared to be a single perfect cube face remained.

To take an example, a crystal was immersed on May 30th, 1924, and Table VI shows the horizontal extent of the complex face A (*i.e.*, the difference in minutes between the extreme images) on successive dates.

TABLE VI.

Date.	Extent.	Date.	Extent.	Date.	Extent.
May 30th	$43\frac{1}{2}'$	June 4th	$7\frac{1}{2}'$	June 18th	0
June 1st	37	„ 5th	9	„ 18th	0
„ 2nd	$8\frac{1}{2}$	„ 9th	14	„ 20th	0
„ 3rd	9	„ 12th	$2\frac{1}{2}$	„ 23rd	$19'$
				„ 30th	$8\frac{1}{2}$

The readings 0 for June 16th, 18th, and 20th indicate that on those days there was a single image in the field. An unusual spell of sunny weather over the week-end June 20th—23rd, during which the glass cover was left on, caused a partial dissolution of the crystal, so that the process takes a new start from that date.

Further, during slow growth, the forms flatten with time in both the horizontal and vertical zones, so that the four faces tend to become alike. The case was never realised where the crystal consists of four perfect cube faces existing simultaneously, although there seems to be no doubt that such a state may be arrived at under favourable conditions. Crystals have been observed where at different times each of the four faces in the zone has yielded an image corresponding to a true cube face. As a rule, only one pair of faces would give a single image in the theoretical place of the cube and the other pair would give duplicate images arranged symmetrically. For instance, a crystal after growing for a period of 24 days gave perfect single images at  $195^{\circ} 50'$  and  $15^{\circ} 50'$  and images of equal intensity arranged symmetrically at  $285^{\circ} 49'$ ,  $285^{\circ} 51'$ , and  $105^{\circ} 49'$ ,  $105^{\circ} 51'$ . The following morning, at  $195^{\circ} 50'$  and at  $15^{\circ} 50'$  there were duplicate images placed one minute above and below the zone, respectively. It is difficult to conceive of a more faithful representation of the symmetry of sodium chlorate.

*The Movement of the Faces.*—Evidence has been given of the continual variation in the positions of the images, and this point has received comment by Miers (*loc. cit.*), who stated that with potash alum the faces replaced each other *per saltum* in accordance with the law of rational indices. Throughout the present experiments, this has been the case with sodium chlorate and also with ammonium phosphate.

On the other hand, with magnesium sulphate, and particularly with sodium potassium tartrate, two kinds of movement have been observed : not only do the images move by successive replacement, but certain of the images were observed to travel across the field in a continuous manner. This motion was quite rapid, the path generally being about five to ten minutes of arc traversed in about one second of time. The most usual form in which the movement was manifested was when two bright faces occurred on the crystal close together; there was often a continuous migration of less bright but perfectly definite images from one to the other, the rate being of the order of one every few seconds. In some instances, an image was observed to leave a relatively fixed face, move out some distance, and then return. The latter fact seems to remove any doubt as to whether the movements may be a spurious effect due to the optical deflection of an image by currents of solution of

varying refractive index. Such deviations do undoubtedly occur, particularly if the solution is gently stirred, but are in the nature of a quick tremor of relatively small displacement during which the outline of the image becomes indefinite.

*Theoretical.*

As an explanation of vicinal faces Miers has suggested that the density of packing of molecules in a crystal is considerably greater than the density of packing in the saturated solution and that the molecules of solute, as they separate out of the crystallising solution, cannot squeeze themselves into the very close packing of a face with simple indices. On the other hand, the reticular density of a face inclined at an angle of a few minutes to one of the principal planes of the crystal is very low and much more suitable for the deposition of new units of the structure.

Some of the experiments which have been described above lend additional support to this view, for it is found that the crystal approximates more and more closely to the ideal form the slower the rate of growth. In fact, by carefully controlling the slow growth of sodium chlorate, single true cube faces may be obtained although these faces are generally absent in the ordinary way. Under such conditions of growth, it seems reasonable that the molecules of solute can easily take their places in a plane of high density.

*Summary.*

Measurements of the vicinal faces in crystals of sodium potassium tartrate, magnesium sulphate, diammonium hydrogen phosphate, and sodium chlorate, taken during the actual growth of the crystal, show that the number of faces undergoes an initial increase with time followed by a decline. The images undergo continual and rapid variations in position, generally by replacement, but in certain cases by continuous progression. The vicinal faces in sodium chlorate are consistent with the symmetry of the crystal, and a method is devised which enables the true positions of the ideal cube faces to be found even when they are absent. The slower the growth of the crystal, the more closely does it approximate to the ideal form. By carefully controlling the slow growth of sodium chlorate, single perfect cube faces may be developed. The experiments support the views of Miers on the cause of vicinal faces.

In conclusion, the author wishes to express his cordial thanks to Sir Henry A. Miers, F.R.S., for the constant encouragement and advice which he has received from him throughout the course of this work.

CVIII.—*The Nitration of Benzamidines.*

By ROBERT FORSYTH, VISHVANATH KRISHNA NIMKAR, and  
FRANK LEE PYMAN.

PYMAN and STANLEY (J., 1924, **125**, 2484) showed that nitration of 2-phenylglyoxaline and its 4(5)-monocarboxylic acid gave mainly the *p*-nitro-compounds (I and II), whereas 2-phenylglyoxaline-4 : 5-dicarboxylic acid gave mainly the *m*-nitro-compound (III).

In view of the fact that 2-phenylglyoxaline and its monocarboxylic acid yield salts with mineral acids whereas its dicarboxylic acid does not, they suggested that the different character of the doubly-linked nitrogen atom, that is, the nitrogen atom which takes part in salt formation (compare Burtles and Pyman, J., 1923, **123**, 361), was responsible for the different results. In 2-phenylglyoxaline, this nitrogen atom would be regarded as saturated or positive by combination with acid according as to whether the hypotheses of Flürscheim or Lapworth were employed, whilst in the dicarboxylic acid it would be regarded as unsaturated or negative.

If this explanation were correct, then one would expect that nitration of benzamidine by the method employed for 2-phenylglyoxaline, that is, addition of the nitrate of the base to sulphuric acid, would yield mainly the *o*- and *p*-nitro-compounds, but as a matter of fact it proves to give more than 90% of *m*-nitrobenzamidine (IV).

Various possible explanations of the essentially different results of nitrating 2-phenylglyoxaline and benzamidine have now been examined. It might be suggested that since glyoxalines do not readily yield acyl derivatives, we should not postulate nitroamine formation in this case, but might reasonably do so in the case of benzamidines. An explanation would then be furnished analogous to that devised by Holmes and Ingold (J., 1925, **127**, 1800) to explain the difference between the results of nitrating secondary and tertiary benzylamines. Such an explanation, however, was found to be inapplicable in our case, since the nitration of benzenyltrimethylamidine, which cannot yield a nitroamine, gave more than 80% of *m*-nitrobenzenyltrimethylamidine (V).

Next, it might be thought that the different results of nitrating 2-phenylglyoxaline and benzamidine might be due to the fact that the two nitrogen atoms were linked together by a closed chain in the former compound and might neutralise each other's influence. This view was disproved by the nitration of 2-phenyl-4:5-dihydroglyoxaline, which gave more than 80% of 2-*m*-nitrophenyl-4:5-dihydroglyoxaline (VI).

It seems to us that the noteworthy difference between the results of nitrating 2-phenylglyoxaline and its dihydro-derivative are probably associated with the fact that glyoxalines have aromatic character whereas their dihydro-derivatives have not. It thus appears that the amidinium ion,  $\left[ \cdot \text{C} \begin{array}{c} \text{NHR} \\ \text{NR'R''} \end{array} \right]^+$ , which is contained in the salts of benzamidine, benzenyltrimethylamidinium, and 2-phenyl-4:5-dihydroglyoxaline, is strongly meta-directive, the nitrogen atoms exerting a similar influence to that of the oxygen atom in the carboxyl group. In the basic 2-phenylglyoxalines, the influence of the nitrogen atoms is suppressed, and the glyoxalinium ion produces an *op*-directive effect, due to the aromatic complex as a whole, and similar to that of phenyl in directing the *p*-nitration of diphenyl. The exceptional predominant *m*-nitration of the non-basic 2-phenylglyoxaline-4:5-dicarboxylic acid may be due possibly to the absence of salt formation in the case of this compound, and a difference in orienting properties between glyoxaline bases and glyoxalinium ions, for evidence of a difference in structure between glyoxalines and their salts may be found in the existence of the two isomeric bases 2:4- and 2:5-diphenylglyoxalines (VII and VIII), which yield a common ion (IX) (Burtles and Pyman, *loc. cit.*).

Nevertheless, the fact that the dicarboxylic acid yields 52% of the *m*- with 19% of the *p*-nitro-compound, whilst the monocarboxylic acid yields 52% of the *p*- with 19% of the *m*-compound, shows that the introduction of carboxyl groups into the glyoxaline nucleus of 2-phenylglyoxaline progressively diminishes the ratio of para- to meta-nitration of the benzene nucleus, and suggests, as an alternative explanation, for which we are indebted to Dr. King, that the results should be ascribed to the accumulation of acidic groups attached to the glyoxaline nucleus. In this sense, they are comparable with the results of nitrating benzyl chloride, benzylidene chloride, and benzotrichloride, where also the ratio of para- to meta-nitration is progressively diminished by the introduction of acidic groups

(Holleman, *Rec. trav. chim.*, 1914, **33**, 1). On the other hand, we found no support of this explanation, possibly owing to experimental difficulties, on the nitration of 4:5-dibromo-2-phenylglyoxaline (X),

which might be expected to yield a considerable proportion of the *m*-nitro-derivative, for here 4:5-dibromo-2-*p*-nitrophenylglyoxaline (XI) was isolated in a yield of 63% together with only 1.8% of an unidentified isomeride.

Nitration of 4(5)-bromo-2-phenylglyoxaline prepared by the reduction of the dibromo-compound with sodium sulphite proceeded less uniformly, possibly owing to nitration of the glyoxaline nucleus, but here the only product isolated was again the para-isomeride, 4(5)-bromo-2-*p*-nitrophenylglyoxaline. Another instance of the *p*-directive effect of the glyoxaline nucleus has been recorded by Tröger and Thomas (*J. pr. Chem.*, 1925, **110**, 42), who find that the nitration of lophine gives 2:4:5-tri-*p*-nitrophenylglyoxaline. Para-nitration of phenyl groups attached to the 2-position of glyoxalines having basic character thus seems to be the rule.

#### EXPERIMENTAL.

*Nitration of Benzamidine.*—Benzamidine nitrate,\* prepared from the base and dilute nitric acid, crystallised from alcohol in large, colourless, rhombic prisms, m. p. 128° (corr.) after softening from 124°, which are anhydrous and very easily soluble in water or hot alcohol (Found: C, 45.7, 45.6; H, 4.9, 5.0. C<sub>7</sub>H<sub>8</sub>N<sub>2</sub>.HNO<sub>3</sub> requires C, 45.9; H, 4.9%). This salt (10 g.) was added gradually to concentrated sulphuric acid (20 c.c.) cooled in ice and salt. After  $\frac{1}{2}$  hour, the solution was heated for 2 hours at 100°, then diluted and mixed with aqueous solutions of barium hydroxide (50 g., hydrated) and barium chloride (46.7 g., hydrated). After removing barium sulphate, the aqueous solution was evaporated to dryness under diminished pressure, and the residue crystallised fractionally from alcohol, when 10.1 g. of pure *m*-nitrobenzamidine hydrochloride were isolated, that is, 91.7%.† The salts remaining in the mother-liquors were hydrolysed by boiling with 40 c.c. of 17% aqueous sodium hydroxide until ammonia was no longer evolved. On addition of concentrated hydrochloric acid, 0.62 g. of *m*-nitrobenzoic acid (m. p. 135°) separated, whilst ether collected a further 0.08 g. of less pure material (m. p. 118–120°). Mixtures of

\* This salt has not been described previously. The reference to it (*Jahresber.*, 1888, 1133) quoted by Beilstein is a mistake, and applies to the nitrite.

† All yields are expressed in percentage of the theoretical.

these products with pure *m*-nitrobenzoic acid melted at 137° and 126—131°, respectively. The amount of these crops represents 7·8% of the theoretical yield, making in all 99·5%, whence it is clear that the nitration of benzamidine yields almost wholly the meta-isomeride.

*m*-Nitrobenzamidine hydrochloride crystallises from alcohol in clusters of cream-coloured, prismatic needles, m. p. 251° (corr.) after sintering from 248°. It is anhydrous and readily soluble in water or hot alcohol (Found: C, 41·9; H, 4·0; Cl, 17·6. Calc., C, 41·7; H, 4·0; Cl, 17·6%). Tafel and Enoch (*Ber.*, 1890, 23, 1552), who prepared this salt by the interaction of the hydrochloride of *m*-nitrobenziminioethyl ether with ammonia, give m. p. 240°. The identity and purity of our preparation were established by hydrolysing the salt (1 g.) with 8·5% aqueous sodium hydroxide (40 c.c.), and adding concentrated hydrochloric acid, when 0·564 g. of *m*-nitrobenzoic acid, m. p. 140° (corr.), separated, and 0·25 g., m. p. 139°, was collected by ether, the total yield being 98·2%. The identity of these crops with *m*-nitrobenzoic acid was established by the mixed-melting point method. The first crop was also analysed (Found: C, 50·3; H, 3·0. Calc., C, 50·3; H, 3·0%).

*Nitration of Benzenyltrimethylamidine.*—*Benzenyltrimethylamidine nitrate* was prepared by the double decomposition of aqueous solutions of silver nitrate and the corresponding hydriodide, previously called dimethylamidobenzenylmethylimidine hydriodide (Pyman, J., 1923, 123, 3372). It crystallises from alcohol in large, colourless, prismatic rods, m. p. 195—196° (corr.). It is anhydrous and readily soluble in water or hot alcohol (Found: C, 53·2; H, 6·5; N, 18·5.  $C_{10}H_{14}N_2 \cdot HNO_3$  requires C, 53·3; H, 6·7; N, 18·7%). This salt (10 g.) was added gradually to concentrated sulphuric acid cooled in ice and salt. The solution was kept for 1 hour at the room temperature, heated for 2 hours at 100°, diluted with water, and mixed with aqueous solutions of barium hydroxide (50 g., hydrated) and barium chloride (46·7 g., hydrated). After removing barium sulphate, the aqueous solution was evaporated to dryness under diminished pressure, when a pale yellow syrup was obtained. Since the hydrochlorides showed little tendency to crystallise, the syrup was diluted and mixed with excess of aqueous sodium iodide, when the hydriodides separated as an oil which soon solidified. ~~After~~ numerous crystallisations from alcohol, using sulphur dioxide as a decolorising agent, 11·01 g. of pure *m*-nitrobenzenyltrimethylamidine hydriodide were isolated (yield 73·9%). The substance remaining in the mother-liquors was hydrolysed with aqueous sodium hydroxide; strong hydrochloric acid then precipitated 0·69 g. of *m*-nitrobenzoic acid, m. p. 133—137°. The filtrate was unfortunately lost.

On recrystallising the acid, 0.52 g. was obtained pure (m. p. 140°) and a further 0.164 g., m. p. 138°. They were identified as *m*-nitrobenzoic acid by the mixed-melting point method. The amount of these crops represents 9.3% of the theoretical yield, making in all 83.2%.

*m*-Nitrobenzenyltrimethylamidine hydriodide crystallises from alcohol in pale lemon-yellow needles, m. p. 243—246° (corr.; decomp.). It is anhydrous, and sparingly soluble in water or cold alcohol, but readily soluble in acetone (Found: C, 35.8; H, 4.1; I, 37.9.  $C_{10}H_{13}O_2N_3.HI$  requires C, 35.8; H, 4.2; I, 37.9%).

The identity and purity of this salt were established by hydrolysing 1.675 g. with aqueous sodium hydroxide, and acidifying the solution, when 0.67 g. of *m*-nitrobenzoic acid, m. p. 140°, was precipitated, and 0.16 g., m. p. 130°, collected from the filtrate by means of ether, the total yield being 99%. Both crops were identified as *m*-nitrobenzoic acid by the mixed-melting point method, and the first crop was also analysed (Found: C, 50.5; H, 3.0. Calc., C, 50.3; H, 3.0%).

*2-Phenyl-4:5-dihydroglyoxaline*.—Hofmann (*Ber.*, 1888, 21, 2334) states, without giving any details, that this base is best prepared by heating dibenzoylthylenediamine in a stream of hydrogen chloride, and this method was adopted after it had been found that dibenzoylthylenediamine was completely hydrolysed by boiling with concentrated sulphuric acid (3 c.c. per g.) for 10 minutes, and was only slowly attacked by boiling concentrated hydrochloric acid (10 c.c. per g.) when, after 2 hours, 82% was recovered unchanged. Ten grams of dibenzoylthylenediamine (prepared from ethylenediamine monohydrate by the Schotten-Baumann method in 91% yield) were heated to 250°, and dry hydrogen chloride was passed through the molten substance for 1 hour. The product was dissolved in hot water; on keeping, benzoic acid and 0.3 g. of unchanged material separated. The filtrate was basified and extracted with ether, which gave 4.56 g. of 2-phenyl-4:5-dihydroglyoxaline, m. p. 100° (yield 83.7%). It crystallised from acetone in colourless, prismatic needles, m. p. 102—103° (corr.). Hofmann gives m. p. 101°.

The nitrate crystallises from acetone in large, colourless, rhombic prisms, which are hydrated to a variable extent. After drying at 98°, it is anhydrous and melts at 118—119° (corr.) after softening from 117°. On cooling, it resolidifies and then melts sharply at 123° (corr.), but on recrystallising this modification, it reverts to the original form, m. p. 118—119°. This salt was described previously by Forssell (*Ber.*, 1892, 25, 2135), who does not record its m. p.

*Nitration of 2-Phenyl-4:5-dihydroglyoxaline*.—The anhydrous

nitrate (10.55 g.) was added to concentrated sulphuric acid (21 c.c.) cooled in ice and salt. The solution was kept for 1 hour at room temperature and then heated for 2 hours at  $100^{\circ}$ . The product was treated with barium hydroxide and barium chloride, just as the nitration product of benzamidine, to give the hydrochloride, which was crystallised from alcohol, when 10.47 g. of pure 2-*m*-nitrophenyl-4 : 5-dihydroglyoxaline hydrochloride were obtained, that is, 84.4%. The mother-liquors contained hydrochlorides (m. p.  $195-200^{\circ}$ ) which could not be separated either as such or as hydriodide or picrate, and the material was therefore oxidised with alkaline permanganate, when a mixture of nitrobenzoic acids was obtained, from which pure *m*-nitrobenzoic acid was isolated in a yield of 3%.

2-*m*-Nitrophenyl-4 : 5-dihydroglyoxaline hydrochloride crystallises from alcohol in coarse, yellow needles containing  $1\text{H}_2\text{O}$ , which is lost at  $100^{\circ}$ . After drying, it has m. p.  $249-251^{\circ}$  (corr.). It is readily soluble in water or hot alcohol, but sparingly soluble in acetone (Found in air-dried salt : loss in a vacuum over  $\text{H}_2\text{SO}_4$ , 7.4, 7.3.  $\text{C}_9\text{H}_9\text{O}_2\text{N}_3\cdot\text{HCl}\cdot\text{H}_2\text{O}$  requires  $\text{H}_2\text{O}$ , 7.3%. Found in dried salt : C, 47.6; H, 4.3; Cl, 15.6.  $\text{C}_9\text{H}_9\text{O}_2\text{N}_3\cdot\text{HCl}$  requires C, 47.5; H, 4.4; Cl, 15.6%). The hydriodide crystallises from water in pale yellow, prismatic needles, m. p.  $207-209^{\circ}$  (corr.), which are anhydrous and sparingly soluble in water (Found : I, 40.0.  $\text{C}_9\text{H}_9\text{O}_2\text{N}_3\cdot\text{HI}$  requires I, 39.8%).

The picrate crystallises from water or alcohol in fine, lemon-yellow needles, m. p.  $224-225^{\circ}$  (corr.). It is anhydrous and sparingly soluble in hot water or hot alcohol, but very readily soluble in acetone.

The orientation of the nitro-group in 2-*m*-nitrophenyl-4 : 5-dihydroglyoxaline was established by oxidation. The hydrated hydrochloride (1.23 g.) in hot water (50 c.c.) was boiled with 17% aqueous sodium hydroxide (20 c.c.) and sufficient aqueous potassium permanganate to give a permanently pink solution. After adding alcohol and filtering, the solution was concentrated and acidified with hydrochloric acid, when 0.577 g. of *m*-nitrobenzoic acid, m. p.  $140^{\circ}$  (corr.), was deposited, whilst ether extracted a further 0.048 g., m. p.  $125-128^{\circ}$ , from the mother-liquor. Mixtures of the two crops with pure *m*-nitrobenzoic acid had m. p.  $140^{\circ}$  (corr.) and  $132-135^{\circ}$ , respectively. The total yield is 74.9%.

*Bromination of 2-Phenylglyoxaline.*—A solution of 1.75 c.c. of bromine (1 mol.) in chloroform (15 c.c.) was added gradually to 2-phenylglyoxaline (5 g.) in chloroform (40 c.c.). After keeping for 15 minutes, the colourless precipitate of 4 : 5-dibromo-2-phenylglyoxaline hydrobromide, m. p.  $250-255^{\circ}$ , was collected, and this

gave on repeated treatment with cold water the base (4.3 g.), m. p. 137—138°. The chloroform mother-liquors were distilled with steam to remove solvent and excess of bromine, and the aqueous residue deposited 0.5 g. of the crude dibromo-base, m. p. 136—138°. The total yield is thus 46%. The final mother-liquors were basified with sodium carbonate and gave crude 2-phenylglyoxaline (2.5 g.; m. p. 138—140°).

4 : 5-Dibromo-2-phenylglyoxaline crystallises from acetone in colourless cubes, which decompose at about 141° (corr.) after darkening earlier (Found : C, 36.0; H, 2.0; Br, 52.8.  $C_9H_6N_2Br_2$  requires C, 35.8; H, 2.0; Br, 53.9%). It is insoluble in cold water and resinifies when heated with water. It is soluble in warm dilute mineral acids, aqueous sodium hydroxide, or ammonia. It is readily soluble in alcohol or acetone, and fairly readily soluble in ether or chloroform.

The hydrochloride crystallises from dilute hydrochloric acid in colourless needles, m. p. 235—237° (corr.). It yields the base on treatment with water. The picrate forms yellow plates, from alcohol, m. p. 170—172° (corr.).

*Nitration.* Potassium nitrate (3.3 g.; 1 mol.) was added to a cold solution of 4 : 5-dibromo-2-phenylglyoxaline (10 g.) in concentrated sulphuric acid (40 c.c.). After heating for 2 hours at 100°, the solution was poured into water, when 4 : 5-dibromo-2-*p*-nitrophenylglyoxaline was precipitated; the filtrate was basified with sodium carbonate, when an isomeric base separated. After crystallising these products from alcohol, 7.0 g. of the *p*-nitro-compound (yield 63%) and 0.2 g. of the isomeride (yield 1.8%) were obtained in a pure state.

4 : 5-Dibromo-2-*p*-nitrophenylglyoxaline crystallises from alcohol in orange needles, m. p. 220—222° (corr.) (Found in air-dried base : loss in a vacuum over  $H_2SO_4$ , 9.3, 9.3.  $C_9H_5O_2N_3Br_2 \cdot 2H_2O$  requires  $2H_2O$ , 9.4%. Found in dried base : C, 31.2; H, 1.8; N, 12.1; Br, 45.8.  $C_9H_5O_2N_3Br_2$  requires C, 31.1; H, 1.4; N, 12.1; Br, 46.1%). It is insoluble in cold water, and resinifies on heating with water. It is insoluble in cold dilute mineral acids, but dissolves slightly on warming. It dissolves in aqueous sodium hydroxide, ammonia, and sodium carbonate, giving red, orange, and yellow solutions, respectively. It is readily soluble in alcohol, acetone, or ether. On oxidation with alkaline permanganate, it gave *p*-nitrobenzoic acid, which was identified by the mixed-melting point method. 4 : 5-Dibromo-2-*o*(or *m*)-nitrophenylglyoxaline crystallises from dilute alcohol in lemon-yellow, glistening plates, m. p. 181—182° (corr.), which are anhydrous (Found : C, 31.0; H, 2.0; N, 12.1.  $C_9H_5O_2N_3Br_2$  requires C, 31.1; H, 1.4; N, 12.1%). It is insoluble

in hot or cold water, slightly soluble in dilute mineral acids, and readily soluble in aqueous sodium hydroxide, ammonia, or sodium carbonate, giving red, orange, and yellow solutions. The quantity available did not permit the identification of the acid produced on oxidation.

*Reduction of 4:5-Dibromo-2-phenylglyoxaline.*—Hot solutions of 4:5-dibromo-2-phenylglyoxaline (5 g.) in alcohol (125 c.c.) and hydrated sodium sulphite (20.5 g.) in water (200 c.c.) were mixed and boiled for 8 hours under reflux. After the alcohol had been removed, a crystalline precipitate (m. p. 185—187°) was deposited, which was separated, by fractional precipitation by hydrochloric acid from its solution in aqueous sodium hydroxide, into 4(5)-bromo-2-phenylglyoxaline (1.43 g.; m. p. 205—206°; yield 39%) and unchanged dibromo-base (1.36 g.).

4(5)-Bromo-2-phenylglyoxaline crystallises from dilute alcohol in small, white needles, m. p. 206—207° (corr.) (Found: C, 48.3; H, 3.1; N, 12.2; Br, 35.7.  $C_9H_7N_2Br$  requires C, 48.4; H, 3.1; N, 12.6; Br, 35.9%). It is slightly soluble in hot water, readily soluble in alcohol or acetone, and moderately readily soluble in ether. It is soluble in warm dilute acids, aqueous sodium hydroxide, or ammonia, but insoluble in aqueous sodium carbonate.

The *hydrochloride* crystallises from dilute hydrochloric acid in hard, white needles, which lose  $1H_2O$  in a vacuum over sulphuric acid and then melt at 118—119° (corr.) (Found in air-dried salt: loss in a vacuum over  $H_2SO_4$ , 6.6.  $C_9H_7N_2Br \cdot HCl \cdot H_2O$  requires  $H_2O$ , 6.5%. Found in dried salt: Cl, 13.8.  $C_9H_7N_2Br \cdot HCl$  requires Cl, 13.7%). On heating at 100°, the vacuum-dried salt suffers a further loss owing to dissociation. The *picrate* crystallises from alcohol in yellow plates, m. p. (air-dried) 164—165° (corr.).

*Nitration.* Potassium nitrate (0.76 g.; 1 mol.) was added to a cold solution of 4(5)-bromo-2-phenylglyoxaline (2 g.) in concentrated sulphuric acid (4 c.c.). After heating for 2 hours at 100°, the solution was poured into water, filtered from a yellow precipitate (1.0 g.; m. p. 95—110°), which was not worked up, and basified with sodium carbonate, when a further precipitate (1.7 g.; m. p. 180—182°) was collected. After crystallisation from dilute alcohol, this gave pure 4(5)-bromo-2-*p*-nitrophenylglyoxaline (0.75 g.; yield 31%).

4(5)-Bromo-2-*p*-nitrophenylglyoxaline crystallises from glacial acetic acid in yellow needles, m. p. 222—223° (corr.) (Found: loss at 100°, 18.1.  $C_9H_6O_2N_3Br \cdot CH_3 \cdot CO_2H$  requires loss of  $CH_3 \cdot CO_2H$ , 18.3%. Found in substance dried at 100°: C, 40.0; H, 2.5; N, 15.8.  $C_9H_6O_2N_3Br$  requires C, 40.3; H, 2.2; N, 15.7%).

It is insoluble in hot water, readily soluble in alcohol, ether, acetone, or glacial acetic acid, and moderately readily soluble in

chloroform. It is soluble in aqueous mineral acids, and dissolves in aqueous alkalis, including sodium carbonate, giving yellow to red solutions.

On oxidation with alkaline permanganate, it gave *p*-nitrobenzoic acid, which was identified by the mixed-melting point method.

### CIX.—*Derivatives of Tetrahydrocarbazole. Part V.* *Carboxylic Acids.*

By WINIFRED MAUDE COLLAR and SYDNEY GLENN PRESTON PLANT.

THE tetrahydrocarbazolecarboxylic acids hitherto described have the carboxyl group either in the reduced portion of the carbazole molecule (Perkin, J., 1904, 85, 418; Baeyer and Tutein, *Ber.*, 1889, 22, 2184) or attached to the nitrogen atom (Perkin and Plant, J., 1923, 123, 683). We have now prepared the four isomeric acids in which the carboxyl group is attached to the benzene nucleus (for the scheme of numbering the positions in tetrahydrocarbazole, see J., 1923, 123, 677) by Fischer's method for the synthesis of indole derivatives. In this way, the hydrazones made by condensing cyclohexanone with *o*- and *p*-hydrazinobenzoic acid lost ammonia and gave respectively tetrahydrocarbazole-8- and 6-carboxylic acids, whilst the hydrazone from *m*-hydrazinobenzoic acid by the same process gave a mixture of two acids, one of which must have the carboxyl group in the 5- and the other in the 7-position. This experience is contrary to that which was found in the case of cyclohexanone-*m*-nitrophenylhydrazone, from which only one of the two possible isomeric nitrotetrahydrocarbazoles, assumed to be 7-nitrotetrahydrocarbazole, was obtained on closing the indole ring (Borsche, Witte, and Bothe, *Annalen*, 1908, 359, 68; Perkin and Plant, J., 1921, 119, 1828). Baeyer and Tutein (*loc. cit.*) prepared an acid which may be tetrahydrocarbazole-2 or 4-carboxylic acid from the phenylhydrazone of cyclohexanone-3-carboxylic acid.

The constitutions of these four tetrahydrocarbazolecarboxylic acids are confirmed by the fact that they easily give tetrahydrocarbazole on distillation with soda-lime.

#### EXPERIMENTAL.

*Tetrahydrocarbazole-6-carboxylic Acid.*—The crude hydrochloride of *p*-hydrazinobenzoic acid, prepared from *p*-aminobenzoic acid (25 g.) by the method of Fischer (*Annalen*, 1882, 212, 337), was

dissolved in hot water (350 c.c.), treated with an excess of sodium acetate, and then with *cyclohexanone* (18 c.c.); on shaking, *cyclohexanone-p-carboxyphenylhydrazone* separated. It crystallised from glacial acetic acid in yellow prisms, m. p.  $236^{\circ}$  (decomp.) (Found : N, 12.5.  $C_{13}H_{16}O_2N_2$  requires N, 12.1%).

The crude hydrazone was added to water (200 c.c.) and sulphuric acid (40 c.c.) and the mixture warmed to boiling. The *tetrahydrocarbazole-6-carboxylic acid* that separated crystallised from dilute alcohol in colourless plates, m. p.  $282^{\circ}$  (Found : N, 6.6.  $C_{13}H_{13}O_2N$  requires N, 6.5%).

The *methyl* ester was produced by boiling the acid with methyl alcohol containing a little sulphuric acid for 4 hours, and precipitating by the addition of dilute aqueous ammonia. It crystallised from dilute acetic acid in colourless leaves, m. p.  $158^{\circ}$  (Found : N, 5.9.  $C_{14}H_{15}O_2N$  requires N, 6.1%). The *ethyl* ester was prepared in a similar way and separated from dilute alcohol in small, colourless prisms, m. p.  $119^{\circ}$ .

*Tetrahydrocarbazole-8-carboxylic Acid*.—The hydrochloride of *o*-hydrazinobenzoic acid was converted by a process similar to that described above into *cyclohexanone-o-carboxyphenylhydrazone*, which separated from benzene in pale yellow needles, m. p.  $162^{\circ}$  (Found : N, 12.0.  $C_{13}H_{16}O_2N_2$  requires N, 12.1%). On warming the hydrazone (6 g.) with water (120 c.c.) and sulphuric acid (30 c.c.), *tetrahydrocarbazole-8-carboxylic acid* separated and, on recrystallisation from benzene, it was obtained in colourless prisms, m. p.  $203^{\circ}$  (Found : N, 6.5.  $C_{13}H_{13}O_2N$  requires N, 6.5%).

The *methyl* ester crystallises from methyl alcohol in long, colourless prisms, m. p.  $124^{\circ}$  (Found : N, 5.9.  $C_{14}H_{15}O_2N$  requires N, 6.1%). The *ethyl* ester separates from dilute alcohol in colourless needles, m. p.  $76^{\circ}$  (Found : N, 5.8.  $C_{15}H_{17}O_2N$  requires N, 5.7%).

*Tetrahydrocarbazole-5- and 7-carboxylic Acids*.—*cyclohexanone-m-carboxyphenylhydrazone*, prepared from *m*-hydrazinobenzoic acid in the usual way, crystallised from dilute alcohol in orange prisms, m. p.  $176^{\circ}$  (decomp.) (Found : N, 11.9.  $C_{13}H_{16}O_2N_2$  requires N, 12.1%). The crude hydrazone was converted into a mixture of *tetrahydrocarbazole-5- and 7-carboxylic acids* on warming with dilute sulphuric acid. The two acids were isolated from the product by fractional crystallisation from either glacial acetic acid or aqueous acetone, and purified by conversion into their methyl esters, from which they were readily obtained on saponification. The acid which separated first in both cases was finally recrystallised from glacial acetic acid and obtained in colourless prisms, m. p.  $287^{\circ}$  (Found : N, 6.6.  $C_{13}H_{13}O_2N$  requires N, 6.5%). Its *methyl* ester crystallised from methyl alcohol in colourless needles, m. p.

155°, and its *ethyl* ester from dilute alcohol in small, colourless plates, m. p. 146°.

The isomeric *tetrahydrocarbazolecarboxylic acid* was ultimately obtained from glacial acetic acid in almost colourless prisms, m. p. 210° (Found : N, 6.1.  $C_{13}H_{13}O_2N$  requires N, 6.5%). Its *methyl* ester separated from aqueous alcohol in colourless prisms, m. p. 93° (Found : N, 6.1.  $C_{14}H_{15}O_2N$  requires N, 6.1%).

The higher-melting acid (m. p. 287°) is the main constituent of the product of this reaction and from 30 g. of the crude material 16 g. of this acid and 6 g. of the isomeride (m. p. 210°) were isolated in a pure condition.

### CX.—*The Oximes of 2:4-Dinitrobenzil and the Beckmann Change.*

By GERALD BISHOP and OSCAR L. BRADY.

In a previous communication (J., 1922, **121**, 2364), two substances, regarded as monoximes of 2:4-dinitrobenzil, were described to which, on account of their behaviour in the Beckmann change, the following structures were assigned :

Further investigation, however, has shown that the supposed  $\beta$ -oxime was a mixture and that its reactions were untrustworthy guides to its constitution. Consequently, our early view of the configurations of the substances requires modification. We are now of opinion that their reactions are best explained by adopting Meisenheimer's view that the Beckmann change takes place in a *trans*- and not in a *cis*-sense (*Ber.*, 1921, **54**, 3206; 1924, **57**, 276, 282, 289), ring closure being assumed to involve no change in configuration (compare, however, Kuhn and Ebel, *Ber.*, 1925, **58**, 919; Böseken, *ibid.*, p. 1470; Meisenheimer, *ibid.*, p. 1491). The  $\alpha$ -oxime has accordingly been given the configuration (I). The Beckmann change leads to benzonitrile and 2:4-dinitrobenzoic acid as previously described. By boiling with the calculated quantity of sodium dissolved in alcohol, the  $\alpha$ -oxime is converted, by elimination of nitrous acid, into a brilliant scarlet compound which, on account of its colour, we consider to be 6-nitro-3-keto-

2-phenyl- $\psi$ -indole-1-oxide (II), the  $\alpha$ -oxime, since the oxygen atom is remote from the nitro-group, reacting in the nitron form. This compound on treatment with excess of alkali gives benzaldehyde and an amorphous compound, thus behaving similarly to the  $\alpha$ -oxime itself when treated with excess of aqueous sodium hydroxide. When the  $\alpha$ -oxime is heated in alcohol to 165°, nitrous acid is eliminated and 7-nitro-4-keto-3-phenyl-1:2-benzoxazine (III) is formed. That this compound is not produced by the action of alkali on the  $\alpha$ -oxime suggests that at the high temperature the oxime undergoes an isomeric change analogous to that of the oximes of benzil under similar conditions; in the new oxime (IV) thus produced, the hydroxyl and nitro-groups are vicinal and consequently nitrous acid is readily eliminated. 7-Nitro-4-keto-3-phenyl-1:2-benzoxazine on hydrolysis gives benzonitrile and 4-nitrosalicylic acid. The benzoxazine melts, by an unfortunate coincidence, at the same temperature (169°) as 4-nitrosalicylonitrile, and we have found that the compound produced by the action of alkali on the supposed  $\beta$ -oxime and described in our previous paper as 4-nitrosalicylonitrile (*loc. cit.*, p. 2369), and for the identification of which we relied on the melting point and hydrolysis to 4-nitrosalicylic acid, was in fact this benzoxazine.

The reactions of the  $\alpha$ -oxime may be summarised thus :

The action of excess of free hydroxylamine on 2:4-dinitrobenzil, by which the supposed  $\beta$ -oxime was obtained, yields a complex mixture, from which 7-nitro-4-keto-3-phenyl-1:2-benzoxazine (III), the  $\alpha$ -oxime (I), and the pure  $\beta$ -oxime (V) have been isolated. The formation of the benzoxazine suggests that the unknown oxime (IV) is first produced and loses nitrous acid with great ease in the presence of excess of hydroxylamine.

The  $\beta$ -oxime, in the Beckmann change, gives benzoic acid and 2:4-dinitrobenzonitrile. On heating with alkali, it gives benzoic

acid and 4-nitrosalicylonitrile through the unstable isooxazole (VI). Its reactions may be represented thus :

There was also evidence that the crude oximation mixture contained the fourth oxime,  $(\text{NO}_2)_2\text{C}_6\text{H}_3\text{-C}\cdot\text{COPh}$ . The presence of

this would account for the isolation, in the previously described experiments, of 2 : 4-dinitroaniline after the supposed  $\beta$ -oxime had undergone the Beckmann change. In a subsequent similar experiment with the crude oximation mixture, we were unable to separate the dinitroaniline from the other products, but isolated 2 : 4-dinitrophenol by heating with concentrated alkali, acidifying, and distilling in steam.

## EXPERIMENTAL.

$\alpha$ -2:4-Dinitrobenzilmonoxime.—The preparation is described in our previous paper. The  $\alpha$ -monoxime (3 g.) was heated for 5 hours with absolute alcohol (5 c.c.) in a sealed tube at 165°. On cooling, a colourless, crystalline compound separated which after crystallisation from alcohol gave 7-nitro-4-keto-3-phenyl-1:2-benzoxazine (III), m. p. 169° (Found: N, 10.4.  $C_{14}H_8O_4N_2$  requires N, 10.4%). This compound was identical in properties with the supposed 4-nitrosalicylonitrile previously obtained by the action of alkali on the impure  $\beta$ -oxime (Bishop and Brady, *loc. cit.*) and on admixture did not depress its melting point. 7-Nitro-4-keto-3-phenyl-1:2-benzoxazine was boiled for a short time with 10% sodium hydroxide; the odour of benzonitrile was observed and on distilling in steam this nitrile was obtained in the distillate; the residue, on being acidified, gave a precipitate from which 4-nitrosalicylic acid was obtained by crystallisation.

The action of alkali in excess on the  $\alpha$ -oxime was described in the previous paper. When, however, the oxime (5 g.), dissolved in absolute alcohol (20 c.c.) containing the calculated quantity of sodium to give the sodium salt (0.36 g.), was boiled for 15 minutes, a brilliant scarlet precipitate of 6-nitro-3-keto-2-phenyl- $\psi$ -indole 1-oxide formed which crystallised from alcohol as a red, crystalline

powder, m. p.  $198^{\circ}$  (Found: C, 62.5; H, 3.1; N, 10.5.  $C_{14}H_8O_4N_2$  requires C, 62.7; H, 3.0; N, 10.4%). Nitrite was detected in the mother-liquor from the preparation. Boiled with excess of aqueous alkali, the compound behaves in a similar manner to the  $\alpha$ -oxime, giving benzaldehyde and an amorphous product.

$\beta$ -2 : 4-Dinitrobenzilmonoxime.—A solution of 2 : 4-dinitrobenzil in alcohol cooled in ice was treated with an alcoholic solution of 3 equivalents of hydroxylamine. After a few moments, crystals of 7-nitro-4-keto-3-phenyl-1 : 2-benzoxazine began to separate and after 12 hours these were collected and the filtrate from them was diluted with water ( $\frac{1}{4}$  vol.); a small quantity of impure  $\alpha$ -monoxime was then precipitated. The filtrate from the  $\alpha$ -oxime was poured into excess of water, kept over-night, and the precipitate repeatedly crystallised from dilute alcohol until its melting point was constant;  $\beta$ -2 : 4-dinitrobenzilmonoxime, m. p.  $168^{\circ}$ , was thus obtained (Found: N, 13.4. Calc., N, 13.3%).

A solution of the  $\beta$ -oxime in ether was cooled in ice, and the calculated quantity of phosphorus pentachloride added. After 12 hours, ice-water was added, and the mixture then kept for 3 hours. The ether layer was shaken several times with 2*N*-sodium carbonate and evaporated; 2 : 4-dinitrobenzonitrile, identified by comparison with an authentic specimen, was thus obtained. The alkaline extracts on acidification and re-extraction with ether gave benzoic acid.

The  $\beta$ -oxime was boiled under reflux for an hour with 2*N*-sodium hydroxide; no darkening or evolution of ammonia occurred as with the  $\alpha$ -oxime, and on cooling and saturating with carbon dioxide 4-nitrosalicylonitrile crystallised. This was identified by comparison with a specimen prepared from 2 : 4-dinitrobenzaldoxime (Borsche and Oppenheimer, *Annalen*, 1912, 390, 10). The carbonate solution, after removal of dissolved nitrosalicylonitrile with ether, gave benzoic acid on being acidified and extracted with ether.

## CXI.—*Synthetical Work on the isoQuinoline Alkaloids.* *Part II. A Method of Opening the Rings of Cyclic Ketones.*

By GEORGE ALFRED EDWARDS.

THE reactions herein described were investigated with the object of obtaining derivatives of  $\beta$ -o-cyanophenylpropionic acid and of o-carboxyphenylacetonitrile, such substances being required for attempts to synthesise ten-membered rings of the cryptopine type.

The sodium salt of 1-nitroso- $\beta$ -naphthol when heated to  $180^\circ$  with sand gives sodium *o*-cyanocinnamate in poor yield (D.R.-P. 116223). This reaction was examined in the hope of bringing about the same change by less violent means. 1-Nitroso- $\beta$ -naphthol was converted by benzoyl chloride and cold caustic soda solution into a benzoyl derivative, which slowly hydrolysed in warm caustic soda solution, yielding benzoic acid and the *o*-cyanocinnamic acid of m. p.  $137^\circ$  (D.R.-P. 411955). The separation of the benzoic acid was rather troublesome, so it is fortunate that benzoyl chloride can be replaced by either benzene- or toluene-sulphonyl chloride, the acyl derivative produced being in each case easily hydrolysed to the above cyano-acid.

This 2-cyanocinnamic acid was at first thought to be *o*-carboxycinnamonitrile, since on hydrolysis it gave *o*-carboxycinnamic acid, and since, if its formation followed the normal course of the Beckmann reaction, ring opening might take place in two ways, thus:  $R \cdot C(NO_2) \cdot COR' \rightarrow R \cdot CO \cdot NH \cdot COR' \rightarrow$  either  $R \cdot CO_2H$  and  $R'CN$  or  $RCN$  and  $R' \cdot CO_2H$ . *o*-Carboxycinnamonitrile was therefore synthesised as follows. Phthalylacetic acid (Neumann and Gabriel, *Ber.*, 1893, 26, 952) was reduced electrolytically to phthalideacetic acid (I). This was converted through its acid chloride into *phthalideacetamide*, which, when boiled in xylene solution with phosphorus pentoxide, lost water and gave *phthalideacetoneitrile* (II). The

lactone ring of this substance was opened on treatment with caustic soda, and by carefully heating the sodium salt in a vacuum *o*-carboxycinnamonitrile was produced.

If the acyl derivatives of 1-nitroso- $\beta$ -naphthol are heated at  $140^\circ$  for a short time, they will give the *o*-cyanocinnamic acid of m. p.  $255-256^\circ$  on hydrolysis.

The low-melting acid itself, when heated above its melting point for a few minutes, is completely converted into the high-melting *o*-cyanocinnamic acid. Since both cyano-acids on electrolytic reduction give  $\beta$ -*o*-cyanophenylpropionic acid (III), the only possible conclusion is that these acids are geometric isomerides similar to cinnamic and *allocinnamic* acids. On the analogy of these, the low-melting acid has been called *o*-cyano*allocinnamic* acid.

As  $\beta$ -*o*-cyanophenylpropionic acid was required in quantity, the most suitable conditions for its preparation were investigated. A method is described, using toluenesulphonyl chloride, which is suitable for large-scale preparations; about 6% of the acyl derivative

is hydrolysed to 1-nitroso- $\beta$ -naphthol, but this is easily separated owing to its insolubility in sodium carbonate solution.

Since in these reactions 1-nitroso- $\beta$ -naphthol obviously reacted in the oxime form, it seemed probable that substances containing the group  $\cdot\text{CH}_2\cdot\text{CO}\cdot$  in a ring, if first converted into their isonitroso-derivatives, would react with acid chlorides in the same way. This was investigated in the case of the hydrindones. Hydrindone itself gave *o*-carboxyphenylacetonitrile in 92% yield, whilst 5:6-dimethoxy- and 5:6-methylenedioxy-hydrindones gave the corresponding cyano-acids. These three cyano-acids have recently been prepared by Haworth and Pink (J., 1925, 127, 1369) by the action of phosphorus pentachloride on the nitrosohydrindones. They easily decompose on warming, but by cautious treatment with thionyl chloride may be converted into their acid chlorides, from which their esters, amides, and substituted amides may be obtained.

#### EXPERIMENTAL.

*Action of Benzenesulphonyl Chloride upon 1-Nitroso- $\beta$ -naphthol.*—1-Nitroso- $\beta$ -naphthol (1 g.-mol.) is mixed with benzenesulphonyl chloride (1 g.-mol.), the whole is dissolved in the minimum quantity of cold acetone, and 8% caustic soda solution (1.2 g.-mols.) is added slowly, with shaking and cooling in ice. The *benzenesulphonyl-1-nitroso- $\beta$ -naphthol* that separates crystallises from a little acetone in yellow prisms, m. p. 124–125° (decomp.) (Found: C, 61.6; H, 3.6.  $\text{C}_{16}\text{H}_{11}\text{O}_4\text{NS}$  requires C, 61.3; H, 3.5%). On being kept at its m. p. for a few minutes, it resolidifies and thereafter melts at 137–139°, having been converted into an isomeride which crystallises from acetone in cream needles, m. p. 141° (Found: C, 61.7; H, 3.5%).

The low-melting acyl derivative is hydrolysed when dissolved in a slight excess of 8% caustic soda solution at 60°. The filtered cooled solution on acidification deposits *o*-cyanoallocinnamic acid in almost colourless needles. This crystallises from water, containing a little animal charcoal, in colourless, felted needles, m. p. 137° (Found: C, 69.7; H, 4.4. Calc. for  $\text{C}_{10}\text{H}_7\text{O}_2\text{N}$ : C, 69.4; H, 4.1%). When the benzenesulphonyl derivative, m. p. 141°, is treated in the same way, *o*-cyanocinnamic acid separates in a gelatinous form; it crystallises from glacial acetic acid in slightly brown, glistening plates, m. p. 256°, identical with the product of heating the sodium salt of 1-nitroso- $\beta$ -naphthol with sand at 180°.

*Direct Preparation of o-Cyanoallocinnamic Acid.*—A solution of 1-nitroso- $\beta$ -naphthol (43 g.) and toluenesulphonyl chloride (47 g.) in the minimum quantity of acetone is kept at 55–60° while caustic soda (8% solution) is added slowly, with constant shaking, so that

the solution is kept faintly alkaline. When the solution finally becomes permanently alkaline, it is cooled, filtered, and acidified, 38 g. of crude *o*-cyanallocinnamic acid being precipitated. For the preparation of *o*-cyanophenylpropionic acid further purification is unnecessary.

*o*-Carboxycinnamic acid, m. p.  $182^{\circ}$ , is produced when either of the *o*-cyanocinnamic acids is refluxed for 2 hours with 10% caustic soda solution, and is precipitated on acidification.

$\beta$ -*o*-Cyanophenylpropionic Acid (III).—A solution of crude *o*-cyanallocinnamic acid (40 g.) in 14% sodium carbonate solution (150 c.c.) is filtered from insoluble gummy impurities and reduced electrolytically for 3 hours at a lead cathode, the current density being 2 amps./100 sq. cm.; the anode cell consists of a lead electrode in 20% caustic soda solution. The product on acidification deposits a slightly brown, sandy powder, which crystallises from water in prisms, m. p.  $127^{\circ}$  (Found: C, 68.9; H, 5.0.  $C_{10}H_9O_2N$  requires C, 68.6; H, 5.2%).

*o*-Carboxycinnamonitrile,  $CO_2H \cdot C_6H_4 \cdot CH:CH \cdot CN$ .—Phthalyl-acetic acid (40 g.) dissolved in caustic soda (200 c.c. of 15% solution) is reduced electrolytically under the conditions described above. The hot solution is acidified with hydrochloric acid and filtered; on cooling, phthalideacetic acid separates in colourless plates, m. p.  $151^{\circ}$ , identical with the substance obtained by the reduction of phthalylacetic acid with sodium amalgam (Gabriel and Michael, *Ber.*, 1877, 10, 391). The acid (10 g.) is boiled with thionyl chloride (20 c.c.) for 15 minutes, the excess of thionyl chloride distilled away, the gummy residue dissolved in a little chloroform, and the solution slowly added to aqueous ammonia (60 c.c.;  $d$  0.880) cooled in ice, the temperature being kept below  $10^{\circ}$  during the addition. The chloroform is then evaporated on the water-bath; on cooling, phthalideacetamide separates in rectangular plates, m. p.  $182$ — $183^{\circ}$  (Found: N, 7.5.  $C_{10}H_9O_3N$  requires N, 7.3%). This amide (2 g.) is heated in boiling xylene (16 c.c.) with phosphorus pentoxide (4 g.) for 15 minutes. The boiling filtered xylene, on cooling, deposits pure white needles, m. p.  $111^{\circ}$ , of phthalideacetonitrile, and more may be obtained by extracting the brown, gummy residue from the xylene with boiling water, the latter depositing slightly brown needles on cooling. The nitrile is insoluble in cold alkali, but dissolves readily on warming, ammonia being evolved from the boiling solution.

A solution of phthalideacetonitrile in the theoretical quantity of warm caustic soda solution is evaporated to dryness on the water-bath, the residue kept at  $200^{\circ}$  in a vacuum for 10 minutes, cooled, and dissolved in water. On acidification a slightly yellow powder

separates which crystallises from water as a microcrystalline powder, m. p. 169—172° (Found: N, 7.3.  $C_{10}H_9O_3N$  requires N, 7.3%). This is *o*-carboxycinnamionitrile and yields *o*-carboxycinnamic acid, m. p. 182°, on hydrolysis (as above).

*o*-Carboxyphenylacetoneitrile.—2-isoNitroso-1-hydrindone (7.2 g.) is dissolved in caustic soda (80 c.c. of 8% solution), and benzenesulphonyl chloride (9 g.) added with constant shaking. The benzenesulphonyl derivative first separates as a white gum, which slowly dissolves on raising the temperature to 80° for a few minutes. The cooled filtered solution on acidification deposits *o*-carboxyphenylacetoneitrile as a white powder crystallising from water in colourless needles, m. p. 126°, identical with the substance obtained by Haworth and Pink (*loc. cit.*).

2-Carboxy-4 : 5-dimethoxyphenylacetoneitrile is obtained from dimethoxyisonitrosohydrindone (3 g.), caustic soda (3 g. in 25 c.c. of water), and benzenesulphonyl chloride (2.2 c.c.) by the method described above; it crystallises slowly in needles, m. p. 166—167°.

2-Carboxy-4 : 5-methylenedioxyphenylacetoneitrile, obtained in exactly the same way as the dimethoxy-compound, crystallises in slightly yellow prisms, m. p. 195° (Found: C, 58.3; H, 3.4. Calc., C, 58.5; H, 3.4%).

The author wishes to express his thanks to the Research Fund Committee of the Chemical Society for a grant which covered the cost of the materials used in this investigation.

KING'S COLLEGE, LONDON.

## CXII.—Trypanocidal Action and Chemical Constitution. Part IV. Arylamides of Aminohydroxyphenylarsinic Acids.

By LESLIE FRANK HEWITT and HAROLD KING.

IN Parts I and II (King and Murch, J., 1924, **125**, 2595; 1925, **127**, 2632) the preparation and properties of a number of arylamides of 4-aminophenylarsinic acid (I) were described. Inasmuch as Fournneau and his colleagues (*Ann. Inst. Pasteur*, 1923, **37**, 551) have shown that on *Trypanosoma brucei* in mice, 3-amino-4-hydroxyphenylarsinic acid (II) and 4-amino-2-hydroxyphenylarsinic acid (III) with chemo-therapeutic indices (curative dose/tolerated dose) of 1/5 and 1/8 respectively are superior to 4-aminophenylarsinic acid with an index of 1/1, it was thought of interest to introduce into these hydroxy-acids certain substituted aminobenzoyl radicals

which were shown in Part II to have a favourable influence on the trypanocidal activity of 4-aminophenylarsinic acid.

The types (IV) and (V), where R is H, OMe, or OH, were obtained by reduction of the corresponding nitro-acids by ferrous chloride and alkali, the preparation of the nitrohydroxybenzoyl derivatives (R = OH) necessitating the use of ethylcarbonatonitrobenzoyl chloride, where the hydroxyl group is protected by the carbethoxyl group.

Although the ethylcarbonato-group in 3'-nitro-4'-ethylcarbonato-benzoyl-4-aminophenylarsinic acid (VI) is readily hydrolysed with negligible fission at the amide link by brief boiling with *N*-alkali (King and Murch, Part II), in the case of 3'-nitro-4'-ethylcarbonato-benzoyl-3-amino-4-hydroxyphenylarsinic acid (VII) hydrolysis of this group by cold *N*-alkali leads to appreciable fission of the amide link and much greater fission occurs on rise of temperature.

The maximum dose tolerated by mice, expressed in milligrams per gram of mouse, and the minimum curative dose, where determined, on an experimental infection of *T. equiperdum* in mice, of this group of twelve related compounds is shown below, R signifying the para-substituent to the amide group and *r* the number of days before relapse occurred.

Type IV. Derivatives of 3-NH<sub>2</sub>·4-OHC<sub>6</sub>H<sub>3</sub>·AsO<sub>3</sub>H<sub>2</sub>.

				( <i>r</i> = 12)	( <i>r</i> > 30)	( <i>r</i> = 12)

On comparing these results with those obtained for the corresponding derivatives of 4-aminophenylarsinic acid (Part II) it will be observed that there is here no enhanced trypanocidal activity such as might be expected from the relative activities of the parent mono-nuclear arsenic acids (I, II, and III). There is, however, a rough parallelism between the activities of the amides of 4-aminophenylarsinic acid and those of 4-amino-2-hydroxyphenylarsinic acid; in each case, the aminoanisoyl derivative is the only one of the three amides with permanent curative properties.\* Expressed otherwise, one might say that the introduction of the 2-hydroxyl group into derivatives of 4-aminophenylarsinic acid has not radically altered the distribution of the main and residual affinities of the molecule on which trypanocidal activity as measured by the two determinants, curative dose and tolerated dose, ultimately depends.

The possession by the six complex amino-arsinic acids above described of a free hydroxyl group emphasised the desirability of the preparation of the corresponding arseno-derivatives, which like salvarsan should be administrable by solution in alkali. The comparison of six arseno-bases with the parent amino-acids was all the more a desideratum because Fournéau has expressed the opinion that on the evidence available the arsenic acids are at least as active as the arseno-derivatives. Unfortunately this object was only realisable in part because, unexpectedly, the possession of a single hydroxyl group in the same nucleus as the arseno-group did not confer alkaline solubility, the sodium salts of the aminobenzoyl and aminoanisoyl derivatives being quite insoluble in water. In addition, the hydroxyl group ortho to the arseno-group in derivatives of 4-amino-2-hydroxyphenylarsinic acid weakens the attachment of the arsenic atom to the nucleus, thus leading under very mild conditions of reduction by hypophosphorous acid to formation of products containing polyarsenides. This is perhaps not surprising, because the parent acid, 4-amino-2-hydroxyphenylarsinic acid, when reduced by the same reagent gives no arseno-base but only free arsenic. The hydroxyaminobenzoyl derivatives (VIII) and (IX) were, however, alkali-soluble, the former substance being of

\* In this series of communications, the term "permanent curative property" indicates no relapse of some of the animals within 30 days, the blood being examined almost daily over that period. As a rule, each dose is tried on five mice.

special interest because of the duplication of the *o*-aminophenol grouping contained in salvarsan. The maximum tolerated and the minimum curative dose of these two arseno-bases in comparison with their parent arsenic acids are shown below.

	Acid.	Arseno (VIII).	Acid.	Arseno (IX).
<i>Dosis tolerata</i> .....	0.3	0.075	0.2	0.075
<i>Dosis curativa</i> .....	0.3	0.03	0.2	0.02
	( <i>r</i> = 8)	( <i>r</i> = 5)	( <i>r</i> = 12)	( <i>r</i> > 30)

Whilst there is little difference in activity between the arseno-derivative (VIII) and its parent acid, the arseno-derivative (IX) is permanently curative on one-fourth of its tolerated dose and is thus far superior to its parent acid. It should, however, be borne in mind that the arseno-derivative (IX) contains a certain proportion of polyarsenides, as has been indicated above.

3'-Nitrobenzoyl-4-amino-2-hydroxyphenylarsinic acid (X) on further nitration yields exclusively 3':5-dinitrobenzoyl-4-amino-2-hydroxyphenylarsinic acid (XI), which on reduction yields the corresponding diaminobenzoylamino-2-hydroxyphenylarsinic acid.

In Part II it was shown that the diamino-arsinic acids were in general permanently curative, but this substance, either on its maximum tolerated dose or on lower doses, was completely devoid of action. Various reasons might be advanced for this, but it is not proposed to discuss them here.

On hydrolysis of (XI) by alkali 5-nitro-4-amino-2-hydroxyphenylarsinic acid was obtained and this on reduction gave a new 4:5-diamino-2-hydroxyphenylarsinic acid of which only one isomeride is known. The activity of this diamino-acid in comparison with the closely related 4-amino-2-hydroxyphenylarsinic acid (III) and 3-amino-4-hydroxyphenylarsinic acid (II) is shown in the following table :

	Diamino-acid.	III.	II.
<i>Dosis tolerata</i> .....	0.3	0.5	1.5
<i>Dosis curativa</i> .....	0.05 ( <i>r</i> = 16)	0.2	0.3

The diamino-acid was very erratic in its curative action and far inferior to (II) or (III). It will be noticed that the indices for (II) and (III) are not as favourable on *T. equiperdum* as those obtained by Fourneau (see opening paragraph) on *T. brucei*.

4-Amino-2-hydroxyphenylarsinic acid (III), required in quantity in this investigation, was prepared by the Bart-Schmidt reaction from 5-nitro-2-aminophenol (Bauer, *Ber.*, 1915, 48, 1582). The

preparation of the latter from 2-aminophenol presents some points of interest to the student of orientation. Meldola and Wechsler (P., 1900, 180) showed that *ON*-diacetyl-2-aminophenol on attempted mononitration gave exclusively 4 : 6-dinitro-2-aminophenol (picramic acid) after hydrolysis, and we find in support that both mono- and tri-acetyl-2-aminophenol on mononitration yield after hydrolysis almost exclusively picramic acid, although in the case of triacetyl-2-aminophenol traces of both 5-nitro- and 4-nitro-2-acetylaminophenol have been isolated. In D.R.-P. 165650, however, 5-nitro-2-aminophenol is said to be prepared by the nitration of ethenyl-2-aminophenol (XII). An examination of this reaction shows that 5-nitro-2-aminophenol (XIII) is indeed formed together with 4-nitro-2-aminophenol (XIV) in the ratio 4 : 1, the main bulk of the 5-nitro-compound after hydrolysis being separable owing to its lesser solubility in water. The remaining mixture can be separated by fractionally crystallising the acetates from benzene, which obviates both the tendency of the two isomerides to separate from water as brilliant red mixed crystals and the formation of the low-melting hydrate of the 4-nitro-derivative.

The sulphonation product of carbonyl-2-aminophenol (XV) is known to yield 2-aminophenol-5-sulphonic acid on hydrolysis (D.R.-P. 197496; King, J., 1921, 119, 1117), but although 5-nitro-carbonyl-2-aminophenol is prepared by the action of nitric acid on carbonylaminophenol and yields nitrocatechol on alkaline hydrolysis (Chelmicki, *J. pr. Chem.*, 1890, 42, 441), there is no record of its hydrolysis by acids. This should also lead to the required 5-nitro-2-aminophenol. This has now been effected, but only with difficulty, as 5-nitrocarbonyl-2-aminophenol is very resistant to acid hydrolysis. Of the two possible routes to the required nitroaminophenol, the one *via* the ethenyl derivative proved the more convenient.

Thus, whilst the nitration of any of the acetyl derivatives of 2-aminophenol yields as main product picramic acid in which the orienting power of the hydroxyl may be said to overwhelm that of the acetylated amino-group in agreement with the behaviour of 4-aminophenol derivatives, in ethenyl- and carbonyl-aminophenol the reverse is true. The latter cases are also in agreement with the nitration of another cyclic derivative of 2-aminophenol, acetylphenoxazine, which yields 3 : 9-dinitrophenoxazine, the nitro-

groups entering the para-position to the nitrogen atom (Kehrmann and Saager, *Ber.*, 1903, **36**, 477).

To Miss F. M. Durham and Miss J. Marchal of this department we again tender our thanks for the efficient and painstaking care bestowed on the biological side of our subject.

#### EXPERIMENTAL.

*o*-Aminophenol.—The large quantities of *o*-aminophenol required were prepared in part by an improvement on Grandmougin's process (*Ber.*, 1906, **39**, 3561). *o*-Nitrophenol dissolved in 2*N*-sodium hydroxide (1 mol.) was treated with solid sodium hyposulphite (1.6 mols.) and sufficient sodium hydroxide to keep the reaction mixture faintly alkaline, the solution being well stirred and the temperature kept below 30°. The yield of *o*-aminophenol, including ether-extracted material, was 67%.

*Nitration of Ethenyl-o-aminophenol* (XII).—Ethenyl-*o*-aminophenol was obtained in 90% yield by a simplification of Ladenburg's method (*Ber.*, 1876, **9**, 1524). *o*-Aminophenol (carefully freed from inorganic salts) was distilled with 3 parts of acetic anhydride, and the distillate refractionated through a short column. The fraction, b. p. 200—210°, consisted of ethenyl-*o*-aminophenol. Of this, 53.9 g. were dissolved in sulphuric acid (200 c.c.) below 0° and treated with nitric acid ( $d$  1.42; 1.1 mols.) dissolved in an equal volume of sulphuric acid. On pouring on to ice, a bulky yellow compound was obtained, but attempts to isolate a pure nitroethenyl-*o*-aminophenol from this were unsuccessful. (When dried in a vacuum, it lost 90% of its weight and liquefied, and repeated crystallisation from alcohol gave eventually pure 5-nitro-2-acetylaminophenol.) The wet, bulky precipitate was heated at 100° with 325 c.c. of hydrochloric acid ( $d$  1.16) until dissolved, and the solution almost neutralised. Orange needles of 5-nitro-2-aminophenol (37.7 g.) separated immediately. On adjusting the reaction of the filtrate to neutrality, a red, crystalline solid (9.4 g.) separated which was almost pure 4-nitro-2-aminophenol. On one crystallisation from benzene with addition of glacial acetic acid, it yielded the pure *acetate*, yellow sheaves, which on drying at 95° gave 8.5 g. of the pure base. Ether extraction of the mother-liquors gave a semi-solid product which, fractionally crystallised as acetate from benzene and a little glacial acetic acid, gave further small quantities of 5-nitro-2-aminophenol (1.8 g.) and 4-nitro-2-aminophenol (3.0 g.). The total yield of pure nitroaminophenols was 83%.

5-Nitro-2-aminophenol (XIII) when quite pure melts at 203—204° and crystallises from water in orange or dark brown needles (Friedlaender and Zeitlin, *Ber.*, 1894, **27**, 192, give m. p. 201—202°).

This compound was also obtained as green plates, which melted at  $170^{\circ}$ , but crystallised almost instantaneously, and then melted at  $203\text{--}204^{\circ}$ . The velocity of transformation in contact with aqueous solutions is, however, slow. The *N*-monoacetyl derivative, obtained by the action of acetic anhydride without the application of heat, is sparingly soluble in boiling alcohol and crystallises in stout, pale yellow prisms, m. p.  $271\text{--}272^{\circ}$  (Found: C, 49.0; H, 4.1.  $\text{C}_8\text{H}_8\text{O}_4\text{N}_2$  requires C, 49.0; H, 4.1%). The ON-diacetyl derivative is formed very readily by boiling the aminonitrophenol with acetic anhydride. It is readily soluble in boiling alcohol and crystallises as a felt of fine needles, m. p.  $193\text{--}194^{\circ}$  (Found: C, 50.5; H, 4.3.  $\text{C}_{10}\text{H}_{10}\text{O}_5\text{N}_2$  requires C, 50.4; H, 4.2%). The triacetyl derivative was isolated from the acetylation mother-liquors of the preceding. It crystallises from absolute alcohol, in which it is readily soluble, in fern-like clusters of stout crystals, m. p.  $138\text{--}139^{\circ}$  (Found: C, 51.6; H, 4.5.  $\text{C}_{12}\text{H}_{12}\text{O}_6\text{N}_2$  requires C, 51.4; H, 4.3%).

4-Nitro-2-aminophenol (XIV) forms an *N*-monoacetyl derivative, m. p.  $279\text{--}280^{\circ}$ , by the action of acetic anhydride at room temperature. It forms clusters of needles from absolute alcohol, in which it is very sparingly soluble at the boiling point (Found: C, 48.9; H, 4.2.  $\text{C}_8\text{H}_8\text{O}_4\text{N}_2$  requires C, 49.0; H, 4.1%). The ON-diacetyl derivative, formed with difficulty by long boiling with excess of acetic anhydride, crystallises from boiling absolute alcohol, in which it is readily soluble, in needles or prisms, m. p.  $187\text{--}188^{\circ}$  (Found: C, 50.2; H, 4.3.  $\text{C}_{10}\text{H}_{10}\text{O}_5\text{N}_2$  requires C, 50.4; H, 4.2%).

*Nitration of Carbonyl-o-aminophenol (XV).*—Carbonyl-o-aminophenol (0.5 g.) was warmed with 2 c.c. of nitric acid (*d* 1.42); a violent reaction then occurred accompanied by frothing. The mononitro-compound crystallised out and was isolated by pouring into water. The yield was 0.5 g., m. p.  $255^{\circ}$  (Bender, *Ber.*, 1886, 19, 2271, gives m. p.  $256^{\circ}$ ). When boiled for 6 hours with 16% hydrochloric acid, it was for the most part undissolved and unchanged, but neutralisation of the filtrate and ether extraction gave 0.15 g. of 5-nitro-2-aminophenol, m. p.  $201^{\circ}$ . The unchanged residue was boiled with hydrochloric acid (32%) and alcohol for 8 hours and gave a portion of unchanged compound and 0.2 g. of 5-nitro-2-aminophenol.

*Nitration of N-Acetyl-2-aminophenol.*—On nitration with nitric acid (1 mol.) as described for ethenyl-2-aminophenol, the sole product obtained was 4:6-dinitro-2-acetylaminophenol (acetyl-picramic acid).

*Nitration of Triacetyl-2-aminophenol.*—When nitrated with nitric acid (1 mol.) as for the ethenyl derivative, this phenol yields small quantities of the monoacetyl derivatives of 4- and 5-nitro-2-amino-

phenol, readily isolated by reason of their sparing solubility in alcohol. If, however, the nitration product be hydrolysed, 4:6-dinitro-2-aminophenol (picramic acid) is readily isolated as the main product of the nitration.

**4-Amino-2-hydroxyphenylarsinic Acid (III).**—4-Nitro-2-hydroxyphenylarsinic acid was obtained in 78% yield from 5-nitro-2-aminophenol as described by Bauer (*loc. cit.*) except that the main bulk of arsenic acid separated on neutralisation to Congo-paper, without proceeding *via* the magnesium salt. On reduction with ferrous chloride by the method of Jacobs, Heidelberger, and Rolf (*J. Amer. Chem. Soc.*, 1918, **40**, 1580) it gives an 84% yield of 4-amino-2-hydroxyphenylarsinic acid. The *hydrochloride*, *nitrate*, and *sulphate* all crystallise from the corresponding *N*-acids in acicular crystals, and with the exception of the sulphate are readily soluble on warming. On addition of nitrite, a yellow colour is developed, and on adding to alkaline  $\beta$ -naphthol, a red colour is produced. The same colour is produced by pouring into alkali, probably through self-coupling. Addition of excess of nitrite destroys the coupling property almost instantaneously.

**3'-Nitrobenzoyl-4-amino-2-hydroxyphenylarsinic Acid (X).**—The *m*-nitrobenzoylation was carried out exactly as described for the isomeric 3-amino-4-hydroxyphenylarsinic acid, an 89% yield of the amide being obtained. It is almost insoluble in hot glacial acetic acid, but slightly soluble in hot 90% formic acid, from which it crystallises in bunches of needles (Found: As, 19.5.  $C_{13}H_{11}O_7N_2As$  requires As, 19.6%). The *sodium* salt crystallises in fine needles.

**3'-Aminobenzoyl-4-amino-2-hydroxyphenylarsinic Acid (V; R = H).**—This acid was prepared as described for the isomeric derivative of 3-amino-4-hydroxyphenylarsinic acid (*vide infra*) in 72% yield. Liberated from acid solution by sodium acetate, it separates micro-crystalline (Found: As, 20.8; 20.7.  $C_{13}H_{13}O_5N_2As$  requires As, 21.3%). The *sodium* salt crystallises in platelets, the *ammonium* salt as a felt of needles. The *hydrochloride*, clusters of needles, and *nitrate*, minute needles, are readily soluble in their respective warm *N*-acids, but the *sulphate*, clusters of needles, is rather sparingly soluble in boiling *N*-sulphuric acid.

The *arseno*-derivative prepared by the action of hypophosphorous acid at 60° contained 30% of As as against 24.8% (theoretical) and consisted therefore mainly of polyarsenides. It was insoluble in sodium hydroxide or mineral acids, but dissolved on adding nitrite.

**3':5-Dinitrobenzoyl-4-amino-2-hydroxyphenylarsinic Acid (XI).**—The above-described mononitro-acid (11.3 g.) was dissolved in sulphuric acid (45 c.c.), cooled to 0°, and nitrated with a mixture

of 2.15 c.c. of nitric acid ( $d$  1.42) and sulphuric acid (2 c.c.). On pouring on to ice, a yellow, microcrystalline precipitate separated. It was collected, dissolved in sodium carbonate, and reprecipitated by acid. The yield was 95% (Found: As, 17.7.  $C_{13}H_{10}O_9N_3As$  requires As, 17.6%). This acid is sparingly soluble in boiling acetic acid and crystallises in microscopic needles, more soluble in formic acid, from which it separates in much longer needles.

On hydrolysis by boiling with 15 volumes of *N*-sodium hydroxide for 40 minutes, it gave pure *m*-nitrobenzoic acid, and 5-nitro-4-amino-2-hydroxyphenylarsinic acid, short, yellow prisms crystallising readily from hot water, in which it is fairly readily soluble. It is sparingly soluble in 3*N*-hydrochloric acid, but readily soluble in concentrated acid. It diazotises with nitrite and thereafter couples with alkaline  $\beta$ -naphthol. Excess of nitrite, however, destroys the coupling property (Found: As, 27.1.  $C_6H_7O_6N_2As$  requires As 27.0%).

3' : 5-Diaminobenzoyl-4-amino-2-hydroxyphenylarsinic Acid.—This was obtained in 71% yield by reduction of the dinitro-acid with ferrous chloride and alkali. When liberated from the alkaline extracts of the ferric hydroxide, it separates in very fine needles, but occasionally as an amorphous, voluminous solid which becomes crystalline on warming the precipitation liquor (Found: As, 20.6.  $C_{13}H_{14}O_5N_3As$  requires As, 20.4%). The hydrochloride is very soluble in *N*-hydrochloric acid, but separates from stronger acid in narrow leaflets with domed ends; the sulphate, minute needles, is only moderately soluble in *N*-sulphuric acid, but the nitrate is very readily soluble in *N*-nitric acid and crystallises from more concentrated acid in needles and in lenticular prisms. On addition of nitrite, it diazotises and then gives the same red colour on pouring into alkali, probably owing to self-coupling, as on adding to alkaline  $\beta$ -naphthol. This acid is very resistant to hydrolysis. It is unchanged after boiling with *N*-alkali for an hour, or after 7 hours' boiling with concentrated hydrochloric acid. It was recovered to the extent of more than 60% after 5 hours' heating with concentrated hydrochloric acid under pressure at 150°. *m*-Aminobenzoic acid was identified as a hydrolytic product.

4 : 5-Diamino-2-hydroxyphenylarsinic Acid.—5-Nitro-4-amino-2-hydroxyphenylarsinic acid (2.0 g.) was dissolved in 22 c.c. of *N*-sodium hydroxide (3 mols.) at 0° and to the vigorously stirred solution were added all at once 5.0 g. of sodium hyposulphite (1 mol. of 80% = 4.7 g.) with removal of the external bath. After being stirred for 2 hours, the solution was filled with fine needles of the required amino-acid. This was collected and washed with ice-cold water (yield 93%). For analysis and physiological testing, it was

dissolved in 20 c.c. of 0.7*N*-hydrochloric acid and reprecipitated by addition of saturated sodium acetate. On 1.65 g. there was a loss of 0.1 g. The *diamino-acid* crystallises from boiling water, in which it is sparingly soluble, in fine needles. It is very soluble in *N*-hydrochloric acid and gives, on addition of nitrite, a red coloration, which becomes pale after a few seconds. This is followed by separation of the *diazoimine*, in rectangular leaflets. The diamino-acid reduces ammoniacal silver nitrate instantly at room temperature. In acid solution, potassium dichromate gives a port wine colour (Found : As, 29.0.  $C_6H_9O_4N_2As \cdot \frac{1}{2}H_2O$  requires As, 29.0%).

*3'-Nitroanisoyl-4-amino-2-hydroxyphenylarsinic Acid*.—Prepared in 83% yield in the same way as its isomeride (*vide infra*), this acid is almost insoluble in hot glacial acetic acid, but crystallises from hot 90% formic acid in spear-shaped needles (Found : As, 18.4.  $C_{14}H_{13}O_5N_2As$  requires As, 18.2%). The *sodium* salt, silky needles, and *ammonium* salt, diamond-shaped plates, were only moderately soluble in water.

*3'-Aminoanisoyl-4-amino-2-hydroxyphenylarsinic Acid* (V; R = OMe).—This acid, obtained in 77% yield by reduction of the nitro-acid with ferrous chloride and alkali at 0°, separates as a jelly on acidification of the alkaline extracts of the ferric hydroxide. It soon crystallises, however, in silky needles (Found : As, 19.4.  $C_{14}H_{15}O_6N_2As$  requires As, 19.6%). The *sodium* salt crystallises in prisms readily soluble in water. The *hydrochloride*, spiked leaflets, is readily soluble in warm *N*-hydrochloric acid, but the *sulphate*, short, white needles and stout prisms, and *nitrate*, soft, woolly needles, are much less soluble in the warm *N*-acids.

The *arseno-base* could not be obtained sufficiently pure for physiological testing. Reduction with hypophosphorous acid under the mildest conditions gave polyarsenides containing between 26% and 56% of arsenic as against 22.6% required by theory. Reduction with hyposulphite even at 70° gave no trace of *arseno-base*.

*3'-Nitro-4'-ethylcarbonatobenzoyl-4-amino-2-hydroxyphenylarsinic Acid*.—3-Nitro-4-ethylcarbonatobenzoyl chloride (28.2 g.; 2 mols.) was added in several portions to 4-amino-2-hydroxyphenylarsinic acid (12 g.), dissolved in 2*N*-sodium hydroxide (45 c.c.), saturated sodium acetate solution (50 c.c.), and water (20 c.c.), with vigorous shaking. The reaction mixture was acidified to Congo-paper, and the precipitate collected after being well washed with dilute acid and water. When dry, it was extracted in a Soxhlet apparatus with ether and reprecipitated from sodium carbonate solution by acid. The yield was 73% of the theoretical. This acid is practically insoluble in hot glacial acetic acid, but separates from 90% formic

acid in microscopic, fluffy needles (Found : As, 15.9.  $C_{16}H_{15}O_{10}N_2As$  requires As, 15.9%).

*3'-Nitro-4'-hydroxybenzoyl-4-amino-2-hydroxyphenylarsinic Acid*.—The preceding acid (18.5 g.) was dissolved in 4 equivalents of *N*-sodium hydroxide (158 c.c.) and kept at room temperature for 18 hours. On acidification carbon dioxide and ethyl alcohol were liberated and a white, microcrystalline precipitate was thrown down. This was collected, dried, and extracted with ether in a Soxhlet apparatus (yield 89%). This acid dissolves in alkali with a bright yellow colour, is almost insoluble in warm acetic acid, but crystallises from 90% formic acid in microscopic needles (Found : As, 18.8.  $C_{13}H_{11}O_8N_2As$  requires As, 18.8%).

*3'-Amino-4'-hydroxybenzoyl-4-amino-2-hydroxyphenylarsinic Acid* (V; R = OH).—Reduced as described for its isomeride (*vide infra*), this acid was obtained in 76% yield. Liberated from alkaline solutions by acid, it separates in a gelatinous condition, but rapidly crystallises, on warming, in elongated leaflets (Found : As, 20.0.  $C_{13}H_{13}O_6N_2As$  requires As, 20.4%). The *hydrochloride*, small needles, is readily soluble in *N*-hydrochloric acid; the *nitrate*, diamond-shaped plates, is sparingly soluble in hot *N*-nitric acid, and the *sulphate*, needles, is moderately soluble in warm *N*-sulphuric acid. On adding nitrite to a salt with mineral acids, a very sparingly soluble yellow *diazo-oxide* is precipitated, of amorphous appearance, but microscopically anisotropic. It couples intensely with alkaline  $\beta$ -naphthol.

*3'-Amino-4'-hydroxybenzoyl-4-amino-2-hydroxyarsenobenzene* (IX).—The above-described arsinic acid (3 g.) was suspended in 15 c.c. of hypophosphorous acid (*d* 1.14), diluted with an equal volume of water, and stirred at 45° for 2½ hours after addition of a crystal of potassium iodide. The orange-yellow arsenohypophosphite was worked up as described for aminobenzoyl-3-amino-4-hydroxy-arsenobenzene. The yield was 1.0 g. When dried, it formed a brittle, brownish-yellow powder, instantly soluble in sodium hydroxide to a pale yellow solution. It was not soluble in mineral acids, but dissolved on adding nitrite and then coupled with alkaline  $\beta$ -naphthol. On analysis, the product proved to contain polyarsenide (Found : As, 28.7.  $C_{26}H_{22}O_6N_4As_2$  requires As, 23.6%). When prepared at 55°, the proportion of polyarsenide was increased, as the arsenic content was 29.8%.

*3'-Nitrobenzoyl-3-amino-4-hydroxyphenylarsinic Acid*.—To a solution of 3-amino-4-hydroxyphenylarsinic acid (7.4 g.) in 2*N*-sodium hydroxide (25 c.c.) and half-saturated sodium acetate solution (200 c.c.) was added 3-nitrobenzoyl chloride (11.8 g.) dissolved in ether. The mixture was vigorously shaken, and sodium

hydroxide solution run in from time to time to maintain a slight alkalinity to phenolphthalein. On completion of the reaction, the mixture was made neutral to Congo-paper, the precipitated solid collected, washed with dilute acid, and, after drying, extracted thoroughly with ether. It was dissolved in alkali, reprecipitated by acid, dried, and again extracted with ether. The yield was 90%. This nitro-acid is almost insoluble in hot glacial acetic acid, but crystallises from hot 90% formic acid in silky needles (Found: As, 19.6.  $C_{13}H_{11}O_7N_2As$  requires As, 19.6%). The *ammonium* salt is sparingly soluble and crystallises in tufts of needles.

*3'-Aminobenzoyl-3-amino-4-hydroxyphenylarsinic Acid* (IV; R = H).—The nitro-acid (7.6 g.) was dissolved in 72 c.c. of 2*N*-sodium hydroxide solution at 0°, and ferrous chloride (28 g.) dissolved in 40 c.c. of water run in slowly with vigorous stirring. A further quantity (72 c.c.) of 2*N*-sodium hydroxide was then run in under the same conditions. After stirring for 90 minutes, the ferric hydroxide was filtered off and extracted twice by thorough disintegration with 150 c.c., each time, of 0.5*N*-sodium hydroxide. The combined alkaline filtrates were neutralised to Congo-paper, and the crystalline precipitate was collected. It was dissolved in 150 c.c. of *N*-hydrochloric acid and reprecipitated by addition of saturated sodium acetate solution. The yield was 44%. This amino-arsinic acid, so prepared, separates in microscopic platelets of indefinite shape (Found: loss at 100°, 4.9, 4.7, 5.1.  $C_{13}H_{13}O_5N_2As \cdot H_2O$  requires  $H_2O$ , 4.9%. Found in anhydrous material: As, 20.8.  $C_{13}H_{13}O_5N_2As$  requires As, 21.3%). It is readily soluble in warm *N*-mineral acids, the *hydrochloride* crystallising in microscopic, narrow leaflets, the *sulphate* in rectangular leaflets, and the *nitrate* in microscopic plates.

*3'-Aminobenzoyl-3-amino-4-hydroxyarsenobenzene*.—The corresponding arsinic acid (1 g.) was suspended in a mixture of 30% hypophosphorous acid (5 c.c.), glacial acetic acid (5 c.c.), and water (5 c.c.), with addition of a crystal of potassium iodide. After stirring for 2 hours at 57°, the orange-yellow solid was centrifuged off, and the deposit washed several times with boiled-out water. It was then made alkaline by addition of aqueous sodium hydrogen carbonate and washed free from alkali by repeated centrifuging with water. The product was dried in a vacuum (yield 0.53 g.). This arsenobenzene is insoluble in aqueous acids or alkalis, but soluble in warm 90% formic acid. In acid solution, it dissolves immediately on addition of nitrite and then couples with alkaline  $\beta$ -naphthol with a deep red colour (Found: As, 24.8.  $C_{26}H_{22}O_4N_4As_2$  requires As, 24.8%).

*3'-Nitroanisoyl-3-amino-4-hydroxyphenylarsinic Acid*.—This acid

was obtained in 80% yield by the same process as is described for the corresponding 3'-nitrobenzoyl derivative. It is practically insoluble in boiling glacial acetic acid, but crystallises from 90% formic acid in square leaflets (Found: As, 17.9.  $C_{14}H_{13}O_8N_2As$  requires As, 18.2%). The *sodium* salt, acicular crystals, is readily soluble in water.

*3'-Aminoanisoyl-3-amino-4-hydroxyphenylarsinic Acid* (IV; R = OMe).—The reduction of the nitro-compound was carried out precisely as described for the preparation of the 3'-aminobenzoyl compound. The yield was 61%. Liberated from acid solution by sodium acetate, this acid crystallises in colourless plates (Found: As, 20.0.  $C_{14}H_{15}O_6N_2As$  requires As, 19.6%). The *hydrochloride*, rosettes of needles, is readily soluble in hot *N*-hydrochloric acid, the *sulphate*, microscopic, square leaflets, is less soluble in hot *N*-sulphuric acid, and the *nitrate*, long, silky needles, is sparingly soluble in hot *N*-nitric acid.

*3'-Aminoanisoyl-3-amino-4-hydroxyarsenobenzene*.—Prepared in the same way as the previously described arsenobenzene in 77% yield, this is a yellow powder insoluble in acids or alkalis, but instantly soluble in acid solution on addition of nitrite. It then couples with alkaline  $\beta$ -naphthol (Found: As, 22.7.  $C_{28}H_{26}O_6N_4As_2$  requires As, 22.6%).

*3'-Nitro-4'-ethylcarbonatobenzoyl-3-amino-4-hydroxyphenylarsinic Acid* (VII).—3-Amino-4-hydroxyphenylarsinic acid (11.6 g.) was dissolved in 100 c.c. of water with addition of 5.3 g. (2 mols.) of sodium carbonate. After addition of 100 c.c. of saturated sodium acetate solution, 27.3 g. (2 mols.) of 3-nitro-4-ethylcarbonatobenzoyl chloride were added in three portions with a few c.c. of ether, and well shaken. After  $\frac{1}{2}$  hour, the solution was made definitely acid to Congo-paper, and the mixture of acids collected, dried, and divided by ether extraction into 17.0 g. of the required arsinic acid, insoluble in ether, and 16.0 g. of recovered nitroethylcarbonatobenzoic acid, soluble in ether. This arsinic acid is readily soluble in cold 90% formic acid and crystallises therefrom in microscopic needles; from glacial acetic acid, in which it is readily soluble when hot, it separates either as needles or rectangular leaflets (Found: As, 16.1.  $C_{16}H_{15}O_{10}N_2As$  requires As, 15.9%).

*3'-Nitro-4'-hydroxybenzoyl-3-amino-4-hydroxyphenylarsinic Acid*.—The foregoing ethylcarbonato-acid (10 g.) was dissolved in *N*-sodium hydroxide (4 mols.) and kept for a day. It was diluted with an equal volume of water and precipitated with concentrated hydrochloric acid. On warming the mixture, the precipitated acid became partly crystalline. The dried acid, when extracted with ether to remove hydroxynitrobenzoic acid, was obtained in 84% yield. The

aqueous mother-liquors, extracted with ether, gave nitrohydroxybenzoic acid and also contained 3-amino-4-hydroxyphenylarsinic acid, as was proved by its coupling strongly with alkaline  $\beta$ -naphthol after diazotisation. The required arsinic acid dissolves in alkali with a bright yellow colour. It crystallises in diamond-shaped spicules from either boiling glacial acetic acid, in which it is sparingly soluble, or boiling 90% formic acid, in which it is readily soluble (Found: As, 19.2.  $C_{13}H_{12}O_6N_2As$  requires As, 18.8%).

*3'-Amino-4'-hydroxybenzoyl-3-amino-4-hydroxyphenylarsinic Acid.* (IV; R = OH).—The nitro-acid (8.8 g.) was dissolved in 33 c.c. of water with the aid of two equivalents (23 c.c.) of 2*N*-sodium hydroxide, and ferrous chloride (31 g.) in 42 c.c. of water added slowly with vigorous stirring at  $-5^\circ$ . Sufficient sodium hydroxide (167 c.c. of 2*N*) was now slowly added to make the reaction of the fluid distinctly alkaline to litmus. The filtered ferric hydroxide was thoroughly extracted, each time, with 170 c.c. of 0.2*N*-sodium hydroxide. On rendering the combined extracts neutral to Congo-paper, a copious separation of crystalline amino-acid ensued. This was purified by solution in 100 c.c. of *N*-nitric acid at  $50^\circ$  and precipitation with sodium acetate, and gave 4.0 g. The main mother-liquors were rapidly concentrated below  $50^\circ$  to a small volume and gave a mixture of the amino-compound and the corresponding azoxy-compound, readily separable by dilute nitric acid into 0.75 g. of azoxy-compound (9% yield) and 1.0 g. of amino-compound. The total yield of amino-compound was 62% (Found: As, 20.4.  $C_{13}H_{13}O_6N_2As$  requires As, 20.4%). The amino-acid diazotises with production of a deep yellow solution, from which an insoluble *diazo-oxide* crystallises in dense clusters of needles. It couples readily with alkaline  $\beta$ -naphthol. The *hydrochloride*, microscopic needles, is very sparingly soluble in boiling *N*-hydrochloric acid; the *sulphate*, leaflets, is sparingly soluble in warm *N*-sulphuric acid; and the *nitrate*, microscopic needles, is readily soluble in warm *N*-nitric acid.

The *azoxy*-compound crystallises very readily from boiling 90% formic acid, in which it is readily soluble, in pale brown, truncate, diamond-shaped plates. It dissolves in ammonia with a pale yellow colour and gives an insoluble magnesium salt on addition of magnesium chloride.

*3'-Amino-4'-hydroxybenzoyl-3-amino-4-hydroxyarsenobenzene* (VIII) was obtained in quantitative yield, allowing for recovered acid, by reduction of the corresponding acid (4.0 g.) with 20 c.c. of hypophosphorous acid ( $d$  1.14), 20 c.c. of water, 10 c.c. of acetic acid, and a crystal of potassium iodide at  $50-55^\circ$  for 3 hours. The pure arseno-base was isolated as described for the preceding members.

It is a yellow powder soluble in caustic alkalis, but forming insoluble orange salts with acids. It is instantly soluble to a yellow solution on addition of nitrous acid. From more concentrated solutions, the amorphous *diazo-oxide* separates; this couples with alkaline  $\beta$ -naphthol (Found: As, 23.8.  $C_{26}H_{22}O_6N_4As_2$  requires As, 23.6%).

### CXIII.—*Liquid-line Corrosion.*

By ERNEST SYDNEY HEDGES.

THERE are many instances of enhanced corrosion occurring at the liquid line, when a solid is partly immersed in a liquid which has a chemical action on it, or which simply dissolves it. The phenomenon was first described by Spring (*Z. physikal. Chem.*, 1889, 4, 658) for calcite dissolving in hydrochloric acid and for sucrose and sodium carbonate dissolving in water. He concluded that the extra dissolution was due to an enhanced reactivity of the solvent at the surface. This explanation was denied by Klobukow (*ibid.*, 1890, 5, 180), who suggested that the greater portion of the solid was protected by the downward streaming of the product, whilst fresh solvent was always being drawn in at the liquid surface. Ganguly and Banerji (*Z. anorg. Chem.*, 1922, 124, 140) believe that the phenomenon is related to the surface tension of the liquid, since the effect was diminished in the cases they investigated by covering with a layer of oil.

The water-line corrosion of metals offers a special case of great practical importance. Here it is generally held that atmospheric oxygen assists in the corrosion near the surface of the liquid. Evans (compare "Corrosion of Metals," Arnold, 1924, p. 106) takes a more definite point of view and ascribes the effect to the automatic removal of ions from the metal in the vicinity of the water line, through the relatively cathodic nature of the portion above. Watson and Watts (*Trans. Amer. Electrochem. Soc.*, 1923, 44, 1) investigated many cases of slow corrosion of metals in aqueous solution and concluded that the effect was due to protection of the rest of the metal through the downward flow of the reaction products.

#### EXPERIMENTAL.

During the course of several years' work on the dissolution of metals in various reagents the author has been continually confronted with this phenomenon, and has had opportunities of studying

it, where the reaction velocity is fairly rapid. These seem to be more suitable and trustworthy conditions than the slow corrosion over periods of several weeks previously investigated.

Strips of zinc and magnesium were partially immersed in *N*-hydrochloric acid. The strips were eaten through along a line about 0.5 mm. above the water line some considerable time before the rest of the metal dissolved. Owing to the vigorous evolution of hydrogen, the reaction products were washed in an upward direction instead of downward, and the effect cannot be due in this case to protection of the metal thereby. Watson and Watts (*loc. cit.*) state that water-line corrosion does not take place when zinc dissolves in hydrochloric acid with disengagement of hydrogen. This statement, however, must be due to error of observation.

The effect has also been repeatedly obtained in the dissolution of magnesium in ammonium chloride solution, dilute sulphuric acid and dilute nitric acid, with zinc in dilute sulphuric acid and dilute nitric acid, and with aluminium in solutions of caustic soda and hydrochloric acid. Scarcely any effect was observed in the dissolution of iron in hydrochloric acid.

In all these cases the rate of gassing was sufficient to prevent any downward streaming of the reaction products. It seemed possible, however, that the depolarising action of oxygen contained in the surface of the solution could account for the increased velocity of corrosion. The experiments were therefore repeated in an atmosphere of hydrogen. Identical results were obtained, and thus it is established that the water-line corrosion of metals occurs in absence of the two causes which have been discussed.

Further evidence against the necessity for oxygen is furnished by the strong preferential liquid-line corrosion when strips of copper or iron are partly immersed in strong solutions of nitric acid. Here, the solution itself is a much more active depolariser than atmospheric oxygen. Again, although iron was not observed to undergo appreciable extra corrosion at the water line in hydrochloric acid, the effect is very marked when a mixture of hydrochloric and nitric acids is used. An idea of the magnitude of the effect is gained from an experiment in which copper sheet 0.022 inch in thickness dissolved in a mixture of 25 c.c. of nitric acid, 10 c.c. of hydrochloric acid, and 65 c.c. of water. When the water line was completely cut through, the thickness of the undissolved metal was 0.010 inch.

The excessive corrosion takes place just above the water line, at the place where a film of liquid creeps up the metal, and it seems that the increased velocity of reaction is a property of this film. Further evidence supporting this suggestion is gained from some observations on the dissolution of magnesium and zinc in dilute

acids. At suitable rates of reaction the ascending bubbles of hydrogen coalesce near the end of their course, forming a large bubble on either side of the metal sheet just under the water line. The bubble bursts in a short time, but is immediately formed again. Thus, during the greater part of the reaction, there exists just below the water line a thin film of solution in contact with the metal and bounded by the large bubble of hydrogen. Subsequent examination of the metal showed in every case a roughly circular patch indicative of strong preferential corrosion in the region adjacent to the bubble.

This explanation appears to account for the observation by McCulloch (*J. Amer. Chem. Soc.*, 1925, 47, 1940) that when a rubber band is wrapped tightly round a piece of iron which is then immersed in dilute hydrochloric acid, the iron is strongly corroded under the rubber band.

The author has also repeated Spring's experiment, dissolving sticks of marble in 0.5*N*-hydrochloric acid and in *N*-nitric acid. Under these conditions, the upward wash of carbon dioxide bubbles causes a visible upward streaming of the soluble product, which can be observed to fall subsequently down the sides of the vessel. Excessive corrosion at the water line occurred in both cases. Here the oxygen theory or the electrolytic theory cannot enter. Gurwitsch also (*Z. physikal. Chem.*, 1924, 109, 375) has performed experiments where the product of solution is specifically lighter than the solvent and yet found increased activity at the surface of the solution.

In experiments where little or no gas evolution occurred and the reaction products were allowed to flow down the metal, the effect was quite different when the metal broke off at the water line. The piece of metal was found to be progressively thinned from the bottom to the water line, resembling a fine wedge. In the other cases, where downward streaming was prevented, the fallen metal was of uniform thickness as though it had been sawn.

Whilst it may be admitted that the downward streaming of reaction products and depolarisation by oxygen may assist in preferential corrosion at the liquid line in suitable circumstances, these experiments indicate that the phenomenon takes place in absence of these causes, thus supporting the original hypothesis of Spring.

# CXIV.—*Observations on Liquid Boundaries and Diffusion Potentials.*

By SYDNEY RAYMOND CARTER and FREDERICK MEASHAM LEA.

DURING an investigation (J., 1925, 127, 487, 499) on the *E.M.F.* of systems involving potassium chloride and concentrated acid solutions, it was necessary to set up chains of connecting solutions having potentials which would be readily reproducible and be subject to the minimum fluctuation with time.

Various types of liquid junctions were studied, therefore, and the main results are collected in this paper. Thus in making up the oxidation cell (Pt)|Oxid. salts,  $xN\text{-HCl}|(a) \dots (b)$   $N\text{-KCl}, \text{Hg}_2\text{Cl}_2|\text{Hg}$  or (Pt)|Oxid. salts,  $xN\text{-HCl}|(a) \dots (b)$   $N\text{-H}_2\text{SO}_4, \text{Hg}_2\text{SO}_4|\text{Hg}$  the chain  $xN\text{-HCl}|(a) \dots (b)|N\text{-KCl}$  or  $xN\text{-HCl}|(a) \dots (b)|N\text{-H}_2\text{SO}_4$  may be completed by connecting the points (a) and (b) in one of the following ways, (i) directly, (ii) through *N*-hydrochloric acid, (iii) through saturated potassium chloride solution.

A. *Acid-Acid Boundaries of the Type  $xN\text{-HCl}|N\text{-HCl}$ .*—This type of boundary occurred in scheme (ii), and two modes of formation of this boundary will be described.

(1) The connecting tube from (a) carries a tap and dips into hydrochloric acid of the same concentration ( $xN\text{-HCl}$ ). Connexion is made to a vessel containing *N*-hydrochloric acid by means of an inverted U tube filled with *N*-hydrochloric acid and, as in other cases, plugged at the ends with filter-paper. It makes but little difference, however (about 0.001 volt), if this connecting tube be filled with the  $xN$ -hydrochloric acid. Diffusion potentials at boundaries so set up show little fluctuation with time.

(2) If the open end of the tube with tap from (a) is immersed directly in *N*-hydrochloric acid, complete mixing of the two acid solutions takes place as far as the tap and it is here that the actual liquid junction occurs. If the  $xN$ -hydrochloric acid be 5*N*, this method gives diffusion potentials differing by about 0.006 volt from those obtained by method A (1).

In the work on the cupric-cuprous potentials, as well as that on the diffusion potentials, method A (1) was invariably employed.

B. *Acid-Salt Boundaries of the Type  $\text{HCl}|\text{KCl}$ .*—(1) Direct connexion between  $xN$ -hydrochloric acid and *N*-potassium chloride is equivalent to scheme (i) and leads to considerable fluctuations of *E.M.F.* when the value of  $x$  is high.

(2) An intermediate solution of *N*-hydrochloric acid between the

two solutions in (1) gives the combination  $xN\text{-HCl}|N\text{-HCl}|N\text{-KCl}$ , which is scheme (ii).

The  $xN\text{-HCl}|N\text{-HCl}$  boundary has already been described, and the  $N\text{-HCl}|N\text{-KCl}$  boundary is made as follows. The connecting tube is filled with  $N$ -potassium chloride, in which case the diffusion potential is constant to about 0.0010 to 0.0015 volt on standing. If the connecting tube be filled with  $N$ -hydrochloric acid, a divergence of about 0.002 volt from the above is observed. Our practice has been to use the potassium chloride solution.

Methods B (1) and (2) give values which differ considerably for the total diffusion potential between  $xN$ -hydrochloric acid and  $N$ -potassium chloride. For very strong hydrochloric acid solutions (10*N*—11*N*) this difference may amount to as much as 0.020 volt.

*C. Saturated Potassium Chloride Solutions.*—The interposition of a saturated potassium chloride solution between  $xN$ -hydrochloric acid and  $N$ -potassium chloride reduces the diffusion potential, but does not eliminate it completely for strong hydrochloric acid solutions. For concentrations of hydrochloric acid up to  $N$ , the conclusion of various workers is that saturated potassium chloride has no diffusion potential against the hydrochloric acid; but this does not hold for stronger hydrochloric acid solutions. Thus between 9*N*-hydrochloric acid and  $N$ -potassium chloride the interposition of a saturated potassium chloride solution reduces the diffusion potential from approximately 0.090 volt to 0.050 volt. A direct connexion  $xN\text{-HCl}|N\text{-KCl}$  always gives a lower diffusion potential than that obtained when an intermediate  $N$ -hydrochloric acid is introduced; for 9*N*-hydrochloric acid it is about 0.015 volt lower.

For 9*N*-hydrochloric acid the approximate values of the following diffusion potentials are:  $xN\text{-HCl}|N\text{-KCl}$ , 0.090 volt;  $xN\text{-HCl}|N\text{-HCl}|N\text{-KCl}$ , 0.105 volt;  $xN\text{-HCl}|\text{Sat. KCl}|N\text{-KCl}$ , 0.050 volt.

*D. Liquid Junctions with Sulphuric Acid of the Type  $xN\text{-HCl}|N\text{-H}_2\text{SO}_4$ .*—Very little difference is observed if direct connexion be made between the  $xN$ -hydrochloric acid and  $N$ -sulphuric acid or  $N$ -hydrochloric acid be interposed, giving the  $xN\text{-HCl}|N\text{-HCl}|N\text{-H}_2\text{SO}_4$  combination.

*Variation of Diffusion Potentials.*—For corresponding concentrations, an acid|salt boundary shows more variation with time than an acid|acid boundary. The latter, even for  $N$ -hydrochloric acid against 10*N*-hydrochloric acid, shows little variation, in general not more than 0.001 volt and usually less. If, however, the  $xN$ -hydrochloric acid contains a high concentration of some salt in solution, then the  $xN\text{-HCl}|N\text{-HCl}$  boundary may show a fluctuation of several millivolts.

In making potential measurements, the most consistent results were obtained when fresh boundaries were used wherever possible, and this is the experience of other workers.

The authors desire to express their thanks to the Advisory Council of the Department of Scientific and Industrial Research for a grant to one of them (F.M.L.) which has enabled this investigation to be carried out.

### CXV.—*The Hydrolytic Action of Low-pressure Superheated Steam on Salts of the Alkaline-earth Metals.*

By PERCY LUCOCK ROBINSON, HAROLD CECIL SMITH, and  
HENRY VINCENT AIRD BRISCOE.

ALTHOUGH it is generally realised that many salts are attacked by steam at high temperatures, and it is well known, as an extreme case, that salts like magnesium chloride are largely hydrolysed at temperatures little above the boiling point of water, there is little definite information in the literature as to the general incidence and extent of the hydrolytic action of steam. The recognition that many chlorides and bromides could thus be decomposed, even by the relatively low concentration of steam formed during their dehydration, led to the general use of the well-known Harvard bottling apparatus in atomic weight determinations, but it is in relation to technical processes of thermal decomposition that most references to such phenomena are found, and the following notes indicate their general nature.

The thermal decomposition of witherite is facilitated by the presence of steam (Priestley, *Phil. Trans.*, 1788, 78, 852; Lenoir, *Jahresber.*, 1867, 13, 256; Heinz, *Chem. News*, 1902, 85, 206) and a similar result is observed, apparently, when mixtures of barium carbonate with calcium carbonate and carbon (Jacquelin, *Compt. rend.*, 1851, 32, 877), and with sodium carbonate (*Dingler's Jour.*, 1884, 254, 436), are employed.

A patented process describes the hydrolytic decomposition of barium sulphide by steam (Leroy and Segay, D.R.-P. 100969, 1897). Fremy stated that fluorspar is decomposed by steam at a red heat, yielding calcium oxide and hydrogen fluoride (*Ann. Chim. Phys.*, 1856, 47, 17), but Poulenc later found that strontium fluoride is not decomposed by steam at a red heat (*ibid.*, 1894, 2, 5). It has been reported (Kunheim, "Über Einwirkung des

Wasserdampfes auf Chlormetalle bei hoher Temperatur," Gottingen, 1861) that when calcined in steam calcium chloride is decomposed less readily than magnesium chloride, but more readily than barium chloride, that this hydrolysis of calcium chloride is incomplete (Pelouze, *Compt. rend.*, 1861, **32**, 1267), and that it is accelerated when silica, alumina, or china clay are present (Solvay, *Dingler's Jour.*, 1885, **255**, 307).

When steam is passed over a red hot mixture of calcium sulphate and sodium chloride, sodium sulphate, lime and hydrogen chloride are produced (Tilghmann, *Dingler's Jour.*, 1847, **106**, 196).

Siemens (*ibid.*, 1863, **169**, 207) reported that if water vapour is passed over a molten mixture of sodium chloride with twice its weight of calcium sulphate, hydrochloric acid, sulphur dioxide, and hydrogen sulphide are evolved, while a mixture of steam and carbon dioxide under the same conditions yields only sulphur dioxide and hydrochloric acid; the residue contained undecomposed sodium chloride, sodium hydroxide, calcium sulphide, calcium oxide, and small traces of sodium thiosulphate and sodium sulphide. It has been pointed out (Buff, *ibid.*, 1864, **172**, 282; Knapp, *ibid.*, 1872, **202**, 513) that in such reactions the materials of the containing vessel, *e.g.*, iron and silica, may play an important part, and the obvious incompatibility of some of the foregoing statements may well be due to such causes.

A recent investigation (Thompson and Tilling, *J. Soc. Chem. Ind.*, 1924, **43**, 39r) has shown that the ferrous sulphide formed, together with free sulphur, on heating pyrites in an inert atmosphere is decomposed (to form ferric oxide and hydrogen sulphide) at a lower temperature in steam than in carbon dioxide or air.

Thus it is evident that the previous investigations of the hydrolytic action of steam are few in number, and with the exception of the last cited, purely qualitative in kind. It has been the object of the present investigation to secure some numerical data in a few typical cases. A weighed quantity of the salt under investigation was heated to a known temperature for a definite time in a current of steam, and the issuing steam was condensed. Titration of this condensate with standard alkali gave a measure of the extent of hydrolytic decomposition which had occurred.

#### EXPERIMENTAL.

Steam was passed at a constant rate over a weighed quantity of material in a porcelain boat placed in a silica tube heated electrically to the desired temperature. In the hot zone, the silica was protected by a liner-tube of stout sheet nickel. Temperatures were measured by means of a platinum-platinum-rhodium thermo-

couple and a Paul millivoltmeter, the hot junction of the couple being held immediately above the boat containing the salt under investigation. The couple and millivoltmeter were standardised before and after use at 100° and at the melting points of tin, lead, zinc and sodium chloride, and found to give consistent readings trustworthy to about  $\pm 5^\circ$ .

Temperature readings were taken every ten minutes (or oftener) throughout the run, and at the end the condensed steam was titrated with *N*/10-sodium carbonate solution and methyl-orange, or, in the case of carbonates, by adding *N*/10-caustic soda solution and back-titrating with *N*/10-sulphuric acid, with phenolphthalein as indicator.

*Chlorides, Bromides, and Carbonates.*—The table gives the data relative to these salts.

Salt.	Weight (g.).	Temp.	Time (mins.).	Acid produced as c.c. of <i>N</i> /10- acid.	Wt. of salt decomposed in 30 mins. (calculated).

*Sulphates.*—At 970° the sulphates of calcium, strontium, and barium were not appreciably decomposed. From the first sample of barium sulphate used, a trace of sulphuric acid, equivalent to 1.2 c.c. of *N*/10-acid, was produced in the first 5 minutes. This was proved to be due to ferric sulphate present as an impurity.

The production of acid did not continue, there was no evidence of true hydrolytic action, and the residue was not alkaline.

*Phosphates.*—Calcium phosphate only was examined. This gave no evidence of hydrolytic decomposition even at 970°.

### Discussion.

The data recorded above make no claim to great precision, but the authors believe that they may properly be held to justify the following general conclusions.

The chlorides and bromides of calcium, strontium, and barium are all hydrolysed by steam under atmospheric pressure at high temperatures, the ease of decomposition decreasing with increasing atomic weight, the lowest temperature at which it is appreciable being as follows:

Calcium chloride . . .	425°	Calcium bromide . . .	348°
Strontium chloride . . .	640°	Strontium bromide . . .	443°
Barium chloride . . .	970°	*Barium bromide . . .	640°

\* Barium bromide appears to be appreciably volatile at 770°.

These figures afford some evidence that the bromides in general are more easily hydrolysed than the chlorides, and, in conjunction with the well-known difficulty of iodide preparation and the work of Fremy and Poulenc (*loc. cit.*) on the fluorides, show that the ease of decomposition for any alkaline-earth metal increases in the order fluoride, chloride, bromide, iodide, whilst for any particular halide it increases in the order barium, strontium, calcium.

In the case of the carbonates of strontium and barium the boat was obviously attacked and this renders the interpretation of the results doubtful. Calcium carbonate evidently decomposes appreciably at 440° in steam and it is interesting to compare this result with the previous observation (Pott, "Studien uber die Dissoziation von Calcium-Strontium- und Barium Karbonat," 1905) that measurable dissociation is observed at 525°.

Qualitative experiments with sodium and potassium nitrates showed that these were largely decomposed at temperatures just under 600°, leaving a strongly alkaline residue in the boat. The gaseous products comprised both nitric acid and oxides of nitrogen, but further investigation of this decomposition was abandoned, as it was likely to require an elaboration of experimental procedure disproportionate to the results anticipated.

The authors desire to acknowledge a grant from the Department of Scientific and Industrial Research enabling one of them (H. C. S. to take part in this work.

CXVI.—*Studies with the Microbalance. Part III.*  
*The Filtration and Estimation of very small*  
*Amounts of Material.*

By ERNST JOHANNES HARTUNG.

QUANTITATIVE micro-analytical work involving precipitation and filtration is beset with considerable difficulty because errors due to adsorption, mechanical loss of material, solubility of precipitates, and accumulation of dust are apt to assume serious proportions in spite of the greatest care on the part of the operator. Moreover, the difficulty of estimating the magnitudes of these errors makes subsequent attempts to correct the experimental results very uncertain. In view of its importance, some preliminary work on the general analytical technique for dealing with 1—2 mg. of material was carried out in this laboratory in 1910 by G. A. Ampt, using the Steele-Grant microbalance. For filtering operations, he employed asbestos in small perforated silica crucibles weighing about 1 g. and transferred the precipitate into them in various ways. The results of his work (unpublished) showed that asbestos was unsuitable as a filtering medium for small amounts of material owing to mechanical and chemical alterations in weight, and that serious losses of precipitate were inevitable in any method of transference from one vessel to another. The obvious remedy is to carry out precipitation in the crucible itself and to adopt reversed filtration through a tube packed with platinum sponge for removal of mother-liquor and washings. Emich (*"Mikrochemisches Praktikum,"* 1924, p. 62) has described such a device for use with 5—10 mg. of material; asbestos is employed instead of platinum sponge and the precipitation vessel with its filtering tube (3—4 g.) is weighed on a Kuhlmann balance to the nearest 0.005 mg. A few examples of analyses are given in which the errors are quoted as usually below 1—2 parts per 1000. As far as the author is aware, however, no general methods for the accurate analysis of amounts of material weighing less than 1 mg. have hitherto been described. When, therefore, the need arose for estimating with precision the composition of very small quantities of mixtures of silver and silver iodide by a procedure involving filtration, the capabilities of the Steele-Grant microbalance were utilised in investigating the conditions for successful quantitative work. The original problem has not yet been solved satisfactorily owing to the great difficulty of separating completely silver iodide from silver, but the methods which have been developed are fairly general in application and may be of use to others who are con-

strained to work with very small amounts of material. The apparatus required consists of a sensitive microbalance (weighing to  $10^{-4}$  mg.), a silica crucible and filtering tube, a dust-free enclosure for carrying out filtration, an evaporator and electric oven, sundry small appliances such as silica pipettes, tubes, etc., and specially prepared reagents.

*The Microbalance.*—Two Steele-Grant instruments were available, each carrying a load of 100 mg. and weighing accurately to  $10^{-4}$  mg. It was impracticable to work with a crucible and filtering tube which weighed together less than 500 mg. and consequently one of the balances was modified to enable it to carry this load without material reduction in its absolute sensitiveness. In the usual form of the instrument, a constant weight fused to one end of the beam counterpoises a load hanging from a silica fibre attached to the other end. This load consists of a very light rack carrying the object to be weighed, certain small weights and a silica bulb by means of which the beam is equilibrated through alteration of air pressure in the balance case. The bulb constitutes the major portion of the load, since it must be stoutly blown in order to resist deformation with varying external pressure. By removing the bulb from the rack and fusing it to the other end of the beam as part of the constant weight, almost the whole of the load on the fibre is available for the object to be weighed. It is, of course, necessary to determine the displacement value of the bulb in its new position, since the ratio of the lengths of the balance arms now enters into each weighing, but this may easily be done by means of a small known weight, the value of which has been found against the bulb of an unmodified instrument in the usual manner. This procedure was followed with one of the two available balances, and weighings consistent to the nearest  $10^{-4}$  mg. could then be made in a load of 500 mg., or 1 part in  $5 \times 10^6$  parts. It is perhaps scarcely necessary to remark that, when material other than silica is weighed, certain corrections are required for the difference in density between silica and the material; but for quantities less than 1 mg., these may usually be neglected.

*Filtering Apparatus.*—The silica crucible in which the analytical operations are conducted is 5–6 mm. in diameter and about 16 mm. in depth (Fig. 1, E), with a capacity of 0.3 c.c. It is provided with two hooks for handling and suspension, the lower of which is shaped to act, in addition, as a support for the filtering tube during weighing so that the point of the tube does not rest on the bottom of the crucible. The tube (Fig. 1, F) is also made from vitreous silica, 30 mm. in total length and 0.3 mm. in bore. It is bent at a right angle in its upper portion and near the lower

end is a constriction above a 3—4 mm. column of platinum sponge. This is made by igniting ammonium chloroplatinate and introduced by suction in water, followed by careful compacting with a platinum wire. The lower orifice of the tube is then somewhat constricted in the oxy-gas flame. A suitable rate of passage of water through the finished filter with strong suction is about 3 c.c. per hour and finely-divided precipitates are completely retained by it. Care must be taken, however, that the filter is never ignited above a low red heat, otherwise the platinum sponge tends to shrink and

FIG. 1.

FIG. 2.

may leave channels which impair its filtering quality. Attempts were made to replace the platinum by finely-ground silica, firmly compacted and then sintered together, but shrinkage was so marked that the resulting filters were useless.

The dust-free enclosure in which filtration is carried out is shown in Fig. 1. A ground glass plate, A, with central perforation is cemented with pitch on top of an ordinary tripod with the ground surface upwards. On this rests a glass "dialysing jar" with ground ends, B, about 12 cm. in diameter and 10 cm. deep; this is closed above with the ground glass plate, C. On the ledge

inside the jar stands a light glass framework, D, provided with suitable hooks from one of which the crucible, E, hangs. The filtering tube, F, is inserted in a short length of clean rubber tubing, G, on the end of the arm of the ground cap, H, of a vertically clamped glass tube, J, which passes snugly through the central perforation of the base plate of the chamber. The enlarged upper end of this tube encloses a silica crucible, K, of rather more than 1 c.c. capacity, which hangs from a hook cemented to the inside of the ground cap. By this device, the filtrate from E may be collected in K without contamination or loss. The lower end of the tube J is connected to an exhaust pump or an evacuated receiver during filtration. The crucible E is introduced by means of a bent silica rod after raising C, and the filtering tube is inserted by a pair of narrow-pointed forceps into the moistened end of G after raising B. The tips of these forceps require special preparation; if they are made of smooth metal or ivory, there is great risk of the silica tube slipping out, whilst if the metal is roughened, some of it is gradually transferred to the smooth silica tube where it is visible as greyish weighable stains. This trouble was obviated by arming the tips with good quality calendered writing paper, cemented on with a little varnish and subsequently trimmed to shape with a razor. After placing the filtering tube and crucible in position, they are easily and safely adjusted for filtration by raising or lowering J and sliding B on A. No lubricant is used on any of the ground surfaces except that of the cap H and, if care be taken that none is allowed to soil the interior of the enlarged end of the tube J, the crucible K may be readily introduced or removed without fear of contamination. By means of this apparatus, distilled water and pure concentrated nitric acid may be passed repeatedly from the crucible through the filtering tube without changes in weight greater than 0.0001 mg. Such constancy is not possible, however, if crucible and tube are made of glass, owing to the solubility and hygroscopic character of this substance. For these reasons also, it is advisable to prevent contamination of the filtrate where this is undesirable, by making the ground cap H and its arm from vitreous silica.

*Evaporator and Electric Oven.*—An evaporator is necessary in which liquids may be evaporated, or kept hot in order to coagulate precipitates, with complete protection from dust. A simple and efficient form is shown in Fig. 2; the wide glass tube, A, is 3.5 cm. in diameter and 18 cm. long and is closed above by a loosely fitting cap, B, carrying a vertical glass rod with a hook from which the crucible, C, hangs. The lower portion is immersed in a glycerol bath, E, regulated in temperature by hand, and a stream of pure

dry filtered air is passed continuously through the tube D. In this way, exclusion of dust is assured and, if the glycerol be kept at 130—150°, aqueous solutions may be rapidly evaporated in a few minutes without loss by boiling or spraying. A small electric oven is used for ignitions up to a dull red heat; it consists of a vertical silica tube sealed at the lower end and surrounded with the usual heating coils and packing. The lid is a silica watch-glass, to the convex lower side of which is sealed a silica hook for suspending the objects to be heated. This cover is provided with a small silica handle and the upper part of the oven is covered with an inverted glass basin as a protection from dust.

*Reagents.*—Special purification of all reagents was found to be necessary, particularly as regards freedom from dust. Water was twice distilled in a silica apparatus in the usual way and preserved in a capped silica flask. The residue on evaporation corresponded to 1 mg. per litre, which included any dust contamination during the operation and was insignificant as a source of error. Acids, ammonia, and other liquids were distilled immediately before use by heating them in conical flasks and exposing to the vapours the outside of a clean silica test-tube full of water. The condensed drops were removed by an ignited silica pipette, fashioned like a medicine dropper, and either added at once to the crucible, or diluted to the required degree with water in small, covered silica tubes. Solid reagents were obtained by twice crystallising the best commercial analytical reagents in silica vessels, special care being taken to avoid contamination with fibres and dust.

The general technique for carrying out an analysis is as follows: The crucible and tube are cleaned by boiling concentrated nitric acid, washed repeatedly with water, dried over a small alcohol flame, and weighed together. During these operations, the crucible is handled on the end of a silica rod and, when clean, hangs from a silica hook mounted on a cork and protected from dust by a glass cover. After weighing, the filtering tube is removed from the crucible by forceps, the sample introduced, the tube replaced in its support so that the lower end does not come in contact with the sample, and the whole reweighed. The filtering tube is then put in place in the filtering apparatus, and the material in the crucible is dissolved by introduction of one or two drops of the appropriate solvent by a silica pipette, followed by heating, if necessary, in the evaporator. It has been found that even if effervescence takes place during solution, *e.g.*, calc-spar in acid, no loss by spraying occurs owing to the depth of the crucible and the very small amount of gas evolved. The precipitating agent is then added and the crucible is heated in the evaporator until

clotting of the precipitate, or sufficient increase in grain size, has taken place. The crucible is then cooled in the filtering chamber, the liquid removed by the filtering tube, and the precipitate washed. The only satisfactory criterion of complete washing is the constancy in weight of the residue, but three or four applications of a few drops of the washing liquid are usually ample, since the filtering tube removes the liquid completely. Should the tube become choked, making filtration very slow, it may be freed by detaching the vertical tube, J (Fig. 1), from the exhaust pump and blowing into it for a few moments. When washing is finished, the filtering tube is detached from the rubber and placed in its support in the crucible, after its upper end has been rinsed with a drop or two of water. The whole is then dried in the evaporator, ignited, if necessary, and finally weighed. Analogous methods may also be applied to the filtrate in the crucible K (Fig. 1), should further analysis of this be desired.

In order to test the general accuracy attainable with this apparatus, certain standard analyses were performed after the various inherent sources of error in each case had been discovered and guarded against. The results are summarised in Table I, in which

\* Known source of error.

all weights are given in milligrams; they have not been specially selected and are therefore typical of the methods described. Carefully purified and tested salts were used, and the positive radicals were estimated in each case. Inspection of the figures shows that

the analyses are reasonably accurate even for quantities of material as small as 0.1 mg., where the errors in the examples tried have not exceeded 1%, and for larger amounts the errors are usually much less proportionately.

There are several sources of error which, though easily controlled in ordinary routine, are apt to assume serious proportions in micro-analytical work of this kind. The most variable of these is due to accumulation of dust, particularly when the crucible and tube are wet; however, a number of trials has shown that, by reducing to a minimum the time during which the apparatus and reagents are freely exposed, by avoiding agitation of liquid reagents, and by washing down the outside of the pipette with a few drops of water immediately before introducing any liquid into the crucible, errors due to dust are insignificant except when dealing with less than 0.1 mg. of material. Mechanical loss of precipitate is another source of error which has caused some trouble, especially when dealing with very finely-divided precipitates which cannot be made coarse-grained by the usual analytical methods. For example, it is practically impossible to precipitate at boiling temperature without loss in a small crucible with 2 or 3 drops of solution, and the only remedy is fairly prolonged heating after precipitation until the solid settles readily. Further, when washing such a precipitate as calcium oxalate, it is essential to allow the drops of washing liquid to fall into the crucible without forming a bridge between this and the point of the pipette, otherwise some of the solid will spread on the latter and be lost. Errors due to adsorption are also difficult to control and are generally much more serious than in ordinary analytical work, for a fraction of a drop may mean a large excess of reagent. For example, calcium oxalate precipitated with a considerable excess of ammonium oxalate may contain as much as 10% of its weight of the ammonium salt, which cannot be removed by washing; in this case, careful ignition of the precipitate to the carbonate at 400° removes the difficulty completely, but the general remedy is to use dilute solutions of reagents of known concentration. When adsorption cannot be prevented, it is sometimes possible to wash out the adsorbed material after ignition of the precipitate, as with barium chloride on barium sulphate (Pregl, "Organische Mikroanalyse," 1923, p. 147), or to estimate it by some means, as with silver nitrate or silver iodide by evaporation with a drop of dilute hydrochloric acid. The most serious of all sources of error is, however, the solubility of the precipitate, especially in the washing liquid. The reason is that the amount of liquid necessary is out of all proportion to the amount of precipitate, because it is mainly used in washing the interior of

the crucible. It is rarely possible to employ less than 0.5 c.c., which, for 0.5 mg. of precipitate, corresponds to 1 litre per g. and involves a possible error of 1%, if the solubility of the precipitate is 10 mg. per litre. In Table I, Experiment 3 shows the effect of using too great an excess of hydrochloric acid in precipitating silver chloride, owing to increased solubility of the salt. Expt. 8 shows the effect of washing with dilute sulphuric acid, in which lead sulphate has the minimum solubility of 5 mg. per litre, instead of diminishing the solubility still further by addition of alcohol, as in Expts. 7 and 9. Some error due to solubility is inevitable, but it may be diminished by careful regulation of the conditions of precipitation, proper choice of the washing liquid, and strict economy in its use. It is, of course, possible to employ a saturated solution of the precipitate itself for washing, but great care is necessary to avoid introduction of solid particles. This procedure has not been adopted in obtaining the results given in Table I, nor have corrections for any possible sources of error been applied.

The technique described may easily be extended to a large number of micro-analytical problems, provided that these are not too complex. There is, of course, no point in using the micro-balance for analysis when sufficient material for the usual laboratory procedure is available, although in some cases, the instrument offers a more accurate and much more expeditious method. For example, the composition of a mixture of sodium and potassium chlorides may be determined rapidly and accurately by evaporating less than 0.5 mg. with a single drop of nitric acid and weighing the mixed nitrates in the residue. Apart, however, from the fact that the chance of accidental error is always greater when dealing with very small quantities, the application of the Steele-Grant micro-balance to analytical problems has certain limitations. Volatile liquids cannot be weighed without much trouble, although, when the composition of a liquid is in question, it may be measured with a small pipette. The simplest way to calibrate a pipette for use with the microbalance is to make up an aqueous solution of some stable anhydrous salt (*e.g.*, potassium chloride) of known concentration in the usual manner; a pipette-full of this solution is then evaporated to dryness and the residue weighed on the micro-balance. Volatile solids and hydrated salts cannot usually be weighed without special contrivances, and also correct sampling of small amounts of heterogeneous material is extremely difficult. Further, some gelatinous precipitates are awkward to manipulate with the filtering tube owing to the tendency to become impacted in the end of it. Nevertheless, in spite of these limitations, the apparatus and micro-analytical methods here described have a

considerable range of application with accuracy, and it is hoped that they may be of use to other investigators who find it necessary to work with very small amounts of material.

## CXVII.—*The Ternary System Sodium Thiosulphate-Sodium Sulphate-Water.*

By RICHARD RANDOLPH GARRAN.

THE system sodium thiosulphate-sodium sulphate-water has been examined at 0.8°, 18°, 25° and 40°, the temperature being maintained constant to within 0.02° in the last three cases and to within 0.1° in the first. The transition between decahydrated and anhydrous sodium sulphate in presence of sodium thiosulphate has also been studied.

Mixtures, prepared as indicated in the descriptions of the various isotherms, were rotated in stoppered glass tubes in a thermostat for periods varying from 3 to 24 hours; then, after allowing the solid to settle, a definite volume of solution was drawn off by means of a pipette fitted with a cotton-wool filter and weighed in a tared bottle; the solid was rapidly drained on a Büchner funnel and a portion of it weighed. The solution was diluted and the solid dissolved to known volumes in each case and aliquot parts of these were taken for analysis. The values of the densities of the solutions are probably not accurate beyond two or three units in the third decimal place.

Thiosulphate was determined by adding a known small excess of standard iodine solution and titrating this excess with a solution of sodium thiosulphate the normality of which was obtained from a hydrochloric acid solution (standardised against calc-spar) by means of a mixture of potassium iodide and iodate.

For the determination of the sulphate, the following methods were decided upon after many trials:

(i) The solution was evaporated to dryness with excess of sulphuric acid, and the residue heated to convert it completely into sulphate and to drive off the excess of acid and the sulphur which was formed. From the total weight of sulphate present and the known amount of thiosulphate, the amount of sulphate originally present was readily calculated.

(ii) The solution of thiosulphate was oxidised, by heating with bromine water in the presence of a little alkali, in accordance with the following equation (Mayr and Peyfuss, *Z. anorg. Chem.*, 1923,

127, 123; 1924, 131, 203):  $\text{Na}_2\text{S}_2\text{O}_3 + 4\text{Br}_2 + 5\text{H}_2\text{O} = \text{Na}_2\text{SO}_4 + \text{H}_2\text{SO}_4 + 8\text{HBr}$ . After the excess of bromine had been expelled, the sulphate was precipitated as barium sulphate and the amount of sodium sulphate originally present calculated as above.

(iii) When thiosulphate was present in large excess, method (ii) was found to be untrustworthy. The sulphate present was then precipitated as barium sulphate in cold neutral solution (barium thiosulphate is soluble under these conditions), allowed to settle for 24 hours, and washed three times by decantation, being allowed to settle during 18 to 24 hours each time. The precipitate was then boiled with dilute hydrochloric acid to make it coarser, filtered off, and weighed. This method was found to be trustworthy, but the time required was considerable.

The isotherms at  $0.8^\circ$  and  $25^\circ$  are based entirely on analyses by the first method: that at  $18^\circ$  almost entirely, and that at  $40^\circ$  partly, on the second and third methods. Compositions are expressed as percentages of components by weight, and mixed crystals are indicated in the tables by *M.C.* followed by the formula of the major constituent.

### *Discussion of Results.*

The results obtained at  $0.8^\circ$  and  $18^\circ$  are shown in Tables I and II and are plotted in the usual triangular diagram in Fig. 1. Only the solution curves at  $0.8^\circ$  are shown, as the two systems are of similar general form. Suitable mixtures were prepared from water, pure (A.R.) crystals of sodium thiosulphate pentahydrate and pure commercial (B.D.H.) crystals of sodium sulphate decahydrate, and heated to homogeneity in stoppered tubes which were then rotated in a thermostat for several hours (generally over-night) after the solid had settled out. In a few cases, in solutions containing a preponderance of thiosulphate, it was necessary to seed the mixture in order to induce crystallisation.

In Fig. 1 the curve *ab* denotes solutions in equilibrium with solids along the line *a'b'*, which is so short that it gives only very slight evidence of mixed-crystal formation between  $\text{Na}_2\text{S}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$  and (possibly)  $\text{Na}_2\text{SO}_4 \cdot 5\text{H}_2\text{O}$ . The curve *bc* denotes solutions in equilibrium with solids along the line *b''c'*, and here there is definite evidence of mixed-crystal formation between decahydrates. The extent of this at  $0.8^\circ$  and  $18^\circ$  is approximately the same.

The two-phase dried solids along the line *b'b''*, which are in equilibrium with the solution at the condensed triple point *b*, were obtained by prolonged drying of the moist solid on blotting paper in a desiccator over the solution *b* at the temperature of the isotherm. Washing with alcohol resulted in partial dehydration of the crystals.

The positions of these solids in the diagram along the line joining the end members, *b'* and *b''*, of the two series of mixed crystals provide strong evidence for the existence of the two series.

The isotherm at  $40^\circ$  (see Table III and Fig. 2) also consists of two curves,  $ad$  denoting solutions in equilibrium with solids along the line  $a'd'$ , and  $df$  solutions in equilibrium with solids along the line  $d''f'$ . Again the larger range is that of mixed crystals at the sulphate end, but at this temperature between anhydrous salts, whilst that showing mixed-crystal formation between  $\text{Na}_2\text{S}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$

FIG. 1.

and (presumably)  $\text{Na}_2\text{SO}_4 \cdot 5\text{H}_2\text{O}$ , although more extensive than at lower temperatures, is still very small. The dried solids along the line  $d'd''$  were obtained by washing the moist solid with warm methylated spirit and drying carefully between folded blotting paper. It was found very difficult in this case to remove all moisture from the solid owing to the finely-divided nature of the anhydrous sodium sulphate which was formed. The complexes in this isotherm were prepared by evaporation, under diminished

pressure, of solutions unsaturated at  $40^\circ$ , using the method employed by Rivett and Lewis (J., 1924, 125, 1163).

The transition point between decahydrated and anhydrous sodium sulphate will be depressed by the addition of sodium thiosulphate to the solution. With an appropriate mixture in a Dewar flask fitted with thermometer and stirrer, temperature-time curves on heating and cooling were obtained. The mixture was heated at  $70^\circ$  for an hour to hasten the formation of mixed crystals and then cooled to  $15^\circ$ , being well inoculated with crystals of  $\text{Na}_2\text{S}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$  and  $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$ . On slow re-heating, this gave

a well-defined arrest at  $20\text{--}30^\circ$  and on cooling at  $19\text{--}80^\circ$ . These temperatures were accurately reproducible, both with the same and with fresh mixtures. The cooling curve was of the usual form, showing undercooling followed by a rise in temperature to the arrest point on seeding. Samples of the solutions in equilibrium with the three solid phases at the arrest points, both on heating and on cooling, were drawn off and analysed, the mean composition being 7.95% of sodium sulphate and 35.0% of thiosulphate. The difference between the two temperatures is probably accounted for by the slow rate of diffusion in the solid phases, the mixed crystals forming above and below the quadruple point being of slightly different compositions. The true transition point should lie between these two temperatures, at about  $20\text{--}05^\circ$ .

\* Metastable.

The isotherm at 25° should then show three curves, since three solid phases may exist at this temperature. The results obtained are in Table IV and are plotted in Fig. 3. The isotherm consists of three curves: *ad* denoting solutions in equilibrium with mixed crystals along the small range *a'd'* (mainly  $\text{Na}_2\text{S}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$ ), *de* denoting those in equilibrium with mixed crystals along the line *d''e''* (mainly anhydrous  $\text{Na}_2\text{SO}_4$ ), and *ef*, where the equilibrium is with mixed crystals along *e'f'* (mainly  $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$ ). The solids along *e''e'* were dried on blotting paper and those along *d'd''* were washed with spirit.

The existence of mixed crystals of decahydrates of the two salts and of a very small range of pentahydrates is clearly shown. The evidence obtained here for the series of mixed crystals of anhydrous salts is not definite, but the work at 40° points to the existence of an analogous series at 25°. The solutions in this isotherm were prepared by dissolving the salt constituent which should mainly

constitute the solid phase in the total amount of water required, then adding the other salt, and rotating the tube in the bath.

The sodium sulphate solution curve has been extended into the metastable region at  $0.8^\circ$ ,  $25^\circ$  and  $40^\circ$ , and in each case it shows a decided increase in curvature. If the metastable solution curve in a system where mixed crystals are formed could be fully realised, it should form a closed loop, and this is indicated by the shapes of the curves in the metastable region.

### *Summary.*

1. The system sodium thiosulphate-sulphate-water has been examined at  $0.8^\circ$ ,  $18^\circ$ ,  $25^\circ$ , and  $40^\circ$ .

2. The existence has been demonstrated of a very short series of mixed crystals of pentahydrates at all four temperatures; of a series of decahydrates at  $0.8^\circ$ ,  $18^\circ$ , and  $25^\circ$ ; and of a series of anhydrous salts at  $25^\circ$  and  $40^\circ$ .

3. The quadruple point at which four phases co-exist, three being mixed crystals and one a solution, is at a temperature very close to  $20^\circ$ .

The author is indebted to Professor A. C. D. Rivett for suggesting this work and for advice during its progress.

UNIVERSITY OF MELBOURNE.

[Received, February 9th, 1926.]

## CXVIII.—*The Ternary System Sodium Sulphide-Sodium Sulphate-Water.*

By ARTHUR ROBERT HOGG.

THE fact that anhydrous sodium sulphite and sulphate, and their corresponding hydrates, crystallise together within limits (Rivett and Lewis, *Rec. trav. chim.*, 1923, 42, 954; J., 1924, 125, 1156, 1162) suggested an inquiry into the relations between sodium sulphide and sodium sulphate. This has been carried out at each of the five temperatures  $0.1^\circ$ ,  $18^\circ$ ,  $25^\circ$ ,  $31^\circ$  and  $40^\circ$ , the complete ternary system being described in each case.

For the most part the salts used have been of analytical reagent (B.D.H.) standard. Mixtures of these and water in varying amounts have been brought to equilibrium in rubber-stoppered glass tubes, the proportions taken being such that about 6% of the total was present as solid when equilibrium was attained. Three methods of attaining equilibrium were employed: (i) cooling homogeneous solutions from higher temperatures, inoculating, if necessary, with

the appropriate solid phase (systems at  $0.1^{\circ}$  and  $18^{\circ}$ ): (ii) heating heterogeneous mixtures from lower temperatures (systems at  $25^{\circ}$  and  $31^{\circ}$ ): (iii) evaporating homogeneous solutions under reduced pressure at the temperature of experiment until sufficient solid appeared (system at  $40^{\circ}$ ). When all phases were present, the tubes were mechanically rotated in a thermostat for from 4 to 40 hours.

The second method is satisfactory in giving the course only of the solution curves: it will not give accurate information as to compositions of solid phases, but it sufficed in the cases where it was used. The third method was carried out in tubes fitted with vertical side limbs and connected in batches of six with a small cooled receiver exhausted to about 40 mm. pressure. The tubes were clamped horizontally to a tilting platform in the bath and were gently rocked during the evaporation, which generally occupied about 3 hours. In order to avoid possible loss of hydrogen sulphide, the mixtures were kept in connexion with the pump for as short a time as possible, the vacuum being maintained by condensation. The distillate from six tubes was collected and tested for sulphide. The amount found, part of which was due to priming, was insufficient to affect the analyses appreciably. When sufficient solid had separated, the vacuum was broken and the rocking continued for from 2 to 12 hours.

On attainment of equilibrium, a sample of the solution was withdrawn in a pipette (suitably heated or cooled) through a cotton-wool plug, and weighed. Densities so obtained are correct to one or two units in the third decimal place. Dilution to an appropriate extent gave the solution which was analysed. The moist solid was obtained by rapid filtration on a Büchner funnel and a weighed amount was dissolved to a known volume. In some cases, the wet solid was washed with alcohol and dried between folds of blotting paper. In analysis, sulphide was determined by titration against standard acid, with phenolphthalein as indicator, and sulphate was determined gravimetrically as barium sulphate.

#### *Discussion of Results.*

The experimental results are given in Tables I to VI. Compositions are expressed in % of anhydrous salt by weight. In the last column, mixed crystals are indicated by M.C. followed by the formula of the major constituent.

The first point to be noted is that at  $0^{\circ}$  sodium sulphide has been obtained as a decahydrate, a form apparently not hitherto described. Analysis of the solid, after washing with alcohol and drying with blotting paper, gave  $\text{Na}_2\text{S}$ , 30.04% :  $\text{Na}_2\text{S} \cdot 10\text{H}_2\text{O}$  requires 30.23 and  $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$  requires 32.49%. In the ternary system at  $0.1^{\circ}$  the

1.041	1.44	2.99	0.45	32.5	

solution curve for this decahydrate is short (see Fig. 1), but there is definite indication of the separation of mixed crystals containing a very little  $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$ .

At the sodium sulphate end the mixed-crystal formation is greater, the limiting member of the series containing 42% of sulphate and 1.5% of sulphide. The points in Fig. 1 marked by crosses within

FF\*

circles represent mixtures of two solid phases in equilibrium with the solution at the intersection of the two solution curves. The solids were obtained almost free from mother-liquor by washing with alcohol and drying with blotting paper. It will be seen that they all lie very near to the line joining the end corresponding to mixed crystals of (mainly)  $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$  containing sulphide and the point representing the composition  $\text{Na}_2\text{S} \cdot 10\text{H}_2\text{O}$ . This gives independent proof of the existence of a decahydrate of the sulphide.

Between it and the nonahydrate in the binary system the transition point has been shown by the cooling method to be  $4.7^\circ$ , the saturated solution then containing 12.46% of sodium sulphide and having a density of 1.128.

At  $18^\circ$  (Table II) the solid separating at the sulphide end is the ordinary nonahydrate containing some dissolved sulphate (see

Fig. 2). Whether the latter is there with water in the same molecular proportion of 1 : 9 cannot be stated. At the sulphate end, however, there is no indication of any appreciable solubility of sodium sulphide in  $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$ . It would seem that  $\text{Na}_2\text{S} \cdot 10\text{H}_2\text{O}$  cannot exist in mixed crystals at  $18^\circ$ , while the nonahydrate of the sulphide is insoluble in the decahydrate of the sulphate.

There is no appreciable mixed-crystal formation at  $25^\circ$  or  $31^\circ$  (Tables III and IV) either in the hydrated or anhydrous sulphate

solid phase. The relations are shown in Fig. 3 and need no discussion. At 40°, where only anhydrous sulphate can exist, there is again no discernible miscibility. At all three temperatures, the part of the system in which solid sulphide appears is so small that one cannot make definite assertions about the solid phase.

By the determination of temperature-time curves in slow cooling and heating of suitably chosen mixtures, the transition points were determined as set out in Table VI, together with the compositions of saturated solutions in equilibrium with the solids indicated in the

first column. Sulphate lowers the transition point between deca- and nona-hydrates of the sulphide from 4.7° to 2.3°, whilst the transition point between decahydrated and anhydrous sulphates

may be reduced by sulphide from  $32.4^{\circ}$  to  $20.6^{\circ}$ . For small concentrations of sodium sulphide, the depression of this transition point has been measured and found to be directly proportional to the concentration of sulphide. It may be expressed by  $D = 0.625C$ , where  $D$  is the depression and  $C$  the concentration of sulphide in g. per 100 g. of solution.

A curious arrest at  $29.6^{\circ}$  (Table VI) has not been explained. The solution has a high density and the arrest may correspond with the formation of a metastable hydrate no trace of which was found in the work on the  $31^{\circ}$ -isotherm.

### *Summary.*

1. The system sodium sulphide-sulphate-water has been investigated between  $0.1^{\circ}$  and  $40^{\circ}$ .

2. Sodium sulphide has been found to form a decahydrate which has not been previously described. The transition point in the binary system between deca- and nona-hydrates is  $4.7^{\circ}$ .

3. Mutual miscibility is shown by the solid decahydrates of sulphide and sulphate at  $0.1^{\circ}$ .

4. At  $18^{\circ}$ ,  $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$  can dissolve sulphate (as nonahydrate?) but neither  $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$  nor  $\text{Na}_2\text{SO}_4$  shows appreciable tendency to include sulphide in its crystals.

5. The transition point between deca- and nona-hydrated sulphides is lowered in the ternary system by sulphate to  $2.3^{\circ}$ ; while that between decahydrated and anhydrous sulphate is lowered by sulphide to  $20.6^{\circ}$ .

The author's best thanks are due to Professor A. C. D. Rivett for suggesting this investigation and for much helpful criticism.

## CXIX.—*The Constitution of Maltose.*

By JAMES COLQUHOUN IRVINE and IAN MACLEOD ARMSTRONG  
BLACK.

A CONSIDERABLE section of the work conducted in this laboratory on the constitution of polysaccharides has been withheld from publication for some years owing to the fact that the results could not be readily explained. As these discordant features accumulated, it became increasingly evident that current views regarding the structure of maltose required revision and that it was necessary to

study the problem anew. This we have done and, as our results differ fundamentally from those upon which the accepted structure for the disaccharide is based, it is desirable to review the whole situation.

The first attempt to solve the constitution of maltose by means of methylation was made by Purdie and Irvine (J., 1905, 87, 1022), who applied the silver oxide reaction directly to the free sugar. Although the alkylation was complicated by oxidation of the reducing group, the decisive result emerged that, on hydrolysis of the product, crystalline tetramethyl glucose was produced. This revealed the structure of one-half of the maltose molecule which, on the basis of the amylene-oxide formula for glucose,\* becomes :

An attempt was subsequently made by Irvine and Dick (J., 1919, 115, 593) to determine the position through which the second glucose residue is attached, the scheme involving the complete methylation of methylmaltoside and the identification of the scission products. In this case an experimental obstacle intervened, it being found that the method employed to prepare methylmaltoside was accompanied by degradation of the sugar so that one of the hydrolytic products finally obtained consisted of a methylated pentose. The research was, however, of some value as, once more, crystalline tetramethyl glucose was isolated, thereby confirming the earlier result of Purdie and Irvine. Subsequently, Haworth and Leitch (J., 1919, 115, 809) applied the methyl sulphate reaction to maltose in two successive stages, the first being designed to convert the sugar into methylmaltoside, which was partly methylated in the second stage and thereafter fully alkylated. Hydrolysis of this product yielded two methylated glucoses, one of which, as was to be expected, was tetramethyl glucose. The object of the research was, however, to ascertain the structure of the *reducing* hexose residue in maltose, so that greater importance must be attached to the constitution of the remaining scission product, *viz.*, trimethyl glucose. The sugar isolated by Haworth and Leitch was a syrup and was stated by them to be the liquid variety of trimethyl glucose in which the terminal  $-\text{CH}_2\text{-OH}$  group is unsubstituted. As originally formulated, this sugar was described as 2 : 3 : 5-trimethyl

\* The amylene-oxide formula for glucose is applied in this paper only tentatively and is restricted to derivatives which are known to be convertible into crystalline tetramethyl glucose. The results now contributed show that it is inadvisable to go further.

glucose (I), but adopting meanwhile the amylene-oxide structure, it may be termed 2 : 3 : 4-trimethyl glucose (II).

Irrespective of the oxygen-ring, the essential point is that the formation of such a sugar implies that the two hexose residues in the disaccharide are coupled through a terminal hydroxyl group. On this basis, Haworth and Leitch ascribed the following structure to maltose and applied, by analogy, a similar constitution to melibiose :

This formula has remained in use for the past seven years, but was modified recently (Charlton, Haworth, and Peat, this vol., p. 89) by the incorporation of an amylene-oxide linkage in each glucose residue, giving the structure :

Evidently the constitution as given above is valid only if each half of the molecule gives rise to the appropriate methylated glucose. With regard to residue B, this was already known from the results of earlier workers, and the additional experimental evidence contributed by Haworth and Leitch consisted in the isolation and identification of the trimethyl glucose derived from residue A. Considering the fundamental structural issues involved (which are by no means confined to maltose), it is of the utmost importance to know that the trimethyl glucose is actually what it was described to be. Our results, unfortunately, show that this is not the case. The trimethyl glucose obtained by us from maltose is the crystalline 2 : 3 : 6-isomeride, and not, as stated by Haworth and Leitch, the liquid 2 : 3 : 4-variety. The erroneous conclusion to which the latter workers came is in no way concerned with the position of the oxygen

ring in glucose or with a difference in the interpretation of results, but is attributable to failure to identify correctly the sugar actually formed. It is regrettable that correction should have been so long delayed, particularly as the constitutional formulæ of other disaccharides and of the polysaccharides based on glucose become involved in the fundamental error.

The evidence upon which Haworth and Leitch identified and ascribed a structure to the trimethyl glucose they obtained from maltose may be discussed. The sugar failed to solidify and was separated from tetramethyl glucose by distillation, a process of doubtful utility in any case where the presence of 2 : 3 : 4-trimethyl glucose might be expected. No crystalline derivative was prepared and the bulk of the material was subjected to oxidation by nitric acid, the product thus formed being described as a trimethyl saccharolactone since it corresponded in composition with such a compound. Inquiry into the particular method of oxidation employed has, however, shown that it is untrustworthy. We have ascertained that unchanged sugar may persist along with oxidation products and, in addition, the removal of nitric acid by evaporation with alcohol results in partial esterification of the oxidation acids. In consequence, the analytical results obtained on *undistilled* products are subject to serious errors. For example, a methyl group may be removed by oxidation from the terminal 6-position of the sugar chain, but an ethyl group may enter the carboxyl position, thus introducing compensation into the methoxyl determinations. We have encountered all of the above complications and may cite the oxidation of monomethyl glucose by nitric acid as a conspicuous, but by no means unique, example of a complex reaction which leads to a mixture of products displaying fortuitously the properties and composition of a simple lactone. This accounts for our recent practice in isolating oxidation products in the form of volatile esters or of crystalline derivatives.

Turning to other properties of the trimethyl glucose described by Haworth and Leitch, it may be mentioned that the specific rotations of the compound did not agree with those determined by previous workers (Irvine and Dick, *loc. cit.*) and failed to reveal the characteristic depression shown after distillation. Information was, in fact, available showing that it is impossible to identify 2 : 3 : 4-trimethyl glucose by observation of the activity of distilled specimens, as the value of the specific rotation may vary as much as 20° to 30° owing to the partial transformation of the dextrorotatory sugar into its levorotatory anhydride. This irregularity was encountered so far back as 1903 and was again emphasised by Irvine and Oldham (J., 1921, 119, 1754).

Consideration of the whole situation shows that the claims of Haworth and Leitch regarding the trimethyl glucose they obtained from maltose rested upon insecure experimental evidence which has not been supplemented as knowledge of methylated sugars increased. There can be no doubt that the material they described as the liquid form of trimethyl glucose was an impure specimen of the 2 : 3 : 6-isomeride, which failed to crystallise owing to the experimental treatment to which it had been subjected. In this connexion, Irvine and Hirst (J., 1922, 121, 1214) state "the capacity of this sugar (2 : 3 : 6-trimethyl glucose) to separate in the solid form is seriously affected by impurities and seems to be inhibited by thorough drying so that, on distillation, a viscous syrup is obtained which solidifies only after several weeks. Even gentle warming above the melting point is sufficient to impair crystallisation." The above statement, taken in conjunction with our experience of oxidations by means of nitric acid, shows that it is hazardous, without the most exhaustive confirmation, to claim that any preparation of a trimethyl glucose which fails to crystallise is the 2 : 3 : 4-isomeride.

In overturning a result upon which so many other constitutional formulæ depend, it has been necessary to exclude sources of error so far as they can be foreseen and to repeat the operations several times and by independent workers. Reference is made in the experimental part to some of the precautions adopted and to variations in the procedure. These fall under three main heads : (1) confirmation of the purity and uniformity of the maltose used, (2) variations in the method of methylation, (3) alternative methods of isolating the scission products. We employed three distinct samples of maltose, one of which was made in the laboratory during the War and was certified as conforming to bacteriological standards. With regard to the process of methylation, we followed in the first instance exactly the method described by Haworth and Leitch, applying the methyl sulphate reaction to the free sugar. In other experiments, methyl sulphate was used only until the product was soluble in chloroform, the methylation being completed by the silver oxide reaction alone. Despite these experimental variations, the same result was obtained, the product on isolation being a viscous syrup showing the properties ascribed by Haworth and Leitch to heptamethyl methylmaltoside.

It may be mentioned, however, that the methoxyl and carbon values determined on this material were consistently low, and that satisfactory analytical figures were obtained only when the initial material consisted of crystalline methylmaltoside. The hydrolysis proceeded normally, the liberated sugars being separated by extrac-

tion of an aqueous solution with chloroform. By this means it was possible to effect a sharp separation of the tetramethyl and trimethyl glucoses without distillation or heating above the melting points of these compounds. In all the experiments, both sugars crystallised and proved to be respectively 2 : 3 : 4 : 6-tetramethyl glucose and 2 : 3 : 6-trimethyl glucose. As a precautionary measure, we examined all the hydrolysis products to ascertain if any 2 : 3 : 4-trimethyl glucose was present, but no trace of this sugar could be detected.

In order to place our procedure beyond question, we have duplicated the entire research, using pure  $\beta$ -methylmaltoside as the starting material. In this case also, the methylation was conducted in two ways, using either the silver oxide method or the methyl sulphate reaction throughout. Here again the same result was obtained, irrespective of the method employed, the hydrolysis of the compound giving, as before, crystalline tetramethyl glucose together with crystalline 2 : 3 : 6-trimethyl glucose free from the liquid isomeride. Finally, for the purposes of the present investigation, Irvine and Oldham prepared 2 : 3 : 4-trimethyl glucose by synthetical operations designed to leave the terminal  $\text{CH}_2\cdot\text{OH}$  group unsubstituted (J., 1925, 127, 2729). The product was entirely different from the isomeride obtained from maltose.

Considering the precautions adopted and the results of collateral investigations designed to test sources of error, we are convinced that maltose cannot be formulated in either of the ways suggested by Haworth. The necessity for correction is not limited to the single case of maltose, but extends to all constitutional schemes in which the maltose structure is either directly or indirectly involved. For example, with the displacement of maltose from the position it has hitherto occupied in the structural classification of the disaccharides, the following constitutional relationships must be again regarded as conjectural: (1) maltose and cellobiose, (2) maltose and gentiobiose, (3) lactose and melibiose (Haworth and Leitch, *loc. cit.*; J., 1918, 113, 188; Haworth and Hirst, J., 1921, 119, 193; Haworth and Wylam, J., 1923, 123, 3120).

Further, speculations on the structure of isomaltose and of the molecular unit of starch, which have naturally been founded on a constitutional formula for maltose, lose their significance, a conclusion foreshadowed by results obtained in this laboratory on the methylation of starch and of the polyamyloses.

It would be premature, even with the additional information now available, to speculate as to the alterations in disaccharide formulæ which are now necessary, and discussion is limited to some general considerations. The question arises as to whether methylation

alters the linkage of one sugar residue with another, but this has already engaged our attention (Irvine and Oldham, J., 1925, 127, 2910), although the argument that maltose and cellobiose give rise to different methylated sugars no longer holds. There remains an analysis of how far conclusions as to structure are logically valid when based on the formation of 2:3:6-trimethyl glucose. This sugar, formulated as an amylene-oxide, may be represented as (A) and on first inspection it might appear that all disaccharides which yield this compound must have the glucose residues attached through position 4. But inspection will show that the number of diglucoses which qualify for this mode of linkage is now larger than stereochemical considerations accommodate. The situation thus created is disconcerting, but is greatly simplified when it is recognised that 2:3:6-trimethyl glucose is capable of reacting as a  $\gamma$ -sugar, this property of the compound having been already pointed out (Irvine and Hirst, *loc. cit.*). It follows that the production of 2:3:6-trimethyl glucose is not absolutely diagnostic in discriminating between positions 4 and 5 as the point of union of two glucose residues. Thus, if we imagine two disaccharides to be constituted as under (V and VI), where R represents the non-reducing hexose residue,

only the compound corresponding to (VI) would yield the stable form of trimethyl glucose directly. The other could, however, do so indirectly, giving in the first place:

The possibility thus revealed invests all such constitutional studies with precisely the same uncertainty as is encountered in the hydrolysis of sucrose and inulin. Evidently the disaccharides must be studied afresh in the light of the possibility that  $\gamma$ -oxidic or other

linkages may be present in one or other of the constituent sugars. These considerations have been made the subject of other investigations now in progress in this laboratory.

According to the evidence now submitted, maltose may be formulated either as :

The methylation process does not discriminate between these alternatives, one of which must represent cellobiose and isocellobiose, whilst the other must be reserved for maltose together with, presumably, isomaltose. The conversion of methylmaltoside into  $\beta$ -methylglucoside appears to favour the allocation of formula (VII) to maltose but, on the other hand, the degradation of maltose is more easily explained in terms of formula (VIII). Work is in progress to decide between the above alternatives.

The results now contributed serve to emphasise a view formerly expressed (Irvine, J., 1923, 123, 898) that no claim for finality can be made regarding the constitution of sugars and that each successive modification represents only a stage in knowledge.

## EXPERIMENTAL.

*Methylation of Maltose.*—In order to economise description, it may be stated that each method of alkylation now described was applied to three distinct specimens of maltose. Two of these were obtained from trustworthy manufacturing firms and were selected as they displayed the correct melting point and specific rotation for the disaccharide. The third specimen was prepared in this laboratory during the War and was subjected, before use, to a special bacteriological examination. It was presumably identical with the material used by Haworth and Leitch. The descriptions of the methylation now given apply therefore to six distinct preparations, and the results quoted are typical.

*Method I.* The directions given by Haworth and Leitch (*loc. cit.*, pp. 813—814) were adhered to in every detail. After three methylations by means of methyl sulphate, the product extractable with chloroform weighed 27.5 g. (from 30 g. of maltose) and contained 50.5% of methoxyl. On distillation, 19.5 g. of a viscous syrup were

obtained (b. p. 189—191°/0.2 mm.;  $n_D$  1.4685), but it may be noted that a small fraction of lower boiling point was also collected and that a viscous residue remained undistilled. The main fraction, on redistillation, boiled at 190°/0.2 mm. and showed  $[\alpha]_D$  in alcohol + 91.1° for  $c = 1.15$ ;  $[\alpha]_D$  in acetone + 92.1° for  $c = 1.256$ ; OMe, 50.4%;  $n_D$  1.4706. After another methylation, the product was separated on distillation into three portions, and, although the boiling point showed no variation, the second fraction (11.2 g.) was selected as being in best agreement with the constants quoted by Haworth and Leitch for heptamethyl methylmaltoside.

The methoxyl content was nevertheless slightly low, but purification was effected by solution in light petroleum and extraction with water. A small amount of discoloured syrup was retained in the hydrocarbon solvent, and the main product, when recovered from the water, was entirely decolorised by boiling in chloroform solution with norit. Average yield, 10 g. per 30 g. of maltose used. Found: C, 52.3; H, 8.6; OMe, 52.7. Calc. for heptamethyl methylmaltoside,  $C_{12}H_{14}O_3(OMe)_8$ , C, 52.9; H, 8.4; OMe, 54.6%;  $n_D$  1.4691;  $[\alpha]_D$  in acetone + 90.6° for  $c = 1.16$ . The maltose provided by manufacturing firms gave results corresponding closely with those described above, although the final yield of methylated maltoside was invariably smaller. The same tendency for the methoxyl value to be low was again observed, successive preparations showing OMe, 52.0 and 52.4, in place of the calculated value 54.6%.

*Method II.* The initial stages in the methylation were conducted as before and the product soluble in chloroform was isolated. Thereafter only the silver oxide method was applied, the following being an account of a typical case. 40 G. of the partly methylated maltoside were alkylated as usual with methyl iodide (6 mols.) and silver oxide (3 mols.), the treatment being continued for 8 hours. The yield of distilled material amounted to 32 g., of which 22 g. were collected at the boiling point of heptamethyl methylmaltoside. The undistilled residue was rejected and the distilled material was again methylated and fractionated. Finally, the middle fraction was redistilled and purified by solution in light petroleum and extraction with water as already described.

The heptamethyl methylmaltoside thus isolated was identical with that obtained by Method I and gave the same hydrolysis products, but the methoxyl content was again low (OMe, 52%) and the refractive index was 1.4700 in place of 1.4691.

*Hydrolysis of Heptamethyl Methylmaltoside.—Method A.* In studying this reaction the preparations of the alkylated maltoside obtained from different specimens of maltose were kept apart and treated separately; identical results were, however, obtained in each case.

The maltoside was hydrolysed by heating with 5% aqueous hydrochloric acid as described by Haworth and Leitch, but a variation was introduced into the method of separating the sugars, the acid liquor being extracted six times with chloroform. The syrup isolated from the chloroform solution crystallised at once and consisted of tetramethyl glucose.

The sugar remaining in the aqueous liquor was recovered in the usual manner and converted into the corresponding methylglucoside by boiling with methyl alcohol containing 1% of hydrogen chloride until the solution was devoid of reducing action. After rendering alkaline by the addition of sodium bicarbonate, the alcohol was removed and the residue taken up in water. On extracting six times with chloroform, the trimethyl methylglucoside passed into solution in the chloroform, from which it was recovered and purified by distillation at  $145^{\circ}/0.6$  mm. This treatment removed traces of impurity and the glucoside was then rehydrolysed with 5% aqueous hydrochloric acid. On isolation of the product in the usual manner, the trimethyl glucose was obtained as a viscous syrup which slowly crystallised in the manner characteristic of 2:3:6-trimethyl glucose. The sugar was recrystallised from ether and identified as afterwards described.

In order to secure control evidence, the above operations were conducted in lots of 10 g., a typical result being that 10.3 g. of heptamethyl methylmaltoside gave 4.7 g. of crystalline tetramethyl glucose and 4.7 g. of syrupy trimethyl glucose. The latter, in turn, yielded 3.6 g. of distilled trimethyl methylglucoside, from which 3.3 g. of the corresponding sugar were obtained.

*Method B.* The hydrolysis of heptamethyl methylmaltoside was in this case conducted under conditions which would convert the liberated sugars into the corresponding methylglucosides. This was effected by boiling with excess of methyl alcohol containing 1% of hydrogen chloride, it being found that, in the course of 7 hours' treatment, the specific rotation, which had gradually diminished, attained a constant value. Boiling was continued for an additional period of 5 hours, after which the acid was neutralised and the solvent alcohol removed. The residue was then dissolved in water and the solution extracted repeatedly with chloroform, a syrup being obtained on evaporating the latter solvent. This syrup was a mixture of tetramethyl and trimethyl methylglucosides which was purified from traces of extraneous products by distillation under diminished pressure. The total distillate was thereafter hydrolysed in the usual manner by means of aqueous hydrochloric acid and the two sugars thus formed were separated by extraction with chloroform as described in Method A. The results were as before, crystal-

line tetramethyl glucose being isolated from the chloroform solution and the aqueous liquor retaining trimethyl glucose. This was isolated initially as a syrup which crystallised on keeping. In this particular instance, the solidification of the sugar was complete only after an interval of 3 weeks owing, it would appear, to the presence of a small proportion of a very viscous syrup which was less soluble in ether and had a smaller methoxyl content than trimethyl glucose. The crystallisation of the sugar was delayed by cooling and proceeded more satisfactorily at room temperature.

*Examination of the Hydrolysis Sugars.*—*Identification of 2 : 3 : 4 : 6-tetramethyl glucose.* The identification of the tetramethyl glucose presented no difficulty. All the specimens were recrystallised three times from light petroleum. The composition, melting point, mixed melting point, and mutarotation determined on the product agreed exactly with the accepted standards for 2 : 3 : 4 : 6-tetramethyl glucose.

*Identification of 2 : 3 : 6-trimethyl glucose.* In the hydrolysis experiments already described, the trimethyl glucose was obtained as a crystalline mass which still retained a small quantity of a viscous syrup. The material was thoroughly incorporated with dry ether containing a little acetone, and the crop of crystals removed by filtration. On evaporation of the filtrate and extraction of the residue with ether any non-crystallisable syrup was left undissolved, while the extract gave further crops of crystalline sugar. In one instance, when the proportion of adhering syrup was larger than usual, it was removed by draining on porcelain, from which it was recovered and examined, with negative results, for 2 : 3 : 4-trimethyl glucose. Each preparation of the sugar was purified by recrystallisation from ether containing a small proportion of low-boiling petroleum. In this way, the compound was obtained in characteristic long needles melting at 113—114° and showing no depression of the melting point when mixed with a standard specimen of 2 : 3 : 6-trimethyl glucose (Found: OMe, 41.2. Calc., 41.9%). When dissolved in water the sugar displayed downward mutarotation, giving the equilibrium value  $[\alpha]_D^{20} + 70.9^\circ$ , the accepted permanent specific rotation for 2 : 3 : 6-trimethyl glucose being  $+70.5^\circ$ . The results quoted are typical of those obtained with all the specimens examined.

*Preparation of Methylmaltoside.*—In order to attain greater accuracy, the reactions of methylation and hydrolysis were duplicated using crystalline methylmaltoside as the starting material. As a number of interesting features were encountered in the preparation of methylmaltoside, these are referred to now, together with such practical details as we have found to be advantageous.

*Stage I.* The preparation of octa-acetyl maltose proceeds most satisfactorily when not more than 30 g. of maltose are used in each experiment. In successive preparations 300 g. of the sugar were converted into the acetate, each experiment yielding on an average 20 g. of product which had been recrystallised from alcohol until the m. p. was 158—159°.

*Stage II.* Trial experiments showed that the action of hydrogen bromide on octa-acetyl maltose gives the best results when carried out on small quantities of the order of 2 g. This may be increased to a maximum of 10 g. but, with larger quantities, degradation of the disaccharide takes place and serious difficulties are introduced into the purification of the acetylated methylmaltoside. By tedious repetition of the typical experiment now described, 250 g. of the octa-acetate were converted into hepta-acetyl methylmaltoside. 2 G. of octa-acetyl maltose were dissolved in 50 c.c. of a mixture consisting of glacial acetic acid saturated with hydrogen bromide (10%), of ether (15%), and of benzene (75%). The use of this particular mixture of solvents secures a permanently clear solution which enables the reaction to be followed by reliable polarimetric readings. The rotation of the solution came to a constant value in about 12 hours, the final specific rotation, recalculated for the change of concentration, ranging between + 184° and + 190°. The solution was washed twice with water and dried over anhydrous sodium sulphate, the solvent being thereafter removed. The residual syrup was dried in a vacuum at a temperature not exceeding 55°, a process which was accompanied by vigorous frothing.

*Stage III.* The bromo-derivative was dissolved by shaking with anhydrous methyl alcohol in the presence of silver carbonate, mixing being conducted on a mechanical shaker until a test sample of the solution was free from bromine. At this stage crystals of the product usually separated and consequently both the silver residues and the filtrate were extracted with hot chloroform. On removal of the solvent, hepta-acetyl methylmaltoside remained as a syrup which crystallised readily and was purified from absolute alcohol. In the course of 10 parallel preparations it was found that, as a rule, three crystallisations from alcohol gave a product melting at 124—125°, but, by repeating the crystallisation, this value could be raised to 128—129° (Found: C, 49.8; H, 5.9; OMe, 4.5. Calc., C, 49.8; H, 5.8; OMe, 4.8%.  $[\alpha]_D$  in chloroform + 53° for  $c = 1.5$ ). This melting point is identical with that quoted by Koenigs and Knorr, who prepared the compound from the corresponding nitrate. The loss sustained in these recrystallisations is considerable, as only about 40% of the original material is obtained in the pure condition.

In addition, a second crystalline product was isolated in amounts which varied in different preparations and it may be noted that when this substance was present in large proportion it was impossible to separate it from hepta-acetyl methylmaltoside by ordinary fractional crystallisation. Normally, this by-product was deposited from the mother-liquors, accumulated in the course of recrystallising hepta-acetyl methylmaltoside, when kept in a cool place. After recrystallisation from alcohol the compound melted at 145–146°, and showed  $[\alpha]_D$  in chloroform + 69.1° for  $c = 1.5$  (Found: OMe, 5.2;  $\text{CH}_3\text{-CO}_2\text{H}$ , 63.3. Calc. for  $\text{C}_{24}\text{H}_{34}\text{O}_{16}$ , OMe, 5.4;  $\text{CH}_3\text{-CO}_2\text{H}$ , 62.3%). The examination in detail of this compound will form the subject of a later communication.

*Stage IV.* Hepta-acetyl methylmaltoside, in quantities of about 40 g., was dissolved in a large excess of absolute alcohol saturated with dry ammonia. After 2 days, the rotation of the solution became constant and thereafter the solvent was removed under diminished pressure. The viscous syrup then remaining was dissolved in the minimum amount of alcohol and the methylmaltoside precipitated by the addition of small quantities of a mixture of chloroform and ether. The product was thereafter repeatedly recrystallised from a mixture of alcohol and ethyl acetate—a process which, if wasteful, is necessary before the maximum melting point of 110–111° is attained. Average yield, 9.5 g. In this condition, methylmaltoside contained 1 molecule of combined water (Found: OMe, 8.3;  $\text{H}_2\text{O}$ , 4.9. Calc. for  $\text{C}_{13}\text{H}_{24}\text{O}_{11}\cdot\text{H}_2\text{O}$ , OMe, 8.3;  $\text{H}_2\text{O}$ , 4.8%).

The following observations were made on a specimen dried over phosphoric anhydride at 100°/15 mm.: C, 43.8; H, 7.0. Calc. for  $\text{C}_{13}\text{H}_{24}\text{O}_{11}$ , C, 43.8; H, 6.75%.  $[\alpha]_D$  in alcohol + 63.5° for  $c = 1$ ; in water, + 83.9° for  $c = 1$ .

*Methylation of Methylmaltoside.*—This methylation was carried out by the silver oxide reaction in a manner parallel with that employed in the case of methylglucoside. In the first three methylations it was necessary to use methyl alcohol as an extraneous solvent, but thereafter the material was freely soluble in methyl iodide alone. After the sixth methylation, the refractive index was 1.4689 and the methoxyl content 50.1%. Two additional methylations failed to alter  $n_D$ , although the methoxyl content had increased to 52.3%. On distillation in a high vacuum, no lower-boiling distillate was obtained and the material distilled sharply at the boiling point of heptamethyl methylmaltoside (Found:  $n_D$ , 1.4662; yield, 76%; C, 52.7; H, 8.45; OMe, 54.1. Calc. for  $\text{C}_{20}\text{H}_{38}\text{O}_{11}$ , C, 52.9; H, 8.4; OMe, 54.6%).

After neutralising the solution with barium carbonate it was decolorised with norit and extracted six times with chloroform. The extract gave crystalline tetramethyl glucose (yield, 91% of the theoretical amount). Trimethyl glucose was recovered from the aqueous liquor by evaporation and extraction of the residue with acetone. Removal of this solvent left a syrup which was taken up in ether containing a trace of acetone and treated as already described. The trimethyl glucose crystallised rapidly, solidification beginning spontaneously in a few hours (yield, 87% of the theoretical amount).

*Tetramethyl glucose.* After two recrystallisations, m. p. 93–95°;  $[\alpha]_D$  in absolute alcohol +112.1° (initial)  $\rightarrow$  83.4° (constant).

*Trimethyl glucose.* After two recrystallisations, m. p. 113–114°; mixed m. p. 113–114°; permanent specific rotation in water +70.2°; OMe, 41.6%. All the above determinations agree exactly with the standard values for 2 : 3 : 6-trimethyl glucose and further confirmation was obtained by converting the sugar into the corresponding  $\beta$ -methylglucoside. This proved to be identical with the trimethyl methylglucoside obtained from cellulose; m. p. 57.5°; mixed m. p. 57°; C, 50.6; H, 8.4; OMe, 51.9. Calc., C, 50.8; H, 8.5; OMe, 52.5%. The specific rotation in methyl alcohol for  $c = 1$  was –29.3°.

The thanks of the authors are due to the Carnegie Trust for a Research Fellowship held by one of them, and also to Dr. J. W. H. Oldham and to Mr. C. B. Purves (Carnegie Fellows) for much valuable help in carrying out control experiments.

CXX.—*The Constitution of the Disaccharides. Part X. Maltose.\**

By CONRAD J. ASTLEY COOPER, WALTER NORMAN HAWORTH,  
and STANLEY PEAT.

THE investigation of the structure of maltose by Haworth and Leitch (J., 1919, **115**, 809) was one of the earliest of those undertaken in the disaccharide series. In the interval which has elapsed, greater familiarity with the properties and mode of identification of the partly methylated glucoses, and particularly of the trimethyl glucoses, has been gained.

During a research, which will shortly be published, on the constitution of Ling and Nanji's isomaltose (J., 1923, **123**, 2666), certain irregularities were revealed which led us to suspect the accuracy of the formula previously applied to maltose. Consequently, the study of the latter sugar has been again undertaken during the past 18 months, with results which seem to require a modification of Fischer's formula for maltose, which was supported by the work of Haworth and Leitch.

In the earlier paper, the structural formula which appeared to represent maltose showed the linking of the two hexoses as occurring through the primary alcohol residue of one hexose with the reducing group of the second. The experimental data on which this conclusion was based were dependent on the recognition of the structure of the trimethyl glucose (II) obtained, along with tetramethyl glucose (III), by hydrolysis of heptamethyl methylmaltoside (I). In these formulæ the revised structure for normal glucose is used (Charlton, Haworth, and Peat, this vol., p. 89); consequently the older 2 : 3 : 5-trimethyl glucose is now written as 2 : 3 : 4-trimethyl glucose.

The facts available at that time pointed to the non-identity of this specimen of trimethyl glucose, which was a liquid, with crystalline 2 : 3 : 6-trimethyl glucose, which was isolated as a hydrolysis product of methylated cellobiose (Haworth and Hirst, J., 1921, **119**,

\* Almost the whole of the experimental results given in this paper were obtained during the early part of 1925, but publication was held over for the inclusion of other confirmatory details. A private communication from Sir James Irvine was received on February 23th, 1926, intimating, but without experimental details, that he had communicated a paper to the Society announcing the isolation of 2 : 3 : 6-trimethyl glucose as a hydrolysis product of methylated maltose. In the circumstances, we consider it is advisable now to submit our results for publication, inasmuch as they may serve to confirm and supplement those obtained by Irvine and his collaborators, whose priority we acknowledge.

193). Moreover, the oxidation of the trimethyl glucose derived from methylated maltose led to the isolation of what was considered to be a trimethyl saccharolactone (IV), and for these reasons, since the primary alcohol residue had apparently undergone oxidation to a carboxyl group without loss of a methoxyl residue, the specimen of trimethyl glucose was considered to have three methoxyl residues in the 2 : 3 : 4-positions, as shown in formula (III).

In a new series of experiments, the whole of the early work was repeated, and gave identical analytical results for the oxidation product of the trimethyl glucose. The method of isolating the trimethyl glucose was then modified, and instead of separating the hydrolysis products of methylated maltose by distillation, the aqueous solution containing the methylated hexoses was repeatedly extracted with chloroform, which entirely removed tetramethyl glucose as the normal crystalline variety (2 : 3 : 4 : 6).

Remaining in the aqueous solution was the trimethyl glucose, and this was recovered by evaporation followed by extraction. The extracted syrup spontaneously crystallised, and yielded about 6% of the total in the form of the readily identifiable 2 : 3 : 6-trimethyl glucose. This was similar in all respects to the specimen previously isolated both from methylated cellobiose and from methylated lactose. Moreover, the remaining syrup appeared to consist of the  $\beta$ -form of this normal sugar, and probably contained also  $\alpha$ - and  $\beta$ -forms of the corresponding  $\gamma$ -sugar, into which the normal variety appears to pass somewhat readily owing to the presence of a free hydroxyl group in the  $\gamma$ -position in the chain. Possibly owing to the latter consideration, crystalline 2 : 3 : 6-trimethyl glucose cannot be isolated in quantity.

An alternative interpretation to that given in the earlier paper by Haworth and Leitch can now be offered, inasmuch as, accepting the trimethyl glucose as in reality 2 : 3 : 6-trimethyl glucose (V), this could pass on oxidation to dimethyl saccharolactone (VI). Under the experimental conditions described by Haworth and Leitch, the oxidation product from the trimethyl sugar was digested with ethyl alcohol for the purpose of removing traces of water, and it would appear to have undergone partial transformation

into the ethyl ester of the dimethyl saccharolactone. The analytical data previously quoted are given in column 1, and those of dimethyl saccharolactone (VI) and its ethyl ester (VII) in columns 2 and 3. The mean of the latter two results, given in column 4, will be seen to be closely similar to the analytical data previously interpreted under column 1 as indicating the constitution of the product as that of a trimethyl saccharolactone.

	1.	2.	3.	4.
C .....	46.03	43.6	48.4	46.0
H .....	6.26	5.45	6.46	5.95
OMe .....	35.9	28.2	37.5	32.85

In order to test this explanation, we have again oxidised the liquid portion of the trimethyl glucose and submitted this to esterification with ethyl alcohol containing hydrogen chloride. The main fraction isolated from this treatment distilled at 110–115°/0.03 mm. and gave titration results which corresponded to those required for compound (VII).

The valuable method of identifying 2:3:4-trimethyl glucose through its crystalline  $\beta$ -glucoside (Irvine and Oldham, J., 1921, 119, 1758) was not known at the time when the maltose paper was published and consequently we were unable then to apply this method of diagnosis. It seems clear, however, that 2:3:4-trimethyl glucose cannot be one of the hydrolysis products of methylated maltose, inasmuch as the specimen in our possession has since failed to satisfy those tests. The  $\beta$ -glucoside, when prepared, did not crystallise on keeping or on nucleation with specimens of 2:3:4-trimethyl  $\beta$ -methylglucoside which had been isolated for purposes of

diagnosis during our work on the constitution of gentiobiose and of amygdalin biose. On the other hand, the isolation of crystalline

2:3:6-trimethyl glucose points to the necessity of revising the structural formula of maltose, to which is now given the constitution (VIII) or (IX). The formula (VIII) differs stereochemically but not structurally from that of cellobiose, since the latter is a glucose  $\beta$ -glucoside and maltose is a glucose  $\alpha$ -glucoside.

The adjustment of the formula of maltose removes many outstanding anomalies as to the behaviour of starch.

#### EXPERIMENTAL.

*Hydrolysis of Heptamethyl Methylmaltoside. Isolation of 2:3:6-Trimethyl Glucose and 2:3:4:6-Tetramethyl Glucose.*—A specimen of heptamethyl methylmaltoside (39.5 g.) prepared as previously described by Haworth and Leitch (*loc. cit.*) (b. p. 201—203°/0.03 mm.) was hydrolysed by digesting with 5% hydrochloric acid at 85° for 1½ hours and at 100° for a further period of 1½ hours. Thereafter the specific rotation of the solution remained constant, and the hydrolysis was complete. The neutralised solution was slightly concentrated under diminished pressure and extracted several times with large quantities of chloroform. The chloroform extract was dried and evaporated; the residual syrup crystallised almost immediately, yielding pure 2:3:4:6-tetramethyl glucose (16.5 g.).

The residual aqueous solution was completely evaporated under diminished pressure and gave a syrup (15 g.) which, on keeping for several weeks, partly crystallised. These crystals (m. p. 106—117°) were drained on porous tile, and purified by solution in dry ether, from which small, colourless needles separated in three fractions: (a) m. p. 105—111°; (b) 108—115°; (c) 102—109°. Further recrystallisation gave crystals (1.25 g.), m. p. 110—116°, which, in admixture with a specimen of 2:3:6-trimethyl glucose derived from methylated lactose (Haworth and Leitch), showed no depression of melting point. It showed in methyl alcohol ( $c = 1.73$ )  $[\alpha]_D +102.6^\circ$  after 15 minutes, changing to  $70.2^\circ$  after 12 hours, and, after catalysis, to  $67.5^\circ$  (Found: C, 48.4; H, 8.3; OMe, 40.4. Calc., C, 48.6; H, 8.1; OMe, 41.9%).

The uncrystallisable syrup from which the above crystals had been obtained was oxidised by digestion with nitric acid ( $d\ 1.2$ ), heating to 80° until brown fumes began to be evolved, and thereafter at 70° for 5½ hours. After being cooled and tested for the presence of free sugar, the solution was again heated for a short period until the whole of the sugar was oxidised. The nitric acid was then removed by distillation under diminished pressure at 35°, water being constantly added during this operation. Finally, the whole of the water was evaporated, and the syrupy residue dissolved in ethyl alcohol containing 2% of hydrogen chloride. This solution

was boiled for 8 hours in order to complete the esterification, and the product was isolated in the usual manner. The methoxyl and ester groups were determined by the Zeisel method, calculating both OMe and OEt in terms of OMe, and showed 40·6%. The ester was then distilled, the first portion being collected at 88—95°/0·03 mm., but the main portion, the analysis of which is given below, distilled at 110—115°/0·03 mm. (Found: OR, 39·3. Calc. for the ethyl ester of dimethyl saccharolactone,  $C_{10}H_{16}O_7$ , 37·5%).

*Titration.* 0·1108 G. required 4·7 c.c. of *N*/10-sodium hydroxide in the cold, and on heating in a water-bath with excess of the alkali for 20 minutes, a total of 8·81 c.c. of *N*/10-sodium hydroxide was required. Calculated for the ethyl ester of dimethyl saccharolactone,  $C_{10}H_{16}O_7$ , 8·92 c.c., and for the trimethyl saccharolactone,  $C_9H_{14}O_7$ , 9·46 c.c. Hydrolysis of this ester gave dimethyl saccharolactone (Found: OMe, 27·8. Calc.: OMe, 28·2%).

On another occasion, the whole of the work described in the paper by Haworth and Leitch (*loc. cit.*) on the constitution of maltose was repeated in every detail, and the lactone derived from the oxidation of trimethyl glucose was titrated and gave the following results: 0·0979 g. required 8·37 c.c. of *N*/10-sodium hydroxide. Calculated for trimethyl saccharolactone,  $C_9H_{14}O_7$ , 8·33 c.c. In the earlier paper, a small typographical error appeared in the account given of the titration results, and the above re-determination was therefore carried out. This anomaly is explained in the introduction.

The authors express their thanks to the Department of Scientific and Industrial Research for the award of a grant to one of them.

## CXXI.—*Synthesis of Derivatives of $\gamma$ -Xylose.*

By WALTER NORMAN HAWORTH and GEORGE CRONE WESTGARTH.

THIS investigation forms a part of a general study of the constitution of the normal and the  $\gamma$ -forms of the sugars. The isolation of derivatives of  $\gamma$ -fructose,  $\gamma$ -galactose, and  $\gamma$ -arabinose encouraged the view that the existence of  $\gamma$ -forms was a general property of the sugars (Haworth and Law, J., 1916, 109, 1314; Haworth, Ruell, and Westgarth, J., 1924, 125, 2468; Baker and Haworth, J., 1925, 127, 365).

In the present paper, another example in the pentose series is

described, namely, *trimethyl  $\gamma$ -xylose*, the structure of which has been investigated by conversion into its lactone and comparison of the properties of the latter with the corresponding lactone which we have isolated from normal trimethyl xylose.

In the case of xylose, the condensation with methyl alcohol in the cold proceeds very tardily, the  *$\gamma$ -methylxyloside* requiring 5 to 7 days for its formation, as contrasted with fructose, which condenses with methyl alcohol in the course of  $\frac{1}{2}$  hour, and galactose and arabinose, which require a period of less than a day after solution of the sugar. In following the formation of the  *$\gamma$ -methylxyloside* polarimetrically, it was observed that the condensation was accompanied by no inversion in the sign of rotation, and indeed, the final value recorded,  $[\alpha]_D + 28.8^\circ$ , differed very little from the initial value,  $+ 28.3^\circ$ , of the original xylose solution, although intermediate readings attained a maximum of  $+ 37.7^\circ$ .

*$\gamma$ -Methylxyloside* is comparable in its properties with  *$\gamma$ -glucosides* in general, exhibiting the usual ease of hydrolysis with acids of extreme dilution, and the characteristic instability in presence of neutral permanganate. From the specimen of  *$\gamma$ -methylxyloside*, the completely methylated derivative, *trimethyl  $\gamma$ -methylxyloside*, was obtained as a colourless liquid,  $[\alpha]_D = + 32.0^\circ$  in methyl alcohol. Hydrolysis of this compound was effected at  $100^\circ$  with either *N/50-* or *N/100-hydrochloric acid*, but for the purpose of the preparation of the corresponding free sugar *N/15-acid* may conveniently be used, the hydrolysis being complete in 4 hours. The rotation changes accompanying the hydrolysis exhibited the usual fall and rise in value, giving a time-period curve characteristic of the  *$\gamma$ -glucosides*, and indicating the presence of two stereochemical forms.

Trimethyl  *$\gamma$ -xylose* was thus isolated as a liquid containing both  $\alpha$ - and  $\beta$ -forms, and its properties were compared with those of the normal trimethyl xylose prepared by Carruthers and Hirst (J., 1922, 121, 2306).

Trimethyl $\gamma$ -xylose.		Normal trimethyl xylose.
Syrup, b. p. $110^\circ/0.04$ mm.		Crystalline, m. p. $87-90^\circ$ .
$[\alpha]_D$	$+ 24.7^\circ \rightarrow 31.2^\circ$ .	$+ 74^\circ \rightarrow 21^\circ$ .
Action of permanganate.	Reduces vigorously.	No action.
Acid methyl alcohol.	Combines rapidly.	Combination slow.

It is noteworthy that these two structurally different forms should display specific rotations of the same sign and of similar magnitude. In this respect, the two varieties of trimethyl xylose may be compared with those of tetramethyl mannose, the  *$\gamma$ -form*

of which is crystalline and shows  $[\alpha]_D + 48.5^\circ$ , whereas the normal form is a liquid, showing  $[\alpha]_D + 17.2^\circ$  (equilibrium in methyl alcohol) (Irvine and Burt, J., 1924, 125, 1343).

With the object of deriving the constitution of trimethyl  $\gamma$ -xylose, the sugar was oxidised to the corresponding lactone, and for the purposes of comparison a similar procedure was followed also with the normal sugar. The properties of the two lactones are indicated below :

Lactone from	(a) Trimethyl $\gamma$ -xylose. Liquid.	(b) Normal trimethyl xylose. Crystalline, m. p. $55^\circ$ .
$[\alpha]_D$ in water.	$+74.1^\circ \rightarrow 61.4^\circ$ (Period, 21 days).	$-3.8^\circ \rightarrow +20.8^\circ$ (Period, 8 days).

A comparison of these rotation values indicates that the lactone from the  $\gamma$ -sugar resists hydrolysis to a much greater extent than the corresponding lactone from the normal sugar, and curves representing these changes have been given in the paper by Charlton, Haworth, and Peat (this vol., p. 93).

Since the constitution (III) allocated to normal trimethyl xylose on the basis of its oxidation to trimethoxyglutaric acid is that of a normal or  $\delta$ -oxide (Hirst and Purves, J., 1923, 123, 1352), it is evident that the structure of the derived lactone is that indicated by formula (IV). We are able to assign the structural formula (II) to the lactone from the  $\gamma$ -sugar for two reasons: (a) Its lactone ring must be situated on the right of the carbon chain on the basis of Hudson's rule, since the substance displays dextrorotation, diminishing in magnitude as the ring opens by hydrolysis to the hydroxy-acid. The lactone ring cannot engage the  $\beta$ -carbon acid, since in this case the lactone would be *lævorotatory*. (b) Its speed of hydrolysis in water is comparable in every respect with the series of  $\gamma$ -lactones examined by Charlton, Haworth, and Peat (*loc. cit.*). We therefore ascribe the constitution of a  $\gamma$ -lactone to this compound (II), whence it follows that the related sugar, trimethyl  $\gamma$ -xylose, has the constitution (I).

#### EXPERIMENTAL.

*Preparation of  $\gamma$ -Methylxyloside.*—Polarimetric observations indicated that at  $15^\circ$  solutions of xylose (2%, 3.5%, and 5%) in dry,

acetone-free methyl alcohol containing 1% of hydrogen chloride attained a maximum rotation after 25–30 minutes from the time of solution, this stage being succeeded by a slow diminution of rotation, and the equilibrium period seemed to be reached in about 24 hours.

The following values were obtained, for example, with a solution of this nature containing 2% of xylose :

Time (mins.) .....	5	10	15	20	30	53	58
$[\alpha]_D$ .....	+28.3°	35.3°	37.2°	37.4°	37.7°	36.1°	35.9°
Time (mins.) .....	163	210	22½ hrs.				
$[\alpha]_D$ .....	+30.9°	29.0°	28.8°				

With a similar solution containing, however, 5% of xylose, the following polarimetric figures were recorded :

Time (mins.) .....	20	26	36	52	62	72	112
$[\alpha]_D$ .....	+37.9°	38.6°	38.8°	38.5°	37.5°	37.0°	35.3°
Time (mins.) .....	167	262	397				
$[\alpha]_D$ .....	+33.5°	32.1°	30.3°				
Time (hours) .....	25	50	75				
$[\alpha]_D$ .....	+29.3°	28.5°	28.2°	(Thereafter, apparently constant.)			

The evidence furnished by tests with Fehling's solution, and also by actual isolation of the product, indicated that xyloside formation was far from complete at the end of these periods.

It thus appeared that glucoside formation proceeded very slowly under these conditions, xylose differing markedly in this respect from fructose, galactose, and arabinose. Moreover, the apparent attainment of a constant rotation after 24 hours was deceptive, in that methylxyloside continued to be formed even after 5 days, although the rotation changes were negligible during this extended period.

The following experimental conditions were therefore adopted for the preparation of larger quantities of  $\gamma$ -methylxyloside : Dried, finely-sieved xylose (11.9 g.) was dissolved in 238 g. of pure dry methyl alcohol containing 2.27 g. of hydrogen chloride, making a 5% solution of xylose in methyl alcohol containing 1% of hydrochloric acid. The mixture was kept at room temperature until it no longer reduced Fehling's solution, this stage being reached after 7 days. The product, isolated in the usual manner, was extracted with ethyl acetate, and consisted of a viscid syrup (8 g.) containing 0.7 g. of xylose crystals, which were removed by solution of the syrup in absolute alcohol. Distillation of the syrup was effected without any decomposition, giving rise to a pale yellow, viscid product, b. p. 161.5°/0.03 mm.,  $[\alpha]_D = +62.8^\circ$  in ethyl alcohol [Found : OMe, 18.4.  $C_5H_9O_4(OMe)$  requires OMe, 18.8%].

In another preparation of  $\gamma$ -methylxyloside, 27.5 g. of xylose

gave 20.6 g. of a syrup from which 15.8 g. of the distillate were obtained, the still residue being 3.4 g. In this experiment, the solution ceased to reduce Fehling's solution after 5 days.

*Methylation of  $\gamma$ -Methylxyloside.*—Methylation of this product was carried out with methyl sulphate and sodium hydroxide, care being taken to prevent development of acidity during the operation. The first eighth of each reagent was added at 40°, the second at 55°, and the remainder at the usual temperature of 70°. The quantities used were:  $\gamma$ -methylxyloside, 6.3 g.; methyl sulphate, 16.3 c.c.; sodium hydroxide, 15.5 g. in 31 c.c. of water. This yielded a pale liquid product which was remethylated with methyl iodide and silver oxide. The liquid product weighed 3.5 g. and had b. p. 78°/0.03 mm.,  $n_D = 1.4407$ . A small quantity of crystals was also collected.

The distilled liquid was colourless and immediately reduced neutral permanganate in the cold, but showed no reduction of Fehling's solution even on vigorous boiling [Found: C, 51.35; H, 8.4; OMe, 56.3.  $C_5H_6O(OMe)_4$  requires C, 52.4; H, 8.7; OMe, 60.2%.  $C_5H_7O_2(OMe)_3$  requires C, 50.0; H, 8.3; OMe, 48.3%].

These figures indicated that the xylose compound contained between three and four methoxyl groups.

The material was mixed with a further 11.2 g. which had been methylated to the same stage, and the whole (14.4 g.) was remethylated six times by Purdie's reagents. On distillation the first few drops were rejected, and a yield of 10.05 g. of the main fraction, b. p. 82.5–84.5°/0.03 mm., was obtained. In order to ensure a better fractionation, this product was re-distilled in the vacuum of the water-pump and then had b. p. 110–114°/14 mm. (Found: C, 52.2; H, 8.8; OMe, 59.0.  $C_5H_{18}O_5$  requires C, 52.4; H, 8.7; OMe, 60.2%).  $[\alpha]_D = +32.0^\circ$  in methyl alcohol ( $c = 0.7975$ );  $n_D 1.4387$ .

The sugar derivative was therefore a fully-methylated pentoside, and was essentially trimethyl  $\gamma$ -methylxyloside.

*Preliminary Hydrolysis.*—Preliminary experiments were instituted with the view of determining the ease of hydrolysis of trimethyl  $\gamma$ -methylxyloside with acid of varying dilutions. For this purpose hydrochloric acid (a) *N*/100; (b) *N*/50; (c) *N*/15 was employed at 100° and the following polarimetric data were recorded :

(a) Time (mins.) ...	5	25	55	85	120	150	210	275
$[\alpha]_D$ .....	+37.9°	17.2°	16.3°	19.7°	22.0°	24.1°	28.6°	33.2°
(b) Time (mins.) ...	3	27	57	89	109			
$[\alpha]_D$ .....	+33.9°	18.2°	24.2°	24.2°	26.4°			
(c) Time (mins.) ...	0	30	60	150	240	360		
$[\alpha]_D$ .....	+35.6°	28.8°	34.2°	36.9°	38.3°	37.8°		

To the solution (c) sufficient concentrated hydrochloric acid was added to increase the *N*/15-acid to 1% strength, and this solution was kept at 100° for an hour, after which the specific rotation diminished from +37.8° to 35.1°. By increasing the acid concentration to 5% and boiling the solution for a further period of 1½ hours the rotation fell to +29.9°. It was evident, therefore, that if any of the normal form of trimethyl methylxyloside was present in the original product, this quantity was extremely small, since normal trimethyl xylose has a lower specific rotation ( $[\alpha]_D + 21^\circ$ ) and is formed from its glucoside by hydrolysis with 5% hydrochloric acid at 100°.

*Isolation of Trimethyl  $\gamma$ -Xylose.*—Trimethyl  $\gamma$ -methylxyloside (4.5 g.) was dissolved in 100 c.c of *N*/15-hydrochloric acid and heated under reflux on a boiling-water bath as in the above control experiment. The hydrolysis was arrested after 5 hours, when a constant rotation was reached. The solution was then neutralised with barium carbonate, filtered, and evaporated at 40°/12 mm. to a syrup. This was dissolved in chloroform, filtered from inorganic salt and evaporated, and the residual product (3.8 g.) was distilled.

Fraction 1. B. p. 96.5°/0.06 mm., 1.3 g.,  $n_D = 1.4509$ .

„ 2. B. p. 110°/0.04 mm., 2.3 g.,  $n_D = 1.4539$ .

The first fraction contained some unchanged xyloside, and any of the normal form of trimethyl methylxyloside which might be present would be collected in this fraction of lower boiling point since it would be unaffected by the *N*/15-acid.

The second fraction, consisting of trimethyl  $\gamma$ -xylose (Found: C, 49.5; H, 8.5; OMe, 47.2.  $C_8H_{16}O_5$  requires C, 50.0; H, 8.3; OMe, 48.4%), was a colourless liquid which reduced Fehling's solution very actively, and also neutral permanganate in the cold.  $[\alpha]_D$  in water, +24.7°  $\rightarrow$  29.5° after 40 hours. After catalysis, the final equilibrium value was +31.2°.

*Oxidation of Trimethyl  $\gamma$ -Xylose with Bromine Water. Isolation of Trimethyl  $\gamma$ -Xylonolactone.*—Trimethyl  $\gamma$ -xylose (1.5 g.) was dissolved in 12 c.c. of water, and 1 c.c. of bromine added gradually with shaking. The solution was then heated for 6½ hours at 30–35°. After keeping in the cold for 60 hours, it slightly reduced Fehling's solution. A further ½ c.c. of bromine was accordingly added and the oxidation completed by again heating for 9 hours at 35–40° and keeping over-night at room temperature. Excess of bromine was then removed by aeration, and the solution concentrated under diminished pressure. Hydrobromic acid was removed by the usual treatment, and the solution evaporated at 40°. The residual syrup was dissolved in dry ether and filtered several times

to remove traces of inorganic matter. In this way, 1.3 g. of a pale yellow liquid were obtained, which was submitted to fractionation in a high vacuum. Nearly the whole distilled at about  $105^{\circ}/0.04$  mm., and showed  $n_D$  1.4465 (Found: C, 50.7; H, 7.6; OMe, 47.4. Calc. for  $C_8H_{14}O_5$ , C, 50.5; H, 7.4; OMe, 48.9%).

On titration, the compound behaved as a lactone: 0.1060 g. required, on heating, 5.4 c.c. of  $N/10$ -sodium hydroxide (Calc. for  $C_8H_{14}O_5$ , 5.6 c.c.). The compound behaved in aqueous solution as a typical  $\gamma$ -lactone; there was a slow change in the value of the specific rotation due to the opening of the lactone ring, with formation of an acid of lower rotatory power. The following rotations were observed in aqueous solution ( $c = 1.1062$ ):  $[\alpha]_D + 74.1^{\circ}$  after 5 minutes,  $71.8^{\circ}$  after 64 hours,  $69.6^{\circ}$  after 7 days,  $61.4^{\circ}$  after 21 days.

The experimental evidence stated above has led to the conclusion that the oxidation product was trimethoxy- $\gamma$ -xylonolactone, and a 1:4 or butylene-oxide structure has thus been assigned to the derivatives of  $\gamma$ -xylose.

*Preparation of Trimethyl  $\delta$ -Xylonolactone from the Normal Form of Trimethyl Methylxyloside.*—A simultaneous hydrolysis and oxidation of crystalline trimethyl  $\beta$ -methylxyloside (m. p.  $48-49^{\circ}$ ) was carried out as follows (compare Pryde, Hirst, and Humphries, J., 1925, 127, 348): A solution of the normal form of the xyloside (1.5 g.) in 16.6 c.c. of 3% aqueous hydrobromic acid was heated at  $85^{\circ}$  for an hour and cooled to  $75^{\circ}$ . Bromine was then added (0.7 c.c.) over a period of 4 hours at the rate of 7 drops every half-hour. The solution stood at room temperature for 24 hours and then a further 1 c.c. of bromine was added at  $75^{\circ}$  over a period of 4 hours at the rate of 10 drops every half-hour. The liquid still reduced Fehling's solution after cooling and keeping over-night. More bromine (0.5 c.c.) was introduced over a period of 6 hours at the same temperature as before. On keeping over-night, the oxidation was found to be complete, and the product was isolated in the usual way. The yellow liquid thus obtained (1.13 g.) crystallised on the addition of ether. It was considered advisable, however, to distil the product in order to decompose any free acid that might be present. The product having been heated on a bath at  $100-110^{\circ}/0.05$  mm. for  $1\frac{1}{2}$  hours, the bath temperature was raised to  $145-150^{\circ}$ ; the product then distilled smoothly at  $115-120^{\circ}/0.05$  mm. as a colourless liquid which solidified, and the crystalline mass was drained on porous tile (m. p.  $52-53^{\circ}$ ). It recrystallised from light petroleum (sparingly soluble) in very long needles melting sharply at  $55^{\circ}$ . A further recrystallisation produced no change in the melting point. The recrystallised material resembled glass wool in appearance,

and analysis proved it to be trimethoxyxylonolactone, which must be the  $\delta$ -lactone, since the normal trimethyl xylose gives rise on oxidation to trimethoxyglutaric acid (Hirst and Purves, *loc. cit.*) (Found: C, 50.8; H, 7.5; OMe, 48.9. Calc. for  $C_8H_{14}O_5$ , C, 50.5; H, 7.4; OMe, 48.9%). On titration the compound behaved as a lactone: 0.1025 g. required, on heating, 5.15 c.c. of  $N/10$ -sodium hydroxide (Calc. for  $C_8H_{14}O_5$ , 5.39 c.c.). The hydrolysis of the lactone in aqueous solution at room temperature ( $c = 1.3289$ ) was followed polarimetrically:  $[\alpha]_D^{25} - 3.8^\circ$  after 4 minutes,  $+ 2.3^\circ$  after  $1\frac{1}{2}$  hours,  $+ 3.0^\circ$  4 hrs.,  $+ 6.9^\circ$  23 hrs.,  $+ 15.8^\circ$  4 days,  $+ 19.5^\circ$  6 days,  $+ 20.8^\circ$  8 days.

The authors express their gratitude to the Department of Scientific and Industrial Research for a maintenance grant to one of them.

## CXXII.—*Termolecular Reactions. Reduction of Silver Acetate by Sodium Formate.*

By ALEXANDER COUTIE.

IN a recent investigation of the reaction occurring between formaldehyde and bases, the author had occasion to make use of various velocity equations, in an attempt to settle the order of reaction. A comparison of the formulæ employed by other experimenters, working along similar lines, showed that in many cases these were in error. This can best be explained by reference to the fundamental differential equation, which is readily arrived at in the following way.

Multimolecular chemical reactions are of two types. The first class consists of those in which the participation of one molecule of each of  $n$  different substances, all originally of the same molar concentration, is necessary and sufficient for the occurrence of the change. The differential equation assumes the form

$$-dC/dt = kC^n \quad (1)$$

(All concentrations in this section may be taken as measured in g.-mols. per litre.) The other class is much more general, and includes those reactions in which the  $n$  molecules, taking part in the change, are not all different. If  $m_1$  molecules of substance A,

reacting with initial concentration  $C_1$ , disappear for every  $m_2$  molecules of substance B—of original concentration  $C_2$ —and so on

$$-dC/dt = kC_1^{m_1}C_2^{m_2}C_3^{m_3} \dots \quad (2)$$

where  $m_1 + m_2 + m_3 + \dots = n$ .

This equation can be put in a more useful form. If several substances A, B, C, . . . , with initial concentrations  $a, b, c, \dots$ , take part in a simple reaction, undisturbed by any simultaneous or secondary changes, and if  $l, m, n, \dots$  are the numbers of molecules of A, B, C, . . . which must react simultaneously before the change considered can take place, then, when  $x$  is the actual fall in concentration, in time  $t$ , of a substance of which only one molecule is necessary for the progress of the reaction,

$$dx/dt = k(a - lx)^l (b - mx)^m (c - nx)^n \dots \quad (3)$$

the number of factors being equal to the number of different substances taking part in the reaction. A similar equation has been given by Wegscheider (*Z. physikal. Chem.*, 1900, 35, 513).

From this general equation can be deduced all the ordinary unimolecular, bimolecular, etc., velocity formulæ, but in certain cases it leads to forms at variance with those already mentioned as being employed by a number of investigators. The disputed equations refer to reactions in which two or more molecules of at least one of the substances present are necessary for the progress of the change, i.e., when one or more of the quantities  $l, m, n, \dots$  in equation (3) is greater than unity. Applied to termolecular reactions of this type, as being those with which the author was chiefly concerned, the general equation gives the following formulæ.

*Termolecular.*—When a change takes place involving the interaction of three molecules of A, the sole reactant present, equation (3) reduces to

$$dx/dt = k(a - 3x)^3 \quad (4)$$

but when two molecular species A and B take part—their initial concentrations being  $a$  and  $b$ , respectively—and two molecules of B react with one of A, then

$$dx/dt = k(a - x)(b - 2x)^2 \quad (5)$$

In a formula such as (4)—where  $a$  is the total initial concentration of the reactant of which three molecules take part in the change, and  $x$  is the reduction in concentration, in time  $t$ , due to *each* molecule reacting—it is quite allowable, if absolute values of the velocity coefficient are not required, to make the substitution  $x_1 = 3x$ , whence

$$[dx_1/dt = k_1(a - x_1)^3 \quad (6)$$

and  $k_1 = 3k$ . It is obviously not justifiable to make such a substitution in one term of a differential equation and not in another. For example, the values of  $k$  obtained from equation (5) are not constant multiples of those derived from the form

$$dx/dt = k(a - x)(b - x)^2 \quad (7)$$

It is in this virtual neglect of the coefficients of  $x$  that the experimenters already referred to were in error.

For instance, Noyes and Cottle (*Z. physikal. Chem.*, 1898, 27, 579; *J. Amer. Chem. Soc.*, 1899, 21, 250) employ formula (7) in their study of the reaction between silver acetate and sodium formate, which may be represented by the equation

They state that in this formula  $a$  and  $b$  are the initial concentrations of sodium formate and silver acetate, respectively, and  $x$  the measured fall in concentration of the latter substance. Although the concentration of the silver acetate falls at twice the rate of that of the sodium formate, their formula does not show this. Moreover, their formula is restricted in its application when  $a$  is less than  $b$ , in which case it can only be employed as long as  $x$  is less than  $a$ , i.e., during the first half of an experiment. Noyes and Cottle continued their work past the point of half-decomposition in all experiments except, unfortunately, those to which this applies. The formula which they should have used is evidently

$$dx/dt = k(a - x/2)(b - x)^2 \quad (8)$$

This is identical in form with equation (5).

The use of erroneous formulæ of the above type by several workers is possibly due to their having accepted without question or appropriate modification those given by Ostwald ("*Lehrbuch der allgemeinen Chemie*," 1887, II, 615—634) and integrated by Fuhrmann (*Z. physikal. Chem.*, 1889, 4, 89), which are all of a simple and straightforward nature.

#### *Reduction of Silver Acetate by Sodium Formate.*

Since the days of van 't Hoff it has been recognised that reactions of order higher than the second are few in number, and certain examples brought forward from time to time have been severely criticised and shown to afford little or no evidence in favour of such changes. A reaction frequently quoted as being one of the most thoroughly investigated and typical examples of a termolecular transformation, and one which has never been seriously called in question, is that under discussion.

In their investigation of this reaction Noyes and Cottle (*loc. cit.*)

obtained velocity coefficients by the use of an erroneous formula (compare previous page).

Substitution of their data in the correct equation gives values which are far from constant, as can be seen from the following example.

$$a = [\text{H}\cdot\text{CO}_2\text{Na}] = 0.050 \text{ N}; \quad b = [\text{CH}_3\cdot\text{CO}_2\text{Ag}] = 0.100 \text{ N}.$$

<i>t</i> (mins.).	<i>b</i> - <i>x</i> .	<i>k</i> <sub>2</sub> (Noyes and Cottle).	<i>k</i> <sub>2</sub> (corrected).
2	0.08103	30.0	26.2
4	0.07180	30.2	23.5
7	0.06395	21.2	20.6
11	0.05920	29.7	16.9
16	0.05625	28.0	13.5

These facts suggested inaccuracy in their experimental work, which, although correct in outline, may be criticised on one or two points.

To begin with a matter of minor importance, the temperature at which they carried out their experiments was the boiling point of water under the atmospheric pressure, and although, owing to the short duration of a single experiment, the error thus introduced would not be appreciable except in the comparison of the velocity coefficients of the various experiments, yet an ordinary change in pressure might result in an error of 10% in the coefficients.

Whilst excessively slow reactions cannot be relied on to give satisfactory results, it must also be recognised that very quick reactions are subject to great experimental error. There was no need for these investigators to perform their experiments at 100°, with consequent times of half-decomposition of the order of a few minutes; a temperature of 75° gives a velocity at once convenient from the point of view of the time required and capable of accurate measurement.

The method of titration employed by Noyes and Cottle is liable to slight inaccuracy on account of difficulties in the quantitative filtration of the finely-divided suspension resulting from the addition of the reaction mixture to the thiocyanate solution. The author considers that the error thus introduced may account, at least in part, for the apparently abnormal data obtained by these investigators.

It need scarcely be emphasised that their experiments afford absolutely no proof that the reaction is of the third order.

#### *Re-investigation of the Reaction.*

The procedure was as follows. Solutions of the two salts at the same temperature ( $74.97^\circ \pm 0.02^\circ$ ) were rapidly mixed in such proportions that the resulting solution was of a known concentration with regard to each. One solution was placed in a boiling tube,

*A*, which was fitted with a syphon tube, leading to the bottom of a similar vessel, *B*, containing the other solution, and also with an inlet tube through which air could be passed to force the liquid from *A* into *B*. The apparatus was standardised in order to allow for the small quantity of solution unavoidably remaining in vessel *A* and in the syphon tube. At a definite time after the two had been mixed and thoroughly agitated by a current of air, an analysis sample of about 10 c.c. was withdrawn, and rapidly cooled in ice. As it was essential to remove the insoluble products of reduction before titration, a very small filter-paper was well washed with 2 c.c. of the cooled solution and the remainder was filtered through it. Attention to the size of paper and the preliminary washing was necessary to reduce the loss due to adsorption of silver salt during filtration. 5 C.c. of the filtered solution were titrated with potassium thiocyanate, ferric alum being used as indicator, the accuracy being 0.02 c.c. Consideration was given to various possible sources of error, such as the colloidal products of reduction not retained by the filter and dissolved by the nitric acid in the indicator solution, and the change in normality of the solutions on heating to 75°.

Silver acetate and sodium formate give alkaline solutions, and as the change to an acid reaction, which takes place during the course of an experiment, might have introduced disturbances, experiments were performed in which varying amounts of acetic acid were added initially. Since the results with and without acid were sensibly the same, this precaution was not considered essential.

The tables of results give the velocity coefficients calculated from the correct formula in the column headed *k* (correct), and, for comparison, those obtained by the use of Noyes and Cottle's formula under the heading *k*(N. and C.). The correct formula,  $\frac{dx}{dt} = k(a - x/2)(b - x)^2$ , where *a* and *b* are the total initial normalities of sodium formate and silver acetate, respectively, and *x* is the fall in normality of silver acetate in time *t*, gives on integration

$$k = \frac{2}{(2a - b)^2 t} \left\{ \frac{(2a - b)x}{b(b - x)} + \log_e \frac{2a(b - x)}{b(2a - x)} \right\},$$

while Noyes and Cottle's equation  $\frac{dx}{dt} = k(a - x)(b - x)^2$ , where *a*, *b* and *x* have the same significance as above, gives

$$k = \frac{1}{(a - b)^2 t} \left\{ \frac{(a - b)x}{b(b - x)} + \log_e \frac{a(b - x)}{b(a - x)} \right\}.$$

The values of *x* given are calculated from the mean titration figures of from three to six experiments for each concentration. The accuracy obtained can best be shown by comparing the figures

for a single concentration:  $t$  is the time in minutes,  $s$  the values (c.c.) from a single experiment, and  $r$  the average of three experiments.

$t$ .....	20	40	70	100	160	240
$s$ .....	8.98	7.19	5.58	4.55	3.28	2.37
$r$ .....	8.97	7.19	5.59	4.56	3.28	2.41

### Tables of Results.

$$a = 0.100; b = 0.050.$$

$t$ (mins.).	$x$ .	$k$ (corr.).	$k$ (N. and C.).	$t$ (mins.).	$x$ .	$k$ (corr.).	$k$ (N. and C.).
20	0.0218	8.28	8.92	100	0.0395	8.84	10.81
40	0.0299	8.26	9.32	160	0.0433	9.79	12.55
60	0.0344	8.36	9.75	240	0.0460	11.94	15.98

The initial concentrations and the ranges of  $k$  (corr.) and  $k$  (N. and C.) in three similar experiments were:

$a = 0.050,$	$b = 0.050,$	$k$ (corr.) = 8.45—10.25,	$k$ (N. and C.) = 9.40—21.77
0.050,	0.025,	9.49—11.46,	9.75—13.73
0.025,	0.050,	8.61—9.48,	9.64—32.52*

\* These figures refer only to the first half of the reaction, as Noyes and Cottle's formula cannot be applied after the point of half-decomposition (compare p. 889).

Values calculated from the bimolecular formula are in all cases far from constant.

The following table gives the velocity coefficients, calculated from the correct formula, corresponding to the times of half-decomposition.

$a$ .....	0.100	0.050	0.050	0.025
$b$ .....	0.050	0.050	0.025	0.050
$k$ .....	8.3	8.5	9.7	9.4

These figures indicate that, whilst the reduction of a silver salt in dilute solution by a formate is not a rigid termolecular reaction, yet, both from the point of view of the constancy of the values in any one experiment and from the slight variation in the magnitude of the constant with change in initial concentration of the reactants, it appears that the reaction is essentially one of the third order.

### Summary.

The correct velocity equation has been deduced for those termolecular reactions in which two molecules of one of the reactants take part in the change.

Definite proof has been advanced that the reduction of silver acetate by sodium formate is essentially a reaction of the third order.

The author wishes to express his indebtedness to Professor Sir James Walker for the interest he has taken in this work and for much helpful criticism and advice.

UNIVERSITY OF EDINBURGH.

[Received, January 27th, 1926.]

### CXXIII.—*The Relative Concentrations of Various Electrolytes required to salt out Soap Solutions.*

By JAMES WILLIAM MCBAIN and ALBERT VINCENT PITZER.

IN a series of papers from this laboratory on the soap-boiling processes, it has been shown that there is a remarkable family likeness between the various soaps, whether pure, mixed or commercial, and that they differ in degree rather than in kind (McBain and Burnett, J., 1922, 121, 1320; McBain and Langdon, J., 1925, 127, 852; McBain and Elford, this vol., p. 421; McBain and Walls, *Fourth Report on Colloid Chemistry of the Brit. Asscn. for the Advancement of Science*, 1922, 244; McBain, Chap. in Vol. I of J. Alexander's forthcoming treatise on Colloids).

It has been shown that the phase-rule equilibria for each soap or mixture of soaps are affected in the same way by various salts; so that numerical ratios exist between the concentrations of individual salts required to produce the same effect upon any soap. Further, the effects in a mixture of electrolytes are additive. Likewise, the behaviour of a mixture of soaps seems to be approximately that expected from their respective constituents, apart from formation of curd or crystals.

Hence in order to be able to predict the concentration of any salt, or mixture of salts, required to obtain a specified equilibrium in any soap or mixture of soaps, two things are necessary. First, sufficient points must be established for the phase-rule diagram of each pure soap, using any one salt. Second, the numerical ratios between the concentrations of various salts required to produce a given salting out must be established with one concentration of any one soap. It is the object of the present communication to obtain the numerical ratios between various salts, using in every case 0.25*N*<sub>∞</sub> (weight normal)-sodium palmitate and making the definite comparison at 90°.

#### EXPERIMENTAL.

The method used has been sufficiently described in the papers previously mentioned. It depends on the separation of two isotropic liquid layers from one homogeneous liquid on gradual cooling from high temperatures.

0.25 $N_w$ -Sodium palmitate solutions were sealed up in strong glass tubes with various weights of specimens of the purest salts obtainable, and heated (in many cases far above the boiling point) until the contents of the tube were seen to be clear and perfectly homogeneous. They were then cooled slowly in a bath of glycerol until separation occurred. The experiments were carried out at different times during the past 5 years by C. S. Adams, L. S. Staddon, and the authors, with different samples of sodium palmitate, but the whole work was repeated this year by one of us (A. V. P.), using three different specimens of soap.

The results are in the following tables, all the qualitative observations of appearance, etc., being suppressed for lack of space.

Concentrations are given in every case in weight normality ( $N_w$ ) defined here as g.-mols. (not equivalents) per 1000 g. of water. The data are also given in g. per 100 g. of total system.

Table I gives results obtained with a sample (a) of ordinary sodium palmitate obtained from Messrs. Kahlbaum in March, 1925. It was shown to be the sodium salt of a mixture of fatty acids of mean molecular weight about half-way between palmitic and stearic.

Table II gives results obtained with a sample (b) of pure sodium palmitate specially prepared by Messrs. Kahlbaum in September, 1925. Analysis showed it to contain 0.0081 equivalent excess alkali per mol.

Table III gives results (c) obtained by making up the systems with palmitic acid "Kahlbaum" and sodium hydroxide solutions, by the method of Bunbury and Martin (J., 1914, 105, 417).

Table IV compares the concentrations of the various salts in mols. and in % by weight required to salt out at 90°, sodium chloride being taken as standard=1.00.

(a) = March sample of sodium palmitate (impure).

(b) = September sample of sodium palmitate (pure).

(c) = Sodium palmitate prepared from palmitic acid "Kahlbaum" and sodium hydroxide.

\* Sodium fluoride also was tested, but it was not sufficiently soluble to salt out the palmitate at  $90^\circ$ .

The electrolytes used, with the exception of sodium thiocyanate, were dried by heating at  $120$ — $130^\circ$ . The sodium thiocyanate was dried to constant weight in a vacuum over calcium chloride at room temperature.

All our numerical results are summarised in Table IV, showing the absolute and relative amounts of the various electrolytes required to salt out sodium palmitate at  $90^\circ$ .

The only published data of sufficient accuracy by which to check our results are those from the Karlsruhe laboratory, which are based upon ratios obtained by Richert (*Dissert.*, Karlsruhe, 1911) for carbonate and hydroxide. He found, for various soaps, that 1.01 mols. of carbonate and 1.27 equivalents of hydroxide had the same effect as 1 equivalent of sodium chloride, whereas we have found 0.93 and 1.19, respectively. The divergence from our results amounts to about 6%.

To show the effect of temperature upon the various electrolytes the results have been plotted in Fig. 1. The figure shows that the ratios are not quite constant and independent of temperature, although the deviation does not exceed about 6%. This gives a second measure of the extent to which these data are generally valid, and they are borne out by an analysis of our unpublished data on commercial oils and fats as well as other results from the Karlsruhe laboratory and also the well-known data of Merklen.

An immense amount of information can be derived from these approximate numerical ratios which enables prediction to be made, well within 10%, of the maximum concentration of salts which

FIG. 1.

*Concentrations of electrolytes required to salt out 0.25N<sub>w</sub>-sodium palmitate.*

*(The crosses indicate results obtained with solutions made up from palmitic acid "Kahlbaum.")*

may be added to any soap solution without salting it out. They enable all the complicated mixtures used in commercial soap boiling to be reduced to a common basis for comparison and control. Taken in conjunction with the equilibrium diagrams now becoming available for pure and commercial soaps, whether derived from sodium or potassium, they facilitate the approximate prediction of the concentration of any mixture of electrolytes required to produce a given effect.

Perhaps the most unexpected feature of Table IV is that, as a first approximation, the salts do not replace each other equivalent for equivalent, but rather mol. for mol. irrespective of their valency. For example, sodium thiocyanate comes, in this respect, between sodium sulphate and sodium tungstate; and one mol. of sodium carbonate exactly replaces one equivalent of acetate or iodide.

The results here discussed bear no relation whatsoever to the

Hoffmeister series, as may be seen from the order of the electrolytes in Table IV. Equally, the results are at variance with what might have been expected from the equation of the Donnan equilibrium, since here the order of the electrolytes is irrespective of their valency.

The most comparable factor common to all the salts seems to be the concentration of the sodium ion. Although no data are available for the actual mixtures in the soap solutions, yet this point may be brought out from an examination of such conductivity data for aqueous solutions of pure electrolytes as are given in Landolt-Börnstein-Roth's "Tabellen." The concentration of the sodium ion for all the electrolytes except the acetate, thiocyanate, carbonate, tartrate, and hydroxide is almost exactly two-thirds normal, whereas for these five cases it is  $0.5N_w$ ,  $0.54N_w$ ,  $0.58N_w$ ,  $0.76N_w$ , and  $0.8N_w$ , respectively. It is clear, therefore, that the equilibria are not exclusively determined by the degree of dissociation into sodium ion, although this is predominant. Matters are not improved by an attempt to substitute for concentration of sodium ion, its activity. The data are available for the chloride and hydroxide and the activities are proportional to the total concentrations required to produce the same effect, whereas they should have been inversely proportional, thus revealing a discrepancy of about 40%.

#### *Summary.*

1. Measurements have been made of the relative salting-out action of eleven different electrolytes on soap solutions.

2. With the aid of numerical ratios derived therefrom it is possible to compare, predict, and control all the various equilibria obtained with pure and commercial soaps with any mixture of electrolytes to within an accuracy of about 5 to 10%.

[Received, January 25th, 1926.]

### CXXIV.—*Hydrofluozirconic Acid and the Analysis of Zirconium Fluoride.*

By EDMUND BRYDGES RUDHALL PRIDEAUX and EDWIN CLAXTON ROPER.

THIS investigation was undertaken with the object of verifying, or disproving, the existence of an acid fluoride of zirconium, or a hydrofluozirconic acid. Preliminary work on the ordinary hydrated fluoride led to results which do not altogether agree with those previously recorded. These previous results, so far as they are

relevant, may be summarised as follows. The evaporation of a solution of zirconium dioxide in hydrofluoric acid yields triclinic tablets, which, when dried to constant weight in air, consist of the trihydrate,  $\text{ZrF}_4 \cdot 3\text{H}_2\text{O}$  (Chauvenet, *Compt. rend.*, 1917, **164**, 727). This compound begins to be dehydrated at  $100^\circ$ ; at  $140^\circ$  it loses 2 mols. of hydrogen fluoride, giving the dihydrate  $\text{ZrOF}_2 \cdot 2\text{H}_2\text{O}$ , and above  $140^\circ$  it becomes converted into  $\text{ZrOF}_2$ . In the cold, this absorbs hydrogen fluoride, giving the monohydrate or  $\text{ZrOF}_2 \cdot 2\text{HF}$ . A solution of the latter in water slowly deposits a substance which, when dried to constant weight, has the composition  $\text{ZrOF}_2 \cdot 2\text{H}_2\text{O}$ , and at  $120^\circ$  is converted into  $\text{ZrOF}_2$ .

Our experience supplements, and leads us to criticise, these results. Evaporation of solutions containing fluorides of zirconium yields only powders of indefinite composition, unless the evaporation is carried out at the ordinary temperature and under reduced pressure. The large crystals thus obtained cannot be dried in air to constant weight without decomposition of the surface layer, since they continually give off hydrogen fluoride. They must therefore be dried quickly and kept enclosed in waxed tubes. Compounds intermediate between the trihydrate and the oxyfluoride may exist, but the isolation of these would require a careful study of the partial pressures of hydrofluoric acid and water. Compounds of constant composition are not likely to be isolated simply by drying or heating to constant weight in contact with the atmosphere. The oxyfluoride is not obtained by heating the trihydrate in air above  $140^\circ$  for any reasonable time; the weight may become constant, but is greater than is required for this compound (*vide infra*). Further, it cannot be considered that the composition of any of these compounds is established by means of the zirconia content alone. There is no evidence in the work of Chauvenet (*loc. cit.*) that any analysis has been attempted beyond the obvious and comparatively easy estimation of zirconia. We have found that none of the methods of estimating hydrogen fluoride was satisfactory in the presence of dissolved zirconium compounds. It has been necessary to devise a new method, which was first tested with potassium hydrogen fluoride and then applied to the best authenticated compound,  $\text{ZrF}_4 \cdot 3\text{H}_2\text{O}$ . This compound, crystallised under the conditions mentioned above, appears as transparent or translucent, polygonal plates, the sides of which contain characteristic angles,  $109^\circ$ ,  $113^\circ$ ,  $121^\circ$ ,  $126^\circ \pm 1^\circ$ .

*Analysis.*—The calcination of this compound to oxyfluoride, with subsequent ignition to dioxide, requires some care, since a part may sublime, if it is heated too rapidly, either as the oxyfluoride or the tetrafluoride. After being gently heated in a covered crucible,

it was converted into the sulphate and then ignited to constant weight. Freshly-prepared crystals gave, as the mean of five analyses, 36.3% Zr, the extreme values being 34.4 and 38.0%. They thus appear to be more highly hydrated than the trihydrate, which requires 41.0%, or even than the tetrahydrate, which would require 38.0% Zr. Later preparations agreed more closely with the composition of the trihydrate. The necessity for determining another constituent was evident, and an apparatus was constructed in which the hydrogen fluoride could be volatilised. This consisted of a copper tube having an internal diameter of about  $\frac{1}{2}$  inch, which was cut with a special reamer and ground to fit a conical platinum stopper. This was continued as a platinum delivery tube which dipped in standard alkali. The platinum boat containing the compound to be analysed was placed in the copper tube close to, and partly entering, the platinum stopper. A current of dry air, or, in later experiments, superheated steam, was passed through the tube. The hydrofluoric acid evolved was absorbed in the alkali without loss, as was proved by analyses of potassium hydrogen fluoride.

*Results of Analysis.*—Samples A and B were prepared at different times but had the same composition. The rest were all taken from one preparation. A was first heated in air, the rest in steam. The relatively small amount of hydrogen fluoride which can be obtained by heating in air is noteworthy. The manner in which hydrolysis proceeds during the heating was determined by weighing the residues and titrating the hydrofluoric acid at various stages. When the compound was heated in dry air it lost hydrogen fluoride, which was formed by hydrolysis with the contained water, and also some of this water. The residue, when heated in undried air, lost no appreciable weight but gave off more hydrogen fluoride. In this case, more of the fluoride must have been hydrolysed, but by external water, some of which was retained :  $\text{ZrF}_4 + \text{H}_2\text{O} = \text{Zr}(\text{OH})\text{F}_3 + \text{HF}$ .

A portion of the residue was ignited to dioxide as described above. The hydrogen fluoride driven off by this operation may be calculated on the assumption that the compound is hydrolysed (a) by its own water, or (b) by external water. These two estimates, when added to the hydrofluoric acid titrated, furnish the two values in the last line of the table. The uncertainty arises from the fact that it is not possible, by the strongest heating which the apparatus permitted (between 300° and 400°) in a current of air, to drive off all combined hydrogen and to convert all the compound into  $\text{ZrOF}_2$ . The ratio of the weight of zirconia to that of the product heated in the tube was 0.77 instead of  $0.8473 = \text{ZrO}_2/\text{ZrOF}_2$ . When steam was used the hydrolysis was more complete. Sample C lost both hydrogen fluoride and water, the ratio of ignited zirconia to steam-

heated product being now 0.823. In the case of sample D, the ratio was 0.836. The percentages of hydrogen fluoride will accordingly be nearer to the higher value in the table. In order to obtain a direct titration of still more hydrofluoric acid, we arranged to hydrolyse at a higher temperature. A small platinum tube, closed at one end by a cap of platinum foil, was placed inside the platinum delivery tube, which was heated to bright redness in a current of superheated steam. Samples B and F were analysed by this method. Sample B yielded 34.0% of hydrogen fluoride when heated in steam below a red heat and a further 3.48% when heated to a bright red heat. The weight of the residue showed that it had been almost completely hydrolysed to oxide. In calculating the results, the quantities of zirconia and hydrogen fluoride were added together, and the water was obtained by difference.

	A.	B.	C.	D.	E.	F.
% $\text{ZrO}_2$ .....	58.8	57.6	53.9	54.0	(54)	(54)
% HF (titrated) .....	8.2	37.5	19.8	22.3	31.2	31.1
% HF total	25.7-	—	30.5-	32.9-	—	—
(estimated) .....	37.8	37.5	39	41.5	—	—

The weighted mean of the zirconia in A and B is 58.5, the hydrogen fluoride is 37.5, the water 4.0; the composition therefore corresponds to  $\text{ZrF}_4 \cdot 2.45\text{H}_2\text{O}$ . The preparation containing 54% of zirconia contains at least 31% of hydrogen fluoride in C and more than 33% in D. We estimate it at 35%, for the reason mentioned on previous page. The water will therefore be 11.0, corresponding to  $\text{ZrF}_4 \cdot 3.4\text{H}_2\text{O}$ . Thus the crystals do contain the tetrafluoride, but the water of crystallisation is proved to be variable.

*The Acid Fluoride.*—Numerous double fluorides have been prepared such as  $2\text{NH}_4\text{F} \cdot \text{ZrF}_4$ ;  $3\text{NH}_4\text{F} \cdot \text{ZrF}_4$ ;  $\text{KF} \cdot \text{ZrF}_4 \cdot \text{H}_2\text{O}$ ;  $2\text{KF} \cdot \text{ZrF}_4$  (Marignac, *Ann. Chim. Phys.*, 1860, 60, 271); also  $2\text{NaF} \cdot \text{ZrF}_4$  (Wells and Foote, *Amer. J. Sci.*, 1866, 3, 466). The salt  $2\text{KF} \cdot \text{ZrF}_4$  is one of the easiest to prepare, yet even in this case a slight excess of potassium fluoride produces  $3\text{KF} \cdot \text{ZrF}_4$ . The free acid might correspond to any of these salts. An acid salt is said to be deposited on rubbing the walls of a vessel containing a solution of zirconia in hydrofluoric acid (Fischer and Thiele, *Z. anorg. Chem.*, 1910, 67, 309). This dissolved readily in water, but with difficulty in concentrated hydrofluoric acid. When treated with lead carbonate, it gave a soluble lead salt which was believed to be  $\text{PbZrF}_6$ . Some soluble lead salt is certainly formed when lead carbonate is added to any solution containing zirconium fluoride, for, after removal of the lead fluoride by filtration, more lead may be precipitated from the filtrate by means of hydrogen sulphide, and the second filtrate contains both zirconium and fluorine.

A hydrofluozirconic acid is also said to be produced when hydrogen fluoride is absorbed by zirconium tetrafluoride (Chauvenet, *loc. cit.*). The isolation of an acid by either of these methods would appear to be difficult. We consider that the only method which offers any reasonable chance of success is to add much anhydrous hydrogen fluoride to a little zirconium fluoride which is already in solution.

*Preparation.*—The anhydrous acid, prepared by distilling dry sodium hydrogen fluoride in a copper still, was condensed in a platinum bottle or crucible which fitted into a copper receiver. After addition of this to the solution of zirconium fluoride or *vice versa*, a fine, white crystalline solid was usually deposited. This was cooled in a freezing mixture and well stirred. The liquid was then decanted, and the solid washed several times by decantation with dry ether and pressed on filter-paper. This substance has been prepared on five occasions. The appearance of the crystals was always the same, but very different from that of the ordinary fluoride. Under the microscope, they were seen to be of uniform type—long prisms with chisel-shaped ends. On exposure they gave off hydrogen fluoride and became dull on the surface. In a few days the whole crystal became opaque. When they were dissolved in a very little water (in which they are extremely soluble) and treated with a few drops of lead acetate, the liquid remained clear. A drop of hydrofluoric acid produced an immediate turbidity. The hydrofluozirconic acid was therefore not much hydrolysed.

*Analysis of the Acid Fluoride.*—One of the earlier samples, weighed rapidly in a closed platinum crucible with a tightly fitting lid and then converted into zirconia, contained 46.0%  $\text{ZrO}_2$ . In the case of the last sample, we were able to determine the hydrogen fluoride separately as described above, and to follow the course of the decomposition: (1) 0.4603 g. was heated in a current of dry air. The loss was 0.1359 g., of which 0.0772 g. was hydrogen fluoride. (2) The residue, 0.3244 g., was heated in steam. The loss was 0.0379 g., and the hydrogen fluoride 0.03619 g. This is the stage in which the hydrolysis proceeds at the expense of water of crystallisation. (3) A portion, 0.0863 g., of the last residue, when heated in steam to a bright red heat, lost 0.0196 g. The hydrogen fluoride was 0.01962 g. (4) Another portion, 0.0911 g., ignited with sulphuric acid, gave 0.0682 g. of dioxide. All quantities being referred to the original weight, the hydrogen fluoride lost in (3) is 0.0658 g., whilst the total loss in (4) is 0.0720 g. Since steaming at a red heat causes conversion nearly into  $\text{ZrO}_2$  with a little  $\text{ZrOF}_2$ , the final loss,  $0.0720 - 0.0658 = 0.0062$  g., represents hydrogen fluoride produced by the reaction  $\text{ZrOF}_2 + \text{H}_2\text{O} = \text{ZrO}_2 + 2\text{HF}$ , the water being derived from external sources such as the sulphuric acid. This loss must corre-

spond to a weight of hydrogen fluoride =  $40 \times 0.0062/22 = 0.0113$  g. The weight of zirconia calculated on the original weight of compound is 0.215 g., or 46.59%. On heating in dry air, 1 mol. of the compound loses rather more than 2 mols. of hydrogen fluoride and rather less than 2 mols. of water. On heating in steam, it loses rather more than 1 mol. of hydrogen fluoride, and, at a bright red heat, rather less than 2 mols. of the acid.

*Composition of the Acid.*—0.4603 G. gave 0.1792 g. HF (titrated) and 0.0113 g. (deduced from final loss of weight), total 0.1905 g.; and 0.0548 g. of  $H_2O$  (by difference). The simplest formula calculated from these results is  $ZrF_4 \cdot 1.5HF$ ,  $3.74H_2O$ , or  $ZrOF_2 \cdot 3.5HF$ ,  $2.74H_2O$ . On account of the difficulty in avoiding loss of hydrogen fluoride during the weighing, etc., and of the hygroscopic character of the compound, we consider that, as originally precipitated, it would probably contain the extra 0.5 mol. of hydrogen fluoride and 0.75 mol. less water, and that it would be hydrofluozirconic acid corresponding to the best known potassium salt, with the addition of about 3 mols. of water of crystallisation, i.e.,  $H_2ZrF_6 \cdot 3H_2O$ .

One of us (E. C. R.) desires to acknowledge the continuance of a maintenance grant from the Department of Scientific and Industrial Research which enabled this work to be completed. We also desire again to record our indebtedness to the Royal Society for a former grant towards the purchase of apparatus.

UNIVERSITY COLLEGE, NOTTINGHAM. [Received, December 14th. 1925.]

### CXXV.—*The Morphine Group. Part III. The Constitution of Neopine.*

By CONSTANT FREDERIK VAN DUIN, ROBERT ROBINSON, and  
JOHN CHARLES SMITH.

THE rare opium alkaloid which is the subject of this communication was discovered by Messrs. T. and H. Smith of Edinburgh in the final mother-liquors from the isolation of opium alkaloids and separated in the form of its readily crystallisable hydrobromide. Dobbie and Lauder (J., 1911, 99, 34) investigated this salt and the amorphous base which could be obtained from it and concluded that neopine is a hydroxycodine. We found that neopine hydrobromide, for a supply of which we are greatly indebted to Messrs. T. and H. Smith, possessed the properties described by Dobbie and Lauder. The analysis, however, gave the formula  $C_{13}H_{22}O_3NBr$  instead of  $C_{13}H_{22}O_4NBr$  required for a hydroxycodine hydro-

bromide. The free base was obtained in a crystalline condition, m. p. 127.5° (corr.), and was found to have the formula  $C_{18}H_{21}O_3N$ . It appeared to be an isomeride of codeine and this was confirmed by the examination of several derivatives. Moreover, like codeine, neopine contains one methoxyl group, one alcoholic hydroxyl group, and one methyl group attached to nitrogen. The close relation of the base to codeine is brought out in a very clear light by the fact that catalytic hydrogenation of neopine leads to the formation of dihydrocodeine. It will be recalled that the decomposition of codeine methohydroxide leads to the formation of  $\alpha$ -methylmorphimethine, which is changed to an isomeric  $\beta$ -methylmorphimethine by means of boiling alcoholic potassium hydroxide. The decomposition of neopine methohydroxide gives at once pure  $\beta$ -methylmorphimethine. Neopine is thus to be regarded as  $\beta$ -codeine; it stands to codeine in the same relationship that  $\beta$ -methylmorphimethine bears to  $\alpha$ -methylmorphimethine. In Parts I and II of this series (J., 1923, 123, 980, 998) Gulland and Robinson suggested a new formula for codeine, but they modified this expression in a subsequent paper\* (*Mem. Manchester Phil. Soc.*, 1925, 69, No. 10), in that they returned to the view that codeine is an unsaturated substance and put forward the formula (I) as the best representation of the constitution of the base. The corresponding expressions for neopine and  $\beta$ -methylmorphimethine (unchanged from Part I) are (II) and (III), respectively.

\* This paper was read at a meeting of the Manchester Literary and Philosophical Society on February 7th, 1925, and a statement of the proposed change in the morphine formula was given in an abstract in *Nature* (1925, 115, 625). The memoir could be purchased in a separate form in July, 1925. About the same time, Wieland and Kotake (*Annalen*, 1925, 444, 69) emphasised the unsaturated nature of codeine and located the double bond in the new position also adopted by Gulland and Robinson. The above particulars are contributed in order to prove that the suggestions of Gulland and Robinson and of Wieland and Kotake were independent and contemporaneous.

The existence of a  $\beta$ -codeine might be anticipated on the basis of many codeine formulæ, but it should be noted that neopine is less readily oxidised by permanganate and also less readily catalytically hydrogenated than codeine. Any hypothesis, therefore, of the relation of codeine to neopine or of  $\alpha$ - to  $\beta$ -methylnorphimethine which suggests that codeine has a bridge ring that becomes an ethylene linking in neopine is definitely opposed to the facts. The only possible conclusion that can be drawn from the circumstance that neopine is more stable than codeine towards reagents for the ethylene linking is that the latter contains a double bond which moves, in the transformation of  $\alpha$ -methylnorphimethine to the  $\beta$ -isomeride, to a more sheltered position or at least to a position in which it exhibits a smaller degree of reactivity.

#### EXPERIMENTAL.

*Neopine Hydrobromide.*—The substance provided by Messrs. T. and H. Smith was anhydrous and remarkably homogeneous. It darkened from about  $240^\circ$ , became very dark at  $279^\circ$ , blackened at  $281^\circ$ , and melted with decomposition at  $282$ – $283^\circ$  (Found: Br, by titration, 21.1.  $C_{18}H_{22}O_3NBr$  requires Br, 21.0%). The salt was dried at  $100^\circ$  for 5 hours (Found: Br, 21.1%); it was then recrystallised and dried at  $100^\circ$  for 5 hours (Found: Br, 21.1%). The identity of the material with that examined by Dobbie and Lauder (*loc. cit.*) is evident from the determination of the rotatory power. The salt supplied by Messrs. T. and H. Smith dried at  $100^\circ$  for 5 hours had  $[\alpha]_D^{25} + 17.08^\circ$  in aqueous solution ( $c = 5.152$ ). After recrystallisation and drying at  $100^\circ$ , we found  $[\alpha]_D^{25} + 17.32^\circ$  ( $c = 3.696$ ). Dobbie and Lauder found  $[\alpha]_D^{20} + 17.07^\circ$  ( $c = 5.1884$ ) and  $[\alpha]_D^{20} 17.4^\circ$  ( $c = 5.0741$ ).

*Neopine.*—The hydrobromide was dissolved in water, decomposed by the addition of sufficient concentrated aqueous potassium hydroxide to produce an emulsion (the base is rather readily soluble in water), and the neopine thrice extracted with benzene. The benzene solutions were dried with potassium carbonate and evaporated, leaving a soft varnish. This was dried at about  $80^\circ$  and after some hours a crystal nucleus was noticed. On cooling and scratching, the whole varnish crystallised and the crude product had m. p.  $125^\circ$ . The base is best recrystallised from light petroleum (b. p.  $80$ – $100^\circ$ ) and separates in long, glistening, brittle, colourless needles, m. p.  $127$ – $127.5^\circ$  (corr.) (Found in material heated at  $80^\circ$ : C, 72.4; H, 7.1; N, 4.6, 4.7\*, 4.7\*; MeO, 10.5\*, 10.4\*; NMe\*, 5.2;  $M$  in camphor, 288.  $C_{18}H_{21}O_3N$  requires C, 72.2; H, 7.0; N, 4.7; MeO, 10.4; NMe, 5.0%;  $M$ , 299).

\* By micro-methods.

In aqueous solution ( $c = 5.1084$ ) the base is apparently optically inactive ( $D$  line at  $20^\circ$ ), but on the addition of hydrochloric acid (Neop.,  $HCl$  in  $0.397N\text{-}HCl$ ) the value  $[\alpha]_D^{25} + 18.85^\circ$  was observed. In dry chloroform ( $c = 7.4740$ ), we found  $[\alpha]_D^{25} - 28.10^\circ$  for the base. With the Froehde and Mandelin reagent, codeine and neopine give yellow colorations changing to blue; this change appears to be slower in the case of neopine. The alkaloid dissolves in water, and a very dilute solution does not immediately decolorise a drop of dilute aqueous potassium permanganate which is added to it. Under similar conditions, codeine rapidly reduces the oxidising agent.

*Acetylneopine*.—A hydroxycodeine has the same state of oxidation as thebaine, and before we were aware of the true composition of neopine an attempt to degrade it was made under the conditions of the preparation of diacetylthebaol from thebaine, but the result was negative. Neopine (4 g.) was acetylated in 2 hours with boiling acetic anhydride (15 c.c.) in presence of anhydrous sodium acetate (2 g.), and the resulting solution added to water and rendered alkaline by means of sodium carbonate. The base, isolated by means of ether, was obtained as a pale yellow varnish which has not yet been crystallised [Found:  $CH_3\cdot CO$ , 12.7 (by A. G. Perkin's method; J., 1905, 87, 107).  $C_{18}H_{20}O_3N\cdot CO\cdot CH_3$  requires  $CH_3\cdot CO$ , 12.6%]. Acetylneopine combines very readily with methyl iodide in methyl-alcoholic solution; the product crystallises from methyl alcohol in long, glistening needles which probably contain solvent of crystallisation, since they lose their lustre on heating. *Acetylneopine methiodide* darkens at  $250^\circ$  and has m. p.  $256\text{--}257^\circ$  (decomp.; corr.) (Found in material dried at  $95\text{--}100^\circ$  to constant weight: C, 52.4; H, 5.5; I, by titration, 26.15.  $C_{21}H_{26}O_4NI$  requires C, 52.2; H, 5.4; I, 26.3%).

*Catalytic Hydrogenation of Neopine with Formation of Dihydrocodeine*.—The reductions were carried out at the ordinary temperature in a vessel filled with hydrogen and provided with a stirrer. Codeine (5 g.) dissolved in water (50 c.c.) and acetic acid (2 c.c.) absorbed in 25 minutes 385 c.c. of hydrogen in presence of colloidal palladium (from 10 c.c. of 0.5% palladous chloride\*). This was equivalent to 370 c.c. at *N.T.P.* The volume theoretically required for the saturation of one double bond is 375 c.c. The isolated product had at first m. p.  $55^\circ$  and was dried at  $110^\circ$ . It then melted at  $112\text{--}113^\circ$  (corr.) after crystallisation from water containing a few drops of methyl alcohol. This was the highest value that could be obtained. Skita and Frank (*Ber.*, 1911, 44, 2865) gave the m. p.

\* The solution employed in both reductions contained also 0.5% of gum arabic.

of dihydrocodeine as  $65^{\circ}$ , whilst Freund (*J. pr. Chem.*, 1920, **101**, 12) gave  $86-88^{\circ}$ . Oldenburg (D.R.-P. 260,233) also quoted the value  $62-63^{\circ}$ . Mannich and Löwenheim (*Arch. Pharm.*, 1920, **258**, 304) showed that dihydrocodeine with  $2\text{H}_2\text{O}$  melts at  $55^{\circ}$  or  $88^{\circ}$ , whilst the anhydrous substance has m. p.  $111-112^{\circ}$ . Wieland and Koralek (*Annalen*, 1923, **433**, 269) crystallised the base from 80% methyl alcohol, a process which we cannot repeat, and gave the m. p.  $112-114^{\circ}$ .

A solution of neopine (2.5 g.) in water (25 c.c.) and acetic acid (1 c.c.) containing colloidal palladium (5 c.c. of 0.5% palladous chloride) was stirred in hydrogen, when the palladium was at once flocculated. More palladous chloride solution (10 c.c.) was added, but flocculation again occurred. In about 15 hours, 180 c.c. of hydrogen were absorbed (equiv. to 176 c.c. at *N.T.P.*; calc., 185 c.c.). The base was rendered to chloroform from the filtered solution and, after removal of the solvent, the residual oil crystallised when inoculated with dihydrocodeine (variety, m. p.  $55^{\circ}$ ). This material melted at  $51-53^{\circ}$ , but after resolidification it had m. p.  $81-84^{\circ}$  and after drying at  $80^{\circ}$  for 1 hour the m. p. was  $110-111^{\circ}$ . After crystallisation from water containing a few drops of methyl alcohol, the substance dried at  $80^{\circ}$  had m. p.  $112-113^{\circ}$  (corr.) (Found: C, 71.5; H, 7.9. Calc. for  $\text{C}_{18}\text{H}_{23}\text{O}_3\text{N}$ : C, 71.7; H, 7.7%). Approximately equal quantities of dihydrocodeine, m. p.  $112-113^{\circ}$ , and dihydroneopine, m. p.  $112-113^{\circ}$ , were melted together on a watch glass. The mixture rapidly crystallised on cooling and had m. p.  $112-113^{\circ}$ .

*Conversion of Neopine into  $\beta$ -Methylmorphimethine.*—Neopine combined rapidly with methyl sulphate in benzene solution to a *methosulphate*, which separated in a resinous condition. It was very deliquescent and readily soluble in water and on the addition of potassium hydroxide to the solution no precipitation occurred. On boiling, the methine suddenly made its appearance as oily drops, and these crystallised at once even in the hot liquid on the introduction of a crystal of  $\beta$ -methylmorphimethine. We are greatly indebted to Dr. R. S. Cahn for a specimen of pure  $\beta$ -methylmorphimethine. The neopinemethine crystallised from alcohol in large, twinned, rhombohedral prisms, m. p.  $135^{\circ}$ , and at the same temperature when mixed with  $\beta$ -methylmorphimethine. It dissolved in sulphuric acid to a deep crimson solution, which became royal blue on heating and on dilution with water, green and then yellow with an intense green fluorescence. This reaction is characteristic of  $\beta$ -methylmorphimethine.

*Neopinemethine methiodide* was prepared from the methine before the latter had been crystallised. The substance crystallised from

water in glistening needles, m. p.  $291^{\circ}$  (decomp.) after darkening from  $260^{\circ}$  (Found : I, 27.8. Calc., I, 27.9%). Knorr and Smiles (*Ber.*, 1902, 35, 3010) and Knorr and Hawthorne (*Ber.*, 1902, 35, 3012) found that  $\beta$ -methylmorphimethine methiodide had  $[\alpha]_D^{25} + 233^{\circ}$  ( $c = 0.6$ ) in 97% and 90% alcohol. Solutions of neopinemethine methiodide having a similar concentration crystallised on cooling, but we now know that neopinemethine is  $\beta$ -methylmorphimethine in an exceptionally pure condition. We found that neopinemethine methiodide had  $[\alpha]_D^{25} + 241.1^{\circ}$  ( $c = 0.506$ ) in absolute methyl alcohol and  $[\alpha]_D^{25} + 262.0^{\circ}$  ( $c = 0.3$ ) in 90% ethyl alcohol.

We desire to thank the Ramsay Memorial Trust for a Fellowship (Netherlands) which enabled one of us to take part in this investigation, and for a similar reason we are also grateful to the Royal Commissioners of the Exhibition of 1851 for a Scholarship.

## CXXVI.—*The Morphine Group. Part IV. A New Oxidation Product of Codeine.*

By ROBERT SIDNEY CAHN and ROBERT ROBINSON.

THE secondary alcohol codeine can be oxidised to the corresponding ketone by means of chromic acid or of potassium permanganate in acetone solution, and apart from the hydroxycodine which accompanies codeinone in the former case (Ach and Knorr, *Ber.*, 1903, 36, 3067) no other products of direct oxidation of the base have been described. This has perhaps led to the impression that the attack of oxidising agents is invariably on the alcoholic group, although attention has occasionally been directed to the fact that the sensitiveness of codeine to permanganate is greater than that of any known saturated alcohol and strongly suggests the existence of an ethenoid group in the molecule (compare Wieland and Kotake, *Annalen*, 1925, 444, 69; Gulland and Robinson, *Mem. Manchester Phil. Soc.*, 1925, 69, No. 10). The remarkable ease with which codeine may be converted into a dihydro-derivative by catalytic hydrogenation is in harmony with this hypothesis, and we now bring forward further evidence tending in the same direction. The action of potassium permanganate on codeine (I) in very dilute aqueous solution leads to the addition of two hydroxyl groups to the molecule and the product is dihydroxydihydrocodeine (II). This substance yields a basic triacetyl derivative and its form-

ation demonstrates the existence of an ethylenic linking in codeine. The position chosen for the double bond in (I) is that independently

selected by Wieland and Kotake and by Gulland and Robinson for different reasons. It is especially required to explain the codeine- $\psi$ -codeine change (analogy to geraniol-linalool) and the reactivity of the chlorine atom of chlorocodide (analogy to allyl chloride and benzyl chloride). A possible objection (compare Gulland and Robinson, *loc. cit.*) is that  $\psi$ -codeinone reacts with benzaldehyde as if it contained the group  $\cdot\text{CH}_2\cdot\text{CO}\cdot$ , whereas it should contain  $\cdot\text{O}\cdot\text{CH}\cdot\text{CH}\cdot\text{CH}\cdot\text{CO}\cdot$  on the suggested basis. The difficulty is removed by recognising the following system of tautomerides :

which might be equilibrated in presence of alcoholic potassium ethoxide or similar reagents. Although it seems probable that general agreement will soon be reached in regard to the occurrence of the group  $\cdot\text{CH}(\text{OH})\cdot\text{CH}\cdot\text{CH}\cdot$  in codeine and its isomerides, and the morphine problem will be to that extent simplified, there is still room for differences of opinion in regard to the point of attachment of the ethanamine chain. Wieland and Kotake (*loc. cit.*) have noted that some substances which on the basis of (I) should contain the group  $\cdot\text{CH}_2\cdot\text{CO}\cdot\text{CH}_2\cdot$  nevertheless have only one reactive position \* and prefer the formula (III) for codeine.

On the other hand, a consideration of the behaviour of the unsaturated centres in the methylmorphimethines appears to us to provide further evidence favouring the formula (I). If (III) represented codeine, we imagine that  $\beta$ -methylmorphimethine would be

\* The attachment of the ethanamine chain in position 13, as in (I), was not based on the production of dipiperonylidene derivatives of thebainol and dihydrothebainone but on the arguments put forward in Part I of this series, to which, with the modification made in our note in the *Manchester Memoirs*, we adhere.—J. M. G., R. R.

(IV), a naphthalene derivative. That the bond migrating from the position 7—8 should halt in the position 8—14 and not proceed to

13—14, where it assists in the formation of a new aromatic nucleus, seems highly improbable. Now  $\beta$ -methylmorphimethine appears to contain non-aromatic unsaturated centres, since it very readily reduces permanganate, more readily than neopine\* does, and on catalytic hydrogenation gives a 9:10-dihydro-derivative (von Braun, *Festschr. phys. Ver.*, Frankfurt a. M., 1924, Sept.; Cahn, *Dissert.*, Frankfurt, 1925). The formula (I), on the other hand, affords a satisfactory explanation of the relations of codeine, neopine, and  $\alpha$ - and  $\beta$ -methylmorphimethines.

#### EXPERIMENTAL.

*Dihydroxydihydrocodeine* (II).—An aqueous solution of potassium permanganate (332 c.c. of 1%) was added during 1.5—2 hours to a mechanically stirred solution of codeine† (10 g.) in water (1500 c.c.) mixed with ice (500 g.) and cooled in an ice-bath. The manganese dioxide was precipitated from the colloidal solution by passing carbon dioxide for  $\frac{1}{2}$  hour and stirring for a further equal period, and the almost colourless filtered liquid was then concentrated to about 400 c.c. by distillation under diminished pressure. Much frothing and decomposition occurred. By means of ether codeine (1.4—1.6 g.) was extracted from the dark brown solution, which was then concentrated to about 40 c.c. and treated with saturated aqueous potassium carbonate (150 c.c.), a semi-solid, almost black material being precipitated. The mixture was twice extracted with 200 c.c. of chloroform, and the solutions were dried with sodium sulphate and evaporated, leaving 5 g. of an amorphous, hygro-

\*  $\beta$ -Methylmorphimethine is also neopinemethine (Van Duin, Robinson, and Smith, this vol., p. 903).

† A similar experiment was carried out with  $\psi$ -codeine, but necessarily in much more dilute solution owing to the sparing solubility of the base in cold water. A large fraction of the  $\psi$ -codeine was recovered and no other crystalline product was isolated.

scopic, dark brown residue (A), which was taken up in dry ethyl alcohol (15 c.c.). Crystallisation was induced by rubbing and after some hours the crude base (1.2 g. or 11.5%) was collected and twice recrystallised from absolute alcohol (yield 0.6 g.) in colourless, glistening, diamond-shaped plates, m. p. 208—209° (Found in material dried in a vacuum at 100°: C, 64.8; H, 7.0; N, 4.5; MeO, 9.4.  $C_{18}H_{23}O_5N$  requires C, 64.8; H, 7.0; N, 4.2; MeO, 9.3%). This substance is easily soluble in water to strongly alkaline solutions but, when pure, it is not very hygroscopic; it is sparingly soluble in ether and benzene and in cold anhydrous methyl or ethyl alcohol. The base does not exhibit many of the colour reactions characteristic of codeine; with Froehde's reagent, it yields a yellow solution which becomes brown on warming, and with Mandelin's reagent it gives a brown solution which on gently warming becomes light green. Unlike codeine, it is only slowly attacked by potassium permanganate in dilute aqueous solution. The salts of this base, including the methiodide, were not obtained in a crystalline condition. As the substance has the same state of oxidation as codeinone and thebaine, a specimen was submitted to the action of hydrochloric acid under the conditions which are employed for the preparation of thebenine from thebaine, but no change occurred. The low yield of the trihydroxy-base is probably due to side reactions, further oxidation and possibly the production of stereoisomerides.

The *triacetyl* derivative is characteristic and may be most conveniently obtained from the material (A) mentioned above. 3 G. of this, heated with acetic anhydride (30 c.c.) for 75 minutes on the steam-bath, gave a brown solution which was decomposed with water, rendered alkaline by ammonia and extracted with chloroform. After removal of the solvent the residue was dissolved in methyl alcohol (10 c.c.) and the crystals which separated on cooling were collected (0.3 g.) and recrystallised from methyl alcohol in colourless plates, m. p. 200° (Found in material dried at 100° over phosphoric anhydride in a vacuum: C, 62.9; H, 6.6; N, 3.3.  $C_{24}H_{29}O_8N$  requires C, 62.7; H, 6.4; N, 3.1% and  $C_{22}H_{27}O_7N$  requires C, 63.3; H, 6.5; N, 3.4%). As the analytical results were in approximate agreement with the theoretical requirements of the formulæ of both the diacetyl and the triacetyl derivative of the parent base, it was vitally important to estimate the acetyl groups directly. We are greatly indebted to Professor K. Freudenberg and Dr. E. Weber, who have kindly carried out the estimations by a new micro-analytical method (Freudenberg, *Annalen*, 1923, 433, 230; Freudenberg and Weber, *Z. angew. Chem.*, 1925, 38, 280) [Found:  $CH_3CO$ , 27.93, 27.78, 27.87.  $C_{18}H_{20}O_5N(COCH_3)_3$

requires  $\text{CH}_3\cdot\text{CO}$ , 28.09%]. The acetyl groups were somewhat resistant to hydrolysis, and two distillations were necessary; the standard process gave  $\text{CH}_3\cdot\text{CO}$ , 24.6%. This might suggest that one of the acetyl groups is attached to nitrogen, were it not for the fact that the substance is a strong base readily soluble even in dilute acetic acid. A compound identical with the above-described derivative was obtained by acetylation of pure dihydroxydihydrocodeine.

Triacetyldihydroxydihydrocodeine is sparingly soluble in water and in cold methyl alcohol; its *perchlorate* crystallises from water in slender, colourless needles, m. p.  $281^\circ$  with slight previous decomposition.

We are indebted to the Department of Scientific and Industrial Research for grants which have enabled one of us to take part in this investigation.

THE UNIVERSITY, MANCHESTER.

[Received, March 5th, 1926.]

### CXXVII.—*Researches on Residual Affinity and Co-ordination. Part XXVI. A Quadridentate Group in Combination with Bivalent Metals.*

By GILBERT T. MORGAN and J. D. MAIN SMITH.

IN the preceding communication of this series we showed that ethylenediaminobisacetylacetone, first prepared by Combes, furnishes a bivalent quadridentate radical which is capable of behaving as a fourfold associating group in co-ordination compounds of the metals. This fact was demonstrated by a study of the co-ordination compounds of bivalent and trivalent cobalt and the investigation has now been extended to the corresponding derivatives of bivalent copper, nickel, and palladium.

Cupric ethylenediaminobisacetylacetone, prepared originally by Combes (*Compt. rend.*, 1889, 108, 1252), is a well-defined, highly crystalline, dark violet derivative behaving as a non-ionised complex containing one bivalent copper atom in combination with one molecular proportion of the bivalent quadridentate radical. Its constitution may be expressed by formula (I), in which the quadri-

dentate radical is grouped round the metallic atom either tetrahedrally or at four points in one plane. It is, however, not possible

to decide between these possibilities, because in either case the co-ordination complex is unsaturated and readily takes up another associating unit as when the anhydrous violet copper compound absorbs water to pass into its dark green monohydrate (II).

Other addenda can be added in a similar manner to the unsaturated complex, for when Combes's violet compound is dissolved in ethylenediamine hydrate, combination occurs with one molecular proportion of the solvent, giving rise to an analogue (III) of the foregoing aquo-derivative (II).

This ethylenediaminehydrato-compound, when exposed in a desiccator over solid caustic soda or calcium chloride, loses all its water and half of its ethylenediamine, giving rise to the anhydrous ethylenediamine derivative (IV), in which two molecular proportions of Combes's compound are associated with one molecule of ethylenediamine.

It is evident from the existence of these three compounds (II, III, and IV) that one characteristic co-ordination number of copper is 5. This conclusion is borne out by the preparation of a stable light green mono-quinoline derivative of copper acetylacetonate,  $[Cu(C_5H_7O_2)_2, C_9H_7N]$  (V). Similar compounds are obtainable from ammonia and pyridine, but the derivatives of these more volatile bases are unstable, losing their addenda rapidly at the ordinary temperature.

#### *Co-ordination Numbers of Bivalent Copper.*

The literature of copper compounds exhibiting residual affinity is very extensive and furnishes many diverse examples of addenda in these copper derivatives varying in number from 1 to 6, with indications of even higher values. Among the lower values, 2 and 3 stand out prominently and are represented by compounds sufficiently stable and well-defined to warrant the belief that there are copper complexes corresponding with co-ordination numbers 2 and 3. There are also numerous and varied examples among copper compounds of the higher even co-ordination numbers 4 and 6.

The results obtained in this investigation with regard to the formation of complexes with co-ordination number 5 warrant a

reconsideration of the constitutions often accepted for such substances as the following:  $\text{CuCl}_2 \cdot 4\text{NH}_3 \cdot \text{H}_2\text{O}$ ;  $\text{CuBr}_2 \cdot 5\text{NH}_3$ ;  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ ;  $\text{CuSO}_4 \cdot 4\text{NH}_3 \cdot \text{H}_2\text{O}$ ;  $\text{CuSO}_4 \cdot 5\text{NH}_3$  and  $\text{CuSO}_4 \cdot 5\text{NH}_2 \cdot \text{OH}$ .

In formulating these copper salts as co-ordination compounds, at least two alternative views present themselves. The associating units may be grouped exclusively round the metallic atom, giving rise to complex cations of the general type  $[\text{Cu}5\text{X}]^{+}$  or contrariwise one or more molecules of the various addenda may be wholly or partly associated with the anions, which thus become hydrated or ammoniated. If the latter condition could be demonstrated in any of these instances, then the co-ordination number for copper would, in such cases, become less than 5.

There are, however, other less equivocal examples of five associating units round copper in which the metallic atom is no longer in a cation but in an anion such as in pentachlorocupric acid,  $\text{H}_3[\text{CuCl}_5]$  (G. Naumann, *Monatsh.*, 1894, **15**, 489) and in the double nitrites  $\text{K}_2[\text{Cu}(\text{NO}_2)_5]$  and  $\text{Rb}_2[\text{Cu}(\text{NO}_2)_5]$  (Kurtenacker, *Z. anorg. Chem.*, 1913, **82**, 204) and  $\text{Ti}_3[\text{Cu}(\text{NO}_2)_5]$  (Cuttica and Paciello, *Gazzetta*, 1922, **52**, i, 141).

Further evidence on this type of copper co-ordination is now under investigation, particularly in regard to complexes derived from cupric iodide. These results, which indicate a descent from 6 to 5 in the number of associating units round bivalent copper, will shortly be submitted.

### *Electronic Structure of the Bivalent Copper Atom.*

The foregoing evidence, which points to 5 as a characteristic co-ordination number for bivalent copper, has been shown by one of us (J. D. M. S.) to be a consequence of the electronic distribution in atoms first propounded two years ago (Main Smith, *J. Soc. Chem. Ind.*, 1924, **43**, 323). According to this general scheme, which was then applied to all elements, the probable structure of the bivalent cupric ion was shown to be 2, 224, 22445, 000, using ciphers to indicate the vacant sub-groups to be filled by electrons derived from associating units.

Then if, in combination with a quadridentate group, each associating atom of the group contributes two electrons to the three empty electronic sub-groups of the cupric ion, the electronic structure of the co-ordinated atom will be 2, 224, 22445, 224. This arrangement differs from the electronic structure 2, 224, 22446, 224 for the atom of krypton, the inert gas next higher than copper in atomic number, only in a shortage of one electron in the 9th sub-group, and this unsaturated arrangement may be accepted as the electronic structure for the co-ordinated cupric atom with co-ordination

number 4. If this incomplete 9th sub-group could be completed by the addition of a single electron (Main Smith, *J. Soc. Chem. Ind.*, 1925, 44, 944) from the fifth associating unit of a copper co-ordination compound, then the cupric atom of co-ordination number 5 would possess the electronic structure 2, 224, 22446, 224, identical with that of the inert gas krypton.

*Co-ordination Numbers of Bivalent Nickel and Palladium.*

The bivalent quadridentate group from ethylenediaminobisacetylacetone also furnishes well-defined, stable derivatives of bivalent nickel and palladium.

*Nickel ethylenediaminobisacetylacetone* (VI), which melts and even boils without decomposition providing that air is excluded, resembles Combes's copper derivative and is an unsaturated substance forming additive compounds with two molecular proportions of ammonia or with one of ethylenediamine. The latter combination is the more stable of the two, its constitution being indicated by formula (VII).

*Palladous ethylenediaminobisacetylacetone* (VIII) is a fairly stable, non-ionised complex insoluble in water but dissolving in the ordinary organic solvents. From these media it separates with addenda of crystallisation. The dichloroformo-derivative, for example (IX), contains two molecular proportions of solvent.

The foregoing results indicate that nickel and palladium have a co-ordination number 4 in their combinations with the bivalent quadridentate group, but these compounds are unsaturated and take up addenda, suggesting that bivalent nickel and palladium have also the higher co-ordination number 6, displayed, however, in less stable derivatives.

*Electronic Structures of the Bivalent Nickel and Palladium Atoms.*

Nickel and bivalent palladium have yielded simple derivatives with ethylenediaminobisacetylacetone, in which the co-ordination number 4 is apparent as in Combes's simple cupric compound, and they further resemble the latter also in being co-ordinatively unsaturated, yielding addition compounds with various addenda, such as ammonia, ethylenediamine, and chloroform.

According to the general scheme of atomic structure above mentioned, the bivalent nickel atom has the probable electronic structure 2, 224, 22444, 000. If the quadridentate group, as with copper, adds four pairs of electrons to the three empty sub-groups, the electronic structure for the co-ordinated nickel atom will be 2, 224, 22444, 224. This differs from the electronic structure for the atom of the inert gas, krypton, only in a shortage of two electrons in the 9th sub-group, and this unsaturated arrangement may be accepted as the electronic structure for the co-ordinated nickel atom with co-ordination number 4.

The electronic structure of the bivalent palladium atom in the above scheme is 2, 224, 22446, 22444, 000, resembling that of the nickel atom with the interpolation of five sub-groups 22446. If the quadridentate group as before adds four pairs of electrons to the three empty sub-groups, the electronic structure for the palladous atom becomes 2, 224, 22446, 22444, 224. This differs from the structure of the inert gas, xenon, 2, 224, 22446, 22446, 224, only in a shortage of two electrons in the 14th sub-group, and this unsaturated arrangement may be accepted as the electronic structure for the co-ordinated palladous atom with co-ordination number 4.

Both nickel and palladous atoms in combination with the quadridentate group, however, yield addition compounds with two molecules or equivalents of ammonia, chloroform, and anhydrous ethylenediamine, and thus differ from the cupric compounds, which yield addition compounds with only one molecule or equivalent of the addenda. As in the case of copper, the addenda for nickel and bivalent palladium atoms may be regarded as due to the intervention of only one electron per bond, for the addenda are even more feebly attached to the metallic atom than in the case of copper. This conclusion is supported by the very numerous cases of organic and inorganic stable nickel compounds having the co-ordination number 4, which yield much less stable addition compounds having the co-ordination number 6. Typical examples are found in nickel acetylacetonate,  $\text{Ni}\{(\text{OCMe})_2\text{CH}\}_2$ , and nickel tetrammines,  $\text{Ni}(\text{NH}_3)_4\text{X}_2$ , which yield much less stable addition compounds with two molecules or equivalents of water, ammonia or ethylenediamine. If, as suggested, the addenda are held by bonds of only one electron as in the case of copper, the addenda add only two electrons to the 9th sub-group of the nickel structure and two electrons to the 14th sub-group of the palladous structure, thus yielding atomic structures identical in electronic arrangement with those of the inert gases, krypton and xenon, respectively.

These considerations give powerful mutual support to the view that the characteristic co-ordination number is 5 for the cupric

atom, and 6 for the nickel and palladous atoms, and to the above-mentioned scheme of distribution of electrons in atoms and in particular to the electronic structures assigned to the atoms of copper, nickel, and palladium.

*Constitution of Ethylenediamine Hydrate.*

It may be inferred from the knowledge that the co-ordination number of the cupric atom is 5 in addition compounds of cupric complexes with a quadridentate group, that the ethylenediamine hydrate addition compound herein described has the constitution  $\text{ecCuNH}_2 \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{NH}_3 \cdot \text{OH}$ , the ethylenediamine hydrate molecule not being a chelate group and being attached to the cupric atom by only one nitrogen atom, and the molecule of water being in consequence necessarily combined with the other nitrogen atom. This view is supported by the fact that on dehydration a compound of chelate ethylenediamine and the cupric atom with the co-ordination number 6 is not obtained. The product contains per cupric atom only half a molecule of ethylenediamine, which is thus still not a chelate group but has the two nitrogen atoms combined with separate cupric atoms having the co-ordination number 5. This product is obtained only by the loss of water and ethylenediamine hydrate simultaneously from two molecules of the original compound, thus indicating that the water molecule of the original compound is not in combination with the cupric atom and is firmly attached to only one nitrogen atom.

Ethylenediamine hydrate is an exceedingly stable substance and is a base nearly as strong as the alkalis, indicating that it has the constitution of an ammonium hydroxide,  $(\text{C}_2\text{H}_4\text{N}_2\text{H}_5)\text{OH}$ . As ethylenediamine does not give rise to basic salts containing only one molecule of acid per molecule of base, it follows that the two basic amino-groups are completely equivalent, and that separation of the water molecule can only be effected by acids on condition that both amino-groups react simultaneously. The two amino-groups consequently must equally share the single hydrogen atom ionised from the hydroxyl group of the hydrate, thus leading to the constitution  $[\text{C}_2\text{H}_4(\text{NH}_2)_2\text{H}]\text{OH}$ . The graphic formula for ethylenediamine hydrate should thus be written :

being a five-membered cyclic structure containing a hydrogen atom with co-ordination number 2.

This formulation is in complete harmony with the known properties of ethylenediamine hydrate and other polymethylenediamine

hydrates, and with the foregoing considerations relating to the ethylenediamine addition compounds of the cupric atom.

### EXPERIMENTAL.

$C_2H_4[N:C(CH_3) \cdot CH:C(CH_3) \cdot O-]_2 = ec$  (dibasic acid radical of ethylenediaminobisacetylacetone).\*

#### 1. Copper Series.

*Aquo-cupric Ethylenediaminobisacetylacetone*,  $H_2O$  Cu $ec$ .—On adding a solution of ethylenediaminobisacetylacetone to an aqueous ammoniacal solution of any cupric salt, glistening, bright violet scales of Combes's anhydrous cupric ethylenediaminobisacetylacetone,  $Cu\ ec$ , are immediately and quantitatively precipitated, but when left in contact with the mother-liquor or on exposure of the damp salt to moist air, the violet scales are wholly transformed into transparent scales varying from sage to dark green in colour. This green salt is the monohydrate of Combes's salt and is the sole product formed when the purple solution of Combes's salt in acetone is poured into dilute aqueous ammonia solution. When the pale blue cupric salt of acetylacetone undergoes prolonged treatment with aqueous ethylenediamine, a simple ethylenediammino-addition compound is not formed, although the copper salt dissolves to an indigo-blue solution. From this solution the green hydrate of Combes's salt alone separates, the ethylenediamine undergoing organic condensation with two molecules of acetylacetone, the aminated dienolic diketone being formed in combination with the cupric atom by elimination of water (Found: N, 9.2; Cu, 21.0; loss at  $100^\circ$ , 6.0.  $C_{12}H_{20}O_3N_2Cu$  requires N, 9.2; Cu, 21.0;  $H_2O$ , 5.9%).

*Aquo-cupric ethylenediaminobisacetylacetone*, forming large, black tablets, dark green by transmitted light, is insoluble in water, dissolves in nearly all organic solvents to form purple solutions of the anhydrous salt, and becomes anhydrous at  $100^\circ$ , but is unaffected by dry or moist air at the ordinary temperature. It melts at the temperature of the anhydrous salt,  $137^\circ$ , to a purple liquid, and, out of contact with air, boils at a high temperature without decomposition. The vapour in contact with air deposits a copper mirror on heated glass surfaces.

*Cupric Ethylenediaminobisacetylacetone Ethylenediamine Hydrate*,  $ecCuNH_2 \cdot CH_2 \cdot CH_2 \cdot NH_2 \cdot OH$ .—A hot solution of Combes's anhydrous cupric ethylenediaminobisacetylacetone in ethylenediamine hydrate, on cooling, deposits large, grass-green plates of a new salt in which

\* For certain details of preliminary work on the metallic derivatives of this quadridentate group we are indebted to Dr. H. D. K. Drew.—G. T. M.

one molecule of the cupric salt is combined with one molecule of the ethylenediamine hydrate (Found: Cu, 17.6, 17.4.  $C_{14}H_{28}O_3N_4Cu$  requires Cu, 17.5%).

Cupric ethylenediaminobisacetylacetone ethylenediamine hydrate crystallises from ethylenediamine hydrate in large, grass-green or ivy-green plates, which are slowly decomposed on exposure to air, emitting white fumes of ethylenediamine hydrate and yielding Combes's violet salt. It dissolves to a purple solution in hot benzene, but is reprecipitated unchanged on addition of a mixture of ethylenediamine hydrate and light petroleum, in which it is insoluble. It loses all its water and half of its ethylenediamine on exposure over solid sodium hydroxide, and is converted into a new salt, sage green in colour.

*Ethylenediammino-dicupric Bisethylenediaminobisacetylacetone*,  $C_2H_4(NH_2Cu ec)_2$ .—On exposure of the foregoing bright green addition compound of Combes's violet salt and ethylenediamine hydrate in a confined space over solid caustic soda or fused calcium chloride, fumes of ethylenediamine hydrate are continuously emitted and a green salt is produced in which two molecules of Combes's salt are combined with one molecule of anhydrous ethylenediamine (Found: N, 13.0; Cu, 19.7.  $C_{26}H_{44}O_4N_6Cu_2$  requires N, 13.3; Cu, 20.2%).

Ethylenediammino-dicupric bisethylenediaminobisacetylacetone forms glistening, sage-green scales which are stable in a confined space but are slowly decomposed on exposure to air with the formation of Combes's violet salt; it is insoluble in water and in 2*N*-caustic soda solution, but is slowly decomposed to form Combes's violet salt, and is thus distinguished from the foregoing hydrated salt, which is not decomposed by 2*N*-caustic soda solution and is only very slowly decomposed by water.

*Quinolino-cupric Acetylacetone* (V).—Pale blue cupric acetylacetone was dissolved in boiling quinoline, forming a dark green solution, from which, on cooling, large, sage-green plates separated. These were removed and dried in air (Found: Cu, 15.9.  $C_{19}H_{21}O_4NCu$  requires Cu, 16.3%). This quinoline addition compound is stable in dry air, but is slowly decomposed by moist air and by water, or by solution in organic solvents, quinoline being lost and the simple cupric salt regenerated.

Cupric acetylacetone forms similar sage-green addition compounds with ammonia and with pyridine on addition of an alcoholic solution of the salt to a concentrated aqueous solution of the base, but these more volatile bases are rapidly lost on removal from the precipitating medium and consequently these addition compounds cannot be dried for analysis.

2. *Nickel Series.*

*Nickel Ethylenediaminobisacetylacetone*, Ni ec.—Hexa-aquo-nickel chloride (2.4 g. = 1 mol.) was dissolved in water (20 c.c.) and mixed with ethylenediaminobisacetylacetone (2.2 g. = 1 mol.) in alcoholic solution (29 c.c.), forming a dark reddish-brown liquid, to which was added 5*N*-sodium hydroxide solution (4 c.c. = 2 mols.). An olive-green precipitate separated, which dissolved to a reddish-black solution on heating on the steam-bath, large, brilliant bronze-red, rhomboidal, transparent scales and plates rapidly separating, which were washed with water, recrystallised from alcohol and air-dried (Found: Ni, 20.8.  $C_{12}H_{18}O_2N_2Ni$  requires Ni, 20.9%).

Nickel ethylenediaminobisacetylacetone, crystallising in bronze-red scales or plates or reddish-black tablets, is insoluble in water, readily soluble in most organic solvents to red solutions, and soluble in mineral acids only with decomposition, forming acetylacetone and nickel and ethylenediamine salts. It melts at 200° to a black liquid, and, out of contact with air, boils without decomposition at a temperature approaching a red heat, forming a heavy yellow vapour, which condenses in bright red needles. The vapour, in contact with air, deposits a glistening nickel mirror on a heated glass surface, similar to the cobalt mirror obtained by heating the corresponding cobaltous salt.

*Ethylenediammino-nickel Ethylenediaminobisacetylacetone*,  $C_2H_4(NH_2)_2Ni$  ec.—The foregoing nickel salt was dissolved in the minimum quantity of boiling ethylenediamine hydrate, forming a brownish-red solution, from which, on rapid cooling, elongated, brownish-red needles separated. These were removed, washed with light petroleum and dried over solid caustic soda (Found: Ni, 17.2  $C_{14}H_{26}O_2N_4Ni$  requires Ni, 17.2%).

The acicular form of ethylenediammino-nickel ethylenediaminobisacetylacetone slowly loses ethylenediamine on exposure; it is insoluble in water and decomposed by this medium, forming the foregoing simple salt and a strongly alkaline solution of ethylenediamine.

*Diammino-nickel Ethylenediaminobisacetylacetone*,  $(NH_3)_2Ni$  ec.—On pouring a saturated solution of the simple nickel salt in alcohol into 18*N*-ammonia solution, brilliant red prisms separated. On drying, these rapidly lost ammonia, even over sodium hydroxide and ammonium carbonate. Analysis was possible only of the partly deaminated salt, the highest percentage of ammonia found being 7.9. The diammine requires 10.8 and the monammine 5.7%, indicating that the product was almost certainly the diammino-nickel salt.

3. *Palladous Series.*

*Palladous Ethylenediaminobisacetylacetone.* Pd ec.—Palladous chloride (0.9 g. = 1 mol.) was dissolved in boiling 10*N*-hydrochloric acid, and the solution rather more than neutralised with sodium carbonate. Ethylenediaminobisacetylacetone (1.2 g. = 1 mol.) and 5*N*-sodium hydroxide solution (2 c.c. = 2 mols.) were then added. On heating on the steam-bath, the yellow mixture assumed a brownish-black colour. After cooling, the liquid was filtered, and the solid residue extracted with acetone until the extracts were colourless. On concentrating the orange-coloured acetone extracts, yellow prisms separated, which were recrystallised from benzene and air-dried (Found: N, 8.3; Pd, 32.4.  $C_{12}H_{18}O_2N_2Pd$  requires N, 8.5; Pd, 32.5%).

Palladous ethylenediaminobisacetylacetone forms canary-yellow needles, m. p. 228°. It is insoluble in water, sparingly soluble in light petroleum, and freely soluble in most other organic solvents, from which it separates in pale yellow prisms with solvent of crystallisation, readily lost on exposure, yielding the simple salt.

*Dichloroformo-palladous Ethylenediaminobisacetylacetone,*  $(CHCl_3)_2Pd$  ec.—From a saturated solution of palladous ethylenediaminobisacetylacetone in chloroform, large, elongated, hexagonal, pale yellow tablets separated, which were removed and dried by a very short exposure to air (Found: loss at 100°, 41.7.  $C_{14}H_{20}O_2N_2Cl_6Pd$  requires  $CHCl_3$ , 42.1%). The addition compound, on exposure to air, only slowly loses chloroform (identified by odour), but is rapidly converted into the simple salt by heating for about an hour at 100°.

The authors desire to thank the Advisory Council of the Department of Scientific and Industrial Research and the Birmingham University Research Committee for grants which have helped to defray the expense of this investigation.

EDGBASTON.

[Received, February 8th, 1926.]

### CXXVIII.—*Derivatives of 2-Keto-1:2-dihydrobenzisothiazole.\**

By ERNEST WILSON McCLELLAND and ALBAN JAMES GAIT.

It has been suggested (McClelland and Longwell, J., 1923, 123, 3310) that the first stage in the production of the disulphide (I) from 2-dithiobenzoyl and a primary amine is the formation of

\* Named "2-thiobenzimide" in previous papers.

hydrogen sulphide and a ketodihydrobenzisothiazole (II). It was pointed out that these benzisothiazoles, if formed, would be

very easily reduced to the corresponding disulphides and that the failure to isolate them was probably due to their reduction by the hydrogen sulphide.

Such compounds appear to be unknown and the present investigation was undertaken with the object of synthesising them and examining their stability towards hydrogen sulphide.

Attempts to prepare 2-keto-1-phenyl-1:2-dihydrobenzisothiazole by the intramolecular condensation of (I; R = Ph), which in the presence of sulphuric acid might be expected to react as the sulphenic acid,  $NHPh \cdot CO \cdot C_6H_4 \cdot S \cdot OH$  (compare Prescott and Smiles, J., 1911, 99, 640), were unsuccessful. According to patent literature (D.R.P.-ann. F. 35230), 2:2'-dithiobenzoic acid on treatment with chlorine yields a sulphur chloride,  $CO_2H \cdot C_6H_4 \cdot SCl$ . It was therefore to be expected that 2:2'-dithiobenzoyl chloride would also yield a sulphur chloride (III) and that this dichloride would condense with primary amines to give the required *N*-substituted ketodihydrobenzisothiazoles (II) thus:

2:2'-Dithiobenzoyl chloride, suspended in carbon tetrachloride, dissolved on treatment with dry chlorine, presumably owing to the formation of the dichloride (III). This chlorinated solution reacted with aqueous ammonia to give 2-keto-1:2-dihydrobenzisothiazole. In a similar way the chlorinated solution reacted with aniline, *o*-toluidine, and aqueous methylamine to give compounds of the type (II) in which R is Ph, *o*-C<sub>6</sub>H<sub>4</sub>Me, and Me, respectively. On oxidation with hydrogen peroxide these compounds were converted into the corresponding "saccharins." The interaction of the chlorinated solution of 2:2'-dithiobenzoyl chloride with *n*-propylamine yielded an oily substance which was undoubtedly 2-keto-1-*n*-propyl-1:2-dihydrobenzisothiazole, as on oxidation it was converted into *N*-*n*-propyl-*o*-benzoic sulphinide.

The 1-phenyl, 1-*o*-tolyl, and 1-methyl derivatives of 2-keto-1:2-dihydrobenzisothiazole in alcoholic solution are rapidly reduced by hydrogen sulphide with deposition of sulphur and formation of disulphides identical with the products obtained by the action of the corresponding amines on 2-dithiobenzoyl. The afore-mentioned suggestion of McClelland and Longwell hereby receives strong

confirmation. 2-Keto-1:2-dihydrobenzisothiazole also is reduced by hydrogen sulphide. The fact that it can be isolated by the action of ammonia on 2-dithiobenzoyl may be due to its being slightly more stable than its derivatives towards hydrogen sulphide, as previously suggested.

Selenium analogues of 2-keto-1:2-dihydrobenzisothiazole and certain of its derivatives have been prepared by an analogous method (Lesser and Weiss, *Ber.*, 1924, 57, 1077).

#### EXPERIMENTAL.

2:2'-Dithiobenzoyl chloride was prepared by the action of phosphorus pentachloride on 2:2'-dithiobenzoic acid (*Ber.*, 1898, 31, 1670) and was crystallised from benzene before use in the following experiments.

The derivatives of 2-keto-1:2-dihydrobenzisothiazole described below were prepared by the following general method. Dry chlorine was bubbled through a suspension of 2:2'-dithiobenzoyl chloride (5 g.) in carbon tetrachloride (40 c.c.; dried over calcium chloride) until solution was complete. The excess of chlorine having been removed by a current of dry air, the solution was added slowly, with vigorous stirring, to aqueous ammonia (40 c.c.;  $d$  0.880), 30% aqueous methylamine (excess), or the amine (aniline, 8 g.; *o*-toluidine, 10 g.) diluted with carbon tetrachloride. During the addition the aqueous ammonia and the solutions of the amines were cooled in ice. The product of the reaction was either precipitated or obtained by evaporation of the dried carbon tetrachloride solution.

2-Keto-1:2-dihydrobenzisothiazole (II;  $R = H$ ) was precipitated on addition of the chlorinated solution of 2:2'-dithiobenzoyl chloride to the aqueous ammonia and was crystallised from methyl alcohol and finally from water (yield 80%). It melted at 155–156°, alone or mixed with a specimen prepared by the action of ammonia on 2-dithiobenzoyl.

2-Keto-1-phenyl-1:2-dihydrobenzisothiazole (II;  $R = Ph$ ).—In this preparation aniline hydrochloride was precipitated; it was filtered off and the carbon tetrachloride allowed to evaporate at room temperature. The residual solid crystallised from methyl alcohol in fine, colourless needles, m. p. 140° (Found: C, 68.4; H, 4.1; S, 13.9.  $C_{13}H_9ONS$  requires C, 68.7; H, 4.0; S, 14.1%).

2-Keto-1-*o*-tolyl-1:2-dihydrobenzisothiazole (II;  $R = o\text{-C}_6\text{H}_4\text{Me}$ ) was obtained as a brown oil which slowly solidified; after crystallisation from methyl alcohol it melted at 122–123° (Found: C, 69.7; H, 4.5; S, 13.4.  $C_{14}H_{11}ONS$  requires C, 69.7; H, 4.5; S, 13.3%).

2-Keto-1-methyl-1:2-dihydrobenzisothiazole (II;  $R = CH_3$ ) was  

$$H \ H^* \ 2$$

obtained from the carbon tetrachloride after separation from the aqueous solution, as a brown oil which slowly solidified; it crystallised from benzene-light petroleum in fine, colourless needles, m. p. 51—52° (Found: C, 58.0; H, 4.3; S, 19.5.  $C_8H_7ONS$  requires C, 58.1; H, 4.3; S, 19.4%).

This isothiazole is sparingly soluble in ether and light petroleum and very soluble in alcohol or benzene. On treatment with hydrochloric acid the crude oil obtained above yielded a *hydrochloride*, which was readily hydrolysed by water but crystallised from hydrochloric acid in colourless needles, m. p. 124—127°. The hydrochloride appears to be unstable, as varying results were obtained in the estimation of the chlorine and its melting point gradually fell on keeping in a vacuum desiccator.

*N-n-Propyl-o-benzoicsulphinide*,  $C_6H_4 \begin{smallmatrix} SO_2 \\ \diagup \quad \diagdown \\ CO \end{smallmatrix} N \cdot C_3H_7$ .—A chlorinated solution of 2:2'-dithiobenzoyl chloride, prepared by the general method, was added to an excess of propylamine diluted with carbon tetrachloride. The solid material was filtered off, and the carbon tetrachloride evaporated. The oil thus obtained was oxidised in glacial acetic acid with hydrogen peroxide (30%). The product crystallised from water in fine, colourless needles, m. p. 73—75° (Found: S, 14.1; N, 6.1.  $C_{10}H_{11}O_2NS$  requires S, 14.2; N, 6.2%).

*Oxidation of the Benzisothiazoles*.—A solution of 2-keto-1-phenyl-1:2-dihydrobenzisothiazole (0.2 g.) in glacial acetic acid was heated with 30% hydrogen peroxide (1 c.c.) for 1 hour at 100°. On cooling, a white, crystalline product was obtained. This, after recrystallisation from glacial acetic acid, melted at 189—190°, and at 189° when mixed with authentic *N*-phenyl-*o*-benzoicsulphinide, m. p. 190.5° (*Amer. Chem. J.*, 1895, 17, 320).

In a similar way 2-keto-1-*o*-tolyl-1:2-dihydrobenzisothiazole yielded a substance, m. p. 171—173° (*N*-*o*-tolyl-*o*-benzoicsulphinide has m. p. 172—175°; *loc. cit.*, p. 327).

2-Keto-1-methyl-1:2-dihydrobenzisothiazole (the crude oil) was instantly converted by cold hydrogen peroxide (30%) into a white, crystalline substance. This, after recrystallisation from glacial acetic acid and finally from methyl alcohol, melted at 129—130°, alone or mixed with *N*-methyl-*o*-benzoicsulphinide.

*Reduction of the Benzisothiazoles*.—Hydrogen sulphide was bubbled slowly through a solution of 2-keto-1-phenyl-1:2-dihydrobenzisothiazole in ethyl alcohol at 50°. In a few minutes a precipitate of sulphur appeared; the current of gas was then stopped, and the solution filtered as quickly as possible. The filtrate slowly deposited colourless needles contaminated with sulphur. After several crystallisations from glacial acetic acid, the product was obtained free from

sulphur; it melted at 236—238°, and at 237° when mixed with 2 : 2'-dithiobenzophenylamide (m. p. 239°), prepared by the action of aniline on 2-dithiobenzoyl.

2-Keto-1-*o*-tolyl-1 : 2-dihydrobenzisothiazole, reduced in a similar way, gave a product which after recrystallisation from methyl alcohol melted at 219—220°, alone or mixed with the product obtained by the action of *o*-toluidine on 2-dithiobenzoyl.

The reduction of 2-keto-1-methyl-1 : 2-dihydrobenzisothiazole by hydrogen sulphide, under the same conditions, yielded a substance which after crystallisation from glacial acetic acid and methyl alcohol melted at 220—221°, alone or mixed with 2 : 2'-dithiobenzomethylamide, prepared by the action of methylamine on 2-dithiobenzoyl.

The authors desire to express their thanks to Professor Smiles for the interest he has taken in this work and for his helpful suggestions.

KING'S COLLEGE, LONDON.

[Received, January 28th, 1926.]

## CXXIX.—*The Vapour Pressures of Chlorine Dioxide.*

By FREDERICK ERNEST KING and JAMES RIDDICK PARTINGTON.

A CONNECTED series of measurements of the vapour pressures of chlorine dioxide from the melting point to the boiling point of the substance does not appear to have been recorded. A few isolated measurements, in poor agreement, are given in the literature. Millon (*Ann. Chim. Phys.*, 1843, 7, 314; *Annalen*, 1843, 46, 281) gives + 20° or + 32° as the boiling point, but does not describe the method used. He correctly states that chlorine dioxide attacks mercury, and dissolves in concentrated sulphuric acid to a bright yellow solution, but his assertion that the latter decomposes at 10° with evolution of chlorine, oxygen, chlorine dioxide, and "chlorine trioxide" we do not confirm. Millon also correctly described the colour of liquid chlorine dioxide as red, "like the brightly-coloured sulphur chloride," i.e., the monochloride containing excess of chlorine, but he overestimated the explosive properties of the liquid. Brandau (*Annalen*, 1869, 151, 340) gives the boiling point of what he calls chlorine trioxide as 8—9° at 745 mm.: the substance must have been the dioxide. Pebal (*ibid.*, 1875, 177, 1) determined the boiling point by a rather crude method as 8.7° at 725.7 mm. Schacherl (*ibid.*, 1881, 206, 68) attempted to determine the vapour pressure by means of a mercury manometer in direct communication with a water manometer, the metal being protected from the gas

by a long column of water. Schacherl first noticed that liquid chlorine dioxide, although exploding violently when the process is initiated, is not liable to spontaneous, erratic detonation, as asserted by Millon, provided that all traces of organic matter are excluded and the substance is manipulated entirely in glass. Schacherl gives the following pressures, which are really those over a saturated solution, although he remarks that the yellow colour of the solution had not passed round the water limb of the manometer before the conclusion of the measurements.

$t^{\circ}$ .....	10.6	7.6	9.6	14.0	14.1	16.9	10.3	7.6
$p$ (mm.) .....	767.8	723.8	734.4	961.9	983.9	1162.7	1335.6	1329.1

It is quite clear, as Schacherl himself admits, that these values are completely vitiated by decomposition of the gas at the higher temperatures, and that the first value only can be taken into account. He concluded that the vapour-pressure method must be abandoned as unsuitable for the determination of the boiling point. This was really an incorrect conclusion, since, if he had taken care not to raise the temperature too far above the boiling point, there would probably have been very little decomposition. Schacherl then made a direct estimation of the boiling point with a mercury thermometer bulb immersed in the liquid contained in a small open bulb in a water-bath. The temperature rose slowly to  $9.9^{\circ}$ , remained constant for a short time, then varied between  $9.9^{\circ}$  and  $10.1^{\circ}$ , then returned to  $9.9^{\circ}$ , and remained constant until practically all the liquid had evaporated. The pressure was 730.9 mm. The liquid, it was found, could be boiled rapidly at  $+30^{\circ}$  without explosion, and the vapour recondensed by cooling at  $8.9^{\circ}$ . During the boiling-point determination, care was taken to avoid superheating, and the liquid during the whole series of measurements boiled steadily without bumping.

#### EXPERIMENTAL.

The chlorine dioxide was prepared by a method stated by Spring (*Bull. Acad. roy. Belg.*, 1875, 39, 882) to yield chlorine trioxide, a substance up to the present unknown. The method involved the action of chlorine on dry silver chlorate. We have convinced ourselves that the only gaseous products of this reaction are chlorine dioxide and oxygen, so that it probably proceeds according to the equation  $2\text{AgClO}_3 + \text{Cl}_2 = 2\text{AgCl} + 2\text{ClO}_2 + \text{O}_2$ . The chlorine dioxide is easily liquefied out of the gas by cooling and can be obtained pure and dry.\*

\* Garzarolli Thurnlackh (*Annalen*, 1881, 209, 184) refers to Spring's work at the end of his paper and suggests that the gas may have been a mixture of the composition  $\text{Cl}_2\text{O} + 4\text{ClO}_2$  rather than  $\text{Cl}_2\text{O}_3$ . He promised to investigate the matter further, but does not appear to have done so.

According to Spring, the reaction begins in the cold, but we have found that it is quite inappreciable below about  $80^{\circ}$  and occurs regularly and smoothly at about  $90^{\circ}$ . The silver chlorate was prepared from chloric acid and silver oxide, dried in a desiccator over phosphorus pentoxide, and then about 10 g. were filled into a U-tube with ground stopcocks (A, Fig. 1), with alternate plugs of dry glass wool. Ramsay lubricant proved to be efficient for the ground joints and stopcocks; it was only very slightly attacked, if at all, during the few hours necessary for actual measurements. Pure dry chlorine, liberated by warming liquid chlorine (from potassium permanganate and hydrochloric acid) in a bulb, B, and dried by passing over phosphorus pentoxide in the tube C, was passed slowly over the chlorate, the tube A being maintained at  $85-95^{\circ}$  in an electrically heated air-bath. With fresh chlorate, the reaction was slow at

FIG. 1.

first and some free chlorine tended to pass over. The issuing gas was then passed to a small bulb, D, immersed in solid carbon dioxide and ether, communicating with a pump and two manometers. These contained mercury covered with concentrated sulphuric acid. The first (not shown) served to indicate the pressure after exhaustion and during filling; the second, which was closed by a tap until the actual measurements were begun, served to measure the pressures. By working in this way, excessive attack of the mercury surface used for measurement was avoided. The columns of acid were of the same length in each limb so as to compensate each other. We satisfied ourselves that, although mercury is attacked with the deposition of a white powder, no permanent gas is evolved from the sulphuric acid, which slowly becomes bright yellow in colour. The oxygen accumulating was removed from time to time by pumping.

The chlorine dioxide condensed in the bulb as a crystalline solid of the colour of potassium dichromate. If any excess of chlorine had passed through, this either floated unchanged on the surface of the solid dioxide or condensed along with dioxide to a deep red liquid which did not solidify in the freezing mixture. In either case, the chlorine was easily removed by pumping for a few minutes with

the bulb immersed in the freezing mixture. The pressure finally fell suddenly and the red crystals remained. The vapour pressure of the solid at  $-80^{\circ}$  was negligible.

By adding ether to the freezing mixture until all the solid carbon dioxide had disappeared, it was possible to raise the temperature slowly in steps to  $-30^{\circ}$ . Melting occurred sharply at  $-59^{\circ}$ , both solid and liquid being at first present, and all the solid melted at this temperature. This result is in agreement with the only previous observation, that of Faraday (*Phil. Trans.*, 1845, 135, 155), who found the melting point  $-59^{\circ}$ .\*

FIG. 2.

By further addition of ether, the temperature was gradually raised, the temperatures being measured on a pentane thermometer. After  $-30^{\circ}$ , a mixture of ice and salt, pure ice, and water were used successively, with a mercury thermometer.

The gauge pressures were subtracted from the mercury column reading corresponding with the vacuum attained in the apparatus before admitting gas. After the measurements, the chlorine dioxide was resolidified by immersing the bulb in solid carbon dioxide and

\* Faraday's result is given in most works of reference as  $-76^{\circ}$ ; this, however, is the temperature on the Fahrenheit scale used by Faraday. The correct figure is given in Watts' Dictionary, 1890, vol. 2, p. 13.

ether, and the original vacuum recovered, showing that decomposition had not occurred during the measurements.

The logarithms of the pressures recorded in Table I are plotted against the reciprocals of the absolute temperatures in Fig. 2, and it will be seen that a fair approach to a straight line is obtained. The part near the boiling point is drawn on an enlarged scale to the left. It so happened that the barometric pressure corresponded exactly with 760 mm. when the boiling point was reached, so that the value of the latter,  $11.0^\circ$ , could be determined directly.

The isolated points observed by Pebal and Schacherl are also shown. The first measurement of the latter in the vapour pressure series, when corrected for the vapour pressure of water at  $15^\circ$ , lies almost on the curve, but the remaining measurements show great irregularity. The direct measurement of the boiling point made by Schacherl, *viz.*,  $9.9^\circ/730.9$  mm., also lies on the curve.

\* Melting point.

† Boiling point.

‡ Not measurable.

From the values of the vapour pressures at different temperatures, it is possible to calculate the latent heat of evaporation of liquid chlorine dioxide by means of the formula :

$$\lambda = 4.576 \{ \log(p_2/p_1) \} T_1 T_2 / (T_2 - T_1) \text{ cal. per mol.}$$

From data near the boiling point the value 6520 is obtained. From this, by division by the absolute boiling point  $T_0$ , we find the Trouton coefficient  $\lambda/T_0$  of 23. The values of this calculated by the two formulæ of Nernst are :

$$8.5 \log T_0 = 20.85 \text{ and } 9.5 \log T_0 - 0.007 T_0 = 21.3,$$

and from Wartenberg's formula  $7.4 \log T_0 + 1.985 = 20.2$ .

The ratio of the absolute temperatures corresponding with vapour pressures of 760 mm. and 200 mm. (really 201 mm.) is 1.114, which is the value shown by Ramsay and Young to correspond with normal liquids (*Z. physikal. Chem.*, 1887, 1, 249). These considerations seem to point to very little, if any, association of chlorine dioxide in the liquid state, so that its formula in both the gaseous and the liquid state may be considered to be  $\text{ClO}_2$ . The colours of the solid, liquid, and gaseous forms would also point to the same conclusion.

CXXX.—*The Oxidation Potential of the System Selenium Dioxide-Selenium.*

By SYDNEY RAYMOND CARTER, JOHN A. V. BUTLER, and  
FRANK JAMES.

SELENIUM dioxide is readily reduced to selenium and it appeared that a study of the oxidation potential of the system selenium dioxide-selenium would furnish interesting data for comparison with that of the analogue: sulphur dioxide-sulphur (Carter and James, J., 1924, **125**, 2231).

Preliminary *E.M.F.* measurements were carried out with various half-elements in combination with the calomel electrode. Each cell contained several platinum foil electrodes, some of which were plain and others platinised. The solid selenium used in cells 2, 3 and 5 was the red amorphous variety. In some cases, the platinum foil was buried in the selenium, whilst in others the selenium was deposited electrolytically.

Cell 1.	(Pt) 0.1 <i>M</i> -SeO <sub>2</sub> ,	0.1 <i>M</i> -Na <sub>2</sub> SeO <sub>4</sub> ,	H <sub>2</sub> O
2.	(Pt) 0.1 <i>M</i> -SeO <sub>2</sub> ,	Se (solid),	H <sub>2</sub> O
3.	(Pt) 0.1 <i>M</i> -SeO <sub>2</sub> ,	Se (solid),	10 <i>N</i> -HCl
4.	(Pt) 0.1 <i>M</i> -SeO <sub>2</sub> ,	Se (in solution),	10 <i>N</i> -HCl
5.	(Pt) Se (solid),	10 <i>N</i> -HCl	

1 and 2 gave ill-defined potentials and they were greatly affected by polarisation. 3 and 4 gave well-defined potentials. In 5, the potential was ill-defined, but on the addition of selenium dioxide it rose several tenths of a volt and became steady.

From these and subsequent experiments it was concluded that a definite potential was exhibited, provided that the solution were strongly acid and that selenium dioxide and selenium were each present in solution. In the case of the selenium, it might be present in quantity to form either a saturated or an unsaturated solution. In this connexion, the solubility of selenium is important and experiment revealed the following facts:

1. Red amorphous selenium was stirred with concentrated hydrochloric acid at 20° for 3 days, but no selenium was dissolved. Moreover, under these conditions no selenium dioxide was formed, although the solution was in contact with air.

2. Selenium is soluble in concentrated hydrochloric acid in presence of selenium dioxide. The solubility of selenium in 0.1*M*-SeO<sub>2</sub> and 11.6*N*-HCl is 1.35 g. per litre (within 5%).

3. The solubility of selenium falls off rapidly with diminishing concentration of acid, and, on dilution of saturated solutions with water, the red amorphous selenium is precipitated.

It was therefore decided to determine the oxidation potential of the system selenium-selenium dioxide-concentrated hydrochloric acid, and to study the influence of changes in concentration of (a) selenium, (b) selenium dioxide.

In order to obtain reproducible values of the *E.M.F.* it was obvious that the quantity of dissolved selenium would have to be carefully controlled.

*Materials.*—Selenium dioxide was prepared by dissolving amorphous selenium (B.D.H.) in concentrated nitric acid and evaporating the solution to dryness. The product was twice sublimed in small quantities in a large crucible and thereby freed from tellurium. Pure amorphous selenium was prepared from the purified selenium dioxide by passing sulphur dioxide through a slightly acid solution; after thorough washing on an asbestos pad, the precipitate was dried in a vacuum. The hydrochloric acid employed throughout was B.D.H., As.T. quality.

*Preparation of Solutions.*—A solution of selenium in concentrated hydrochloric acid containing selenium dioxide was prepared by shaking amorphous selenium with the liquid for several days. The clear solution (deep amber colour) was withdrawn into a pipette through a pad of glass wool and portions were analysed. The stock solution had the following composition: 0.066*N*-SeO<sub>2</sub>, 0.0134*N*-Se, 11.6*N*-HCl. This was used for making up the cell solutions by suitable dilution with hydrochloric acid of the same concentration and addition of the proper amounts of selenium dioxide either as the solid or from the stock solution. The composition of some of the solutions was checked by analysis.

*Analysis.*—The determination of selenium dioxide was based on that of Norris and Fay (Gooch, "Methods in Chemical Analysis," 1912, p. 383) for acid solutions. 10 C.c. of the concentrated acid solution are added to 300 c.c. of ice and water. 50 C.c. of *N*/10-sodium thiosulphate are then run in, the excess being titrated with standard iodine solution, starch paste being used as indicator. This method gave accurate results if the conditions were strictly observed.

The estimation of the amount of dissolved selenium was a more difficult matter. At first, the greater part of the hydrochloric acid was evaporated on the water-bath, and the selenium precipitated by the addition of water. This method gave variable results owing apparently to the volatilisation of a portion of the selenium. The method finally adopted was to dilute 100 c.c. of the solution with a litre of water. The selenium separated in a very finely-divided form which did not settle readily. On adding a few c.c. of a strong solution of potassium chloride, however, the precipitate rapidly

settled in a compact curdy form, which was filtered off through a Gooch crucible, dried at  $110^{\circ}$ , and weighed. Long heating at this temperature caused no loss of weight by volatilisation. The filtrate showed no sign of containing any free selenium. It was colourless and clear, and no perceptible turbidity appeared on further dilution.

Hydrochloric acid was determined in a separate portion by suitable dilution and titration with standard sodium carbonate.

*Electrical Measurements.*—It was feared that the presence of concentrated hydrochloric acid in one half of the cell would give rise to a troublesome liquid boundary and make accurate measurements impossible.

The following type of cell was finally found to be most suitable for the purpose:

This arrangement gave reproducible results and was not liable to fluctuations of more than a few tenths of a millivolt during the experiments. Moreover the boundary potentials are of types which may be evaluated if required.

A stationary junction being used at the  $N\text{-HCl} \mid \text{KCl (sat.)}$  boundary, variations of 0.0025 volt over a 10-minute range were experienced, whilst, with the flowing junction, readings constant to 0.0001 volt during 15 minutes were obtained. This is of interest, since the flowing junction has hitherto been applied to junctions of the type  $\text{HCl} \mid \text{KCl}$  for concentrations of 0.1*N* and *N* (Lamb and Larson, *J. Amer. Chem. Soc.*, 1920, 42, 229). The present work shows how it may be employed advantageously in connecting a saturated potassium chloride solution with highly concentrated acid.

The electrodes were of platinum platinised in the usual way. A fresh electrode took some time to acquire a definite potential, but electrodes that had been immersed in one of the solutions, after being washed once or twice with a fresh solution, rapidly assumed a steady potential. In some preliminary experiments a metre bridge in conjunction with a capillary electrometer was employed. With this arrangement, it was found that the electrodes, particularly in the more dilute solutions, were very readily polarised, even with the small currents which passed in finding the balance point, and took some time to recover the original potential. In the later work a Cambridge ionisation potentiometer was used, giving readings direct to 0.2 millivolt with a sensitive A. M. galvanometer. No

trouble was experienced with this arrangement on account of polarisation.

Three electrodes were placed in the electrode vessel. After use in a few cells an electrode often became irregular and differed from the other two. Fairly frequent replatinising was necessary. The electrode vessel was kept in a thermostat at  $20^{\circ} \pm 0.1^{\circ}$  during the measurements. The saturated calomel electrode was one of a battery of four which were frequently compared and at no time differed by more than 0.25 millivolt. The calomel electrodes were at room temperature. This was determined exactly by a thermometer in the liquid of one of them, at the time of every measurement, and the correction introduced.

*Reproducibility and Constancy.*—Although with the more concentrated solutions the mean potentials were easily reproduced to within a fraction of a millivolt (e.g., cell D), minor fluctuations, usually less than a millivolt, were sometimes observed. On the other hand, the solutions containing the more minute concentrations of selenium exhibited a gradual drift in the potential. This was most apparent in cell C, where a gradual decrease from 0.5452 to 0.5247 volt at  $12^{\circ}$  over a period of 22 hours was observed. This was not due to changes in the immediate vicinity of the electrodes, for only a minute alteration of the potential occurred on shaking the cell. The drift appeared to be due to some decomposition in the cell, which was accelerated by the higher temperature of the thermostat, this being slightly above that of the room. A portion of the solution C, which had remained at room temperature for 24 hours, gave a slightly lower potential than the original reading; when placed in the electrode vessel in the thermostat, its rate of drift was greater. It appeared that the reaction concerned was the reduction of selenium dioxide by hydrochloric acid:  $\text{SeO}_2 + 4\text{HCl} = \text{Se} + 2\text{H}_2\text{O} + 2\text{Cl}_2$ .

The formation of selenium to only a slight extent in this reaction would have an appreciable effect on the selenium concentration at the minute concentrations of the more dilute cells. This supposition was supported by the fact that a stock solution of selenium dioxide in concentrated hydrochloric acid, kept at room temperature, acquired after some days a faint yellow tint. The potential of a platinum electrode in this solution measured against the saturated calomel electrode was 0.614 volt, which would correspond to a selenium concentration of about  $10^{-5}M$ .

*Measurements.*—A typical set of potentiometer readings is in Table I, which gives the observations for three freshly prepared cells, D1, D2 and D3, respectively. (The selenium electrode is positive with respect to the calomel.)

$E(t^\circ)$  is the observed *E.M.F.* when the oxidation cell is at  $20^\circ$  and the calomel electrode is at room temperature,  $t^\circ$ :  $E(20^\circ)$  is the *E.M.F.* after correcting the calomel electrode to  $20^\circ$ .

TABLE I.

$[\text{SeO}_2] = 0.0866$ ,  $[\text{Se}] = 0.00134$ ,  $[\text{HCl}] = 11.6$ .

F	0.0087	0.000134	0.5720	0.0260
C	0.00087	0.000134	0.5436	

In Cell A<sub>1</sub>, the junction  $N\text{-HCl}|\text{KCl}(\text{sat.})$  is stationary, but in A<sub>2</sub> and all the other cells the flowing junction was used.

*The Influence of Concentration of Selenium Dioxide and of Selenium on Oxidation Potential.*

(a) *Selenium*.—Table II gives this relation, since in Cells A<sub>2</sub>, D and E the  $[\text{SeO}_2] = 0.087$  is constant and  $[\text{Se}]$  undergoes tenfold changes. Cells B and F afford a similar comparison.  $\Delta E$  is the difference in *E.M.F.* for a tenfold change in  $[\text{Se}]$  and it amounts to 0.0222 to 0.0260 volt.

(b) *Selenium Dioxide*.—Table III gives this relation similarly, and it will be seen that  $\Delta E$  for a tenfold change in  $[\text{SeO}_2]$  varies from 0.0250 to 0.0284 volt.

TABLE III.

Cell.	$[\text{SeO}_2]$ .	$[\text{Se}]$ .	$E(20^\circ)$ .	$\Delta E$ .

F	0.0087	0.000134	0.5720	
C	0.00087	0.000134	0.5436	0.0284

*Mechanism of the Oxidising Action of Selenium Dioxide and of Sulphur Dioxide.*

The reduction of selenium dioxide in concentrated acid solution may conceivably proceed in a number of ways, of which the following may be considered.

1. The selenium dioxide dissolves in concentrated acid to form selenium tetrachloride, which ionises into quadrivalent selenium ions,  $\text{Se}^{++++}$ . On reduction, the four positive charges are removed and elementary selenium results:

The potential variations,  $\Delta E$ , would be given by  $\Delta E = 0.058/4 \cdot \log [\text{Se}]/[\text{SeO}_2]$ , and for a tenfold change in  $[\text{Se}]$  or in  $[\text{SeO}_2]$ ,  $\Delta E = 0.058/4 = 0.0145$  volt.

2. The reduction does not proceed entirely from the quadrivalent state down to elementary selenium, but only through certain intermediate stages, for example, from quadrivalent to bivalent selenium. The essential portion of such a process may be represented

whence  $\Delta E = 0.058/2 \cdot \log [\text{Se}^{++}]/[\text{Se}^{++++}] = 0.058/2 \cdot \log [\text{Se}]/[\text{SeO}_2]$ , and for a tenfold change in  $[\text{Se}]$  or in  $[\text{SeO}_2]$ ,  $\Delta E = 0.058/2 = 0.029$  volt.

Since part of the selenium dioxide is used in dissolving the selenium, the effective concentration is actually less than  $[\text{SeO}_2]$  and a value somewhat smaller than 0.029 for  $\Delta E$  will be obtained.

The existence of derivatives of bivalent selenium is indicated by the solubility of selenium in strong acid solutions containing selenium dioxide:  $\text{SeO}_2 + \text{Se} = 2\text{SeO}$ . In this connexion, it may be observed that selenium dissolves in selenic acid giving a green solution believed to contain  $\text{Se}_2\text{O}_3$ , an analogue of  $\text{SeSO}_3$  which is formed by dissolving selenium in sulphuric acid (*Chem. News*, 1889, 59, 268).

Either hypothesis depends on certain assumptions regarding the degree of ionisation and the unimolecular nature of the respective constituents in the equations. Experiments on these points are still proceeding. The experimental results for  $\Delta E$  fall between those demanded by the two theories, but are rather in favour of the second.

The hypothesis that selenium acquires positive charges and behaves as an electropositive element is reasonable, since it has certain characteristics of a metal which are exhibited by its analogue tellurium, although scarcely at all by sulphur. Nevertheless the

analogy with sulphur, even if only shown to a slight extent, is of interest in a study of the oxidising properties of sulphur dioxide and would furnish an explanation if sulphur could also become electropositive in acid solution (J., 1920, 117, 1246).

Since negatively charged selenium ions  $\text{Se}''$  or  $\text{Se}_n''$  have already been identified in alkaline solutions, the present indication of positively charged selenium ions in acid solution furnishes additional evidence of the amphoteric nature of selenium (compare Le Blanc, Reichenstein, Müller, and Abegg; references, *Z. physikal. Chem.*, 1921, 97, 257; 1922, 100, 346).

*The Effect of Light.*—The potential of one of the oxidation cells, which had been kept in darkness, was not affected by sudden exposure to direct sunlight, or to the light of four filament lamps at a distance of a foot. On the other hand, bright metallic electrodes (made by melting selenium on platinum) in hydrochloric acid solutions of selenium dioxide and selenium gave a potential which was distinctly influenced by exposure to light. The selenium rapidly lost its brightness and the photosensitiveness disappeared. A selenium electrode made by the cathodic deposition of selenium on a selenium rod, and therefore covered with a layer of the amorphous kind, was quite unaffected by light.\*

The photosensitiveness of the *E.M.F.* of selenium in aqueous solutions has been observed by Sabine and others (for references see C. Ries, "Das Selen," 1918, p. 188) and, although the significance of the presence of concentrated acid, selenium dioxide and dissolved selenium in determining the potential has not hitherto been emphasised, it is obviously of value in explaining the processes underlying many of their experiments.

These considerations are also useful in explaining the electro-metric titration of selenium solutions by the bimetallic electrode system of Willard and Fenwick (*J. Amer. Chem. Soc.*, 1923, 45, 933).

### Summary.

The system selenium dioxide-selenium in concentrated hydrochloric acid gives a reproducible oxidation potential which has been measured.

The potential is unaffected by the action of light.

The influence of concentration of selenium and of selenium dioxide on potential has been studied, the changes for tenfold dilutions corresponding to 0.022—0.028 volt.

The oxidising action of selenium dioxide is provisionally attributed

\* We are indebted to Mr. W. F. Waters for some assistance in these experiments.

to the presence of selenium tetrachloride, which yields positively charged selenium ions.

The oxidising action of selenium dioxide and of its analogue, sulphur dioxide, are compared.

We desire to express our thanks to the Department of Scientific and Industrial Research for a grant which enabled one of us (F. J.) to take part in this investigation.

### CXXXI.—*Applications of Thallium Compounds in Organic Chemistry. Part III. Alkylations.*

By CHRISTINA MARY FEAR and ROBERT CHARLES MENZIES.

THE preparation of alkyl derivatives by heating organic thallous compounds with alkyl iodides, suggested by the resemblance between thallous and silver halides, proceeds smoothly if the thallous compound is soluble in the alkylating agent, or if, being of an amorphous nature, it presents to it a large surface, whilst sparingly soluble, well-crystallised substances enter into the reaction slowly, if at all.

Thallous palmitate, for instance, which is appreciably soluble in methyl iodide, is completely converted into methyl palmitate by boiling with this solvent for 4 hours. Again the thallous salt of ethyl acetoacetate, readily soluble in cold ethyl iodide, requires 3 hours for ethylation, and the amorphous yellow *trithallium methylglucoside*, insoluble in methyl iodide, gives, after treatment for 5 hours, a trimethyl methylglucoside in good yield. On the other hand, treatment of the well-crystallised, sparingly soluble tetrathallium tartrate with boiling methyl iodide for 100 hours gives an incompletely methylated product, whilst an attempt to methylate the thallous salt of *o*-nitrophenol had to be discontinued. The preparation of trimethyl methylglucoside from trithallium methylglucoside is interesting in view of McKenzie's suggestion (J., 1899, 75, 765) that the most plausible explanation of methylation by Purdie's silver oxide method is that an intermediate unstable silver derivative is formed which subsequently undergoes double decomposition with the alkyl halides (see also Lander, J., 1900, 77, 747; 1903, 83, 416).

The rotations observed both in this case and in that of the product of methylation of tetrathallium tartrate indicate that at any rate in these instances racemisation does not occur.

## EXPERIMENTAL.

Treatment of their thallous salts with alkyl iodides affords a useful means of preparing small quantities of the esters of higher fatty acids. Thus from 0.47 g. and 0.55 g. of thallous stearate, 0.18 g. (m. p. 38.5°; yield 62%) and 0.26 g. (m. p. 37.5°; yield 79%) of methyl stearate were obtained, respectively, after refluxing for 4 hours with methyl iodide, and recovery of excess of this solvent, by extracting the resulting mixture of methyl stearate and thallous iodide with ether (Found in the latter sample: C, 76.4; H, 12.9. Calc., C, 76.4; H, 12.8%). By using larger quantities of material and benzene as solvent, almost theoretical yields may be obtained, thus 3.24 g. (theory, 3.26 g.) of methyl stearate (m. p. 38.5°) were produced by boiling 5.33 g. of thallous stearate with methyl iodide in benzene, a quantitative yield of thallous iodide also resulting.

The smaller-scale preparations, however, illustrate a convenient technique when small quantities of the higher fatty acids are under examination, it being easy to obtain from less than 1 g. of the acid its titration value, and its ethyl or methyl ester pure and in quantity sufficient for analysis and determination of melting point. Thus 0.579 g. and 0.557 g. of palmitic acid dissolved in alcohol required respectively 7.5 c.c. and 7.0 c.c. of 0.307*N*-aqueous thallous hydroxide (calc., 7.35 c.c. and 7.0 c.c.). On evaporation of the solution resulting from the former titration and treatment of the residual dry thallous palmitate with boiling methyl iodide, 0.4 g. of methyl palmitate was obtained (yield 66%; m. p. after recrystallisation from methyl alcohol 29.5°. Found: C, 75.4; H, 13.0. Calc., C, 75.5; H, 12.7%). Evaporation to dryness before treatment with methyl iodide is essential, as, on addition of methyl iodide to the solution resulting from the second titration and boiling under reflux as before, a product was obtained which had an acid reaction and a high melting point (31.5°).

By using propyl iodide, 2 g. of *propyl palmitate* were obtained from 5 g. of thallous palmitate by boiling for 1 hour (yield 63%; m. p. 15.3—15.4°, b. p. 209°/22 mm. Found: C, 76.5; H, 12.95.  $C_{19}H_{38}O_2$  requires C, 76.4; H, 12.8%). The low yield was due to loss in manipulation.

*Ethylation of Ethyl Acetoacetate.*—A boiling solution of 23.4 g. of thallous ethyl acetoacetate (Christie and Menzies, J., 1925, 127, 2372) in ethyl iodide rapidly deposited thallous iodide as a brick-red powder which became yellow after 2 hours. After boiling for a further hour, it was filtered off from the cooled mixture (yield, 21.8 g.; calc., 23.3 g.). On fractionation, 8.6 g. of ethyl ethyl-acetoacetate (yield 77.5%), distilled between 192° and 195° (uncorr.)/

756 mm. (Found: C, 60.7; H, 9.0. Calc., C, 60.7; H, 8.9%.  $D_D^{25}$  0.9924,  $n_D^{25}$  1.4237.  $R_D$ , 40.72. Calc. for keto-form, 40.98, for enol-form, 41.92; and for the isomeric ethyl  $\beta$ -ethoxycrotonate, 42.08. Compare Lander, *loc. cit.*, p. 738).

*Trithallium methylglucoside* may be obtained in good yield as a yellow, amorphous powder by adding methylglucoside dissolved in a little water to a hot concentrated solution of thallous hydroxide. If 4 equivalents of the latter be used to each molecular equivalent of methylglucoside, the thallium content of the product approximates closely to that required for trithallium methylglucoside (Found as iodide: Tl, 76.4, 76.15.  $C_7H_{11}O_6Tl_3$  requires Tl, 76.2%). The trithallium methylglucoside used for the methylation described below was prepared from 21.6 g. of  $\alpha$ -methylglucoside (m. p. 165.5°;  $[\alpha]_D +158.8^\circ$  for a 5.2% solution in water) in 13 c.c. of water and 206 c.c. of 1.62*N*-thallous hydroxide (3 equivs.), which immediately before the addition of the methylglucoside was concentrated by boiling to about half-bulk; 76.8 g. (yield 85%) separated at once (Found as iodide: Tl, 73.8%). 36.5 G. of this product were boiled with methyl iodide for 5 hours; the reaction was then complete. The excess of methyl iodide was removed, and the residue extracted with methyl alcohol; 9.8 g. of syrup (dried in a vacuum at 100°) were obtained, the theoretical yield calculated for trimethyl methylglucoside being 10.7 g. On distillation three fractions were obtained: (1) 2.25 g., b. p. 137°/2.2 mm.; (2) 4.35 g., b. p. 136.6°/2.3 mm. to 137.2°/1.5 mm.; (3) 1 g., b. p. 140°/2.5 mm. to 164°/1.8 mm. The optical and analytical data are in the following table:

$n_D$ .	$[\alpha]_D$ in water.	$[\alpha]_D$ * in ethyl alcohol.	C %.	H %.	OMe %.
(1) 1.4569	164° (1.6%)	165.9° (0.8%)	50.4	8.65	50.4
(2) 1.4592	153.1° (1.2%)	154.6° (1.2%)	50.9	8.5	49.0
(3) 1.464					46.0
Calc. for trimethyl methylglucoside:			50.8	8.5	52.5

\* Compare Purdie and Bridgett, J., 1903, 83, 1037, and Haworth, J., 1915, 107, 13.

*Attempted Preparation of Methyl Dimethoxysuccinate.*—From 75 g. of tetrathallium tartrate, boiled under reflux with methyl iodide for approximately 100 hours, 12.5 g. of a syrup were obtained, which distilled as a homogeneous liquid, b. p. 146°/25 mm. to 146.1°/23 mm.,  $n_D$  1.4363,  $[\alpha]_D$  72.17° (Found: OMe, 50.8, 51.6. Calc. for four methoxy-groups, OMe, 60.2%; for three methoxy-groups, OMe, 48.4%). The syrup did not solidify and a nucleus of methyl dimethoxysuccinate, kindly supplied by Professor Haworth, was dissolved.

*Preparation of o-Methoxybenzaldehyde.*—From 20.2 g. of thallous

salicylaldehyde, refluxed for 50 hours with methyl iodide in benzene, after removal of unchanged thallium salicylaldehyde by agitation with aqueous sodium hydroxide and subsequent distillation in steam, 5.2 g. of *o*-methoxybenzaldehyde, m. p.  $36.3^{\circ}$  (yield 62%) were obtained (Found: OMe, 21.0. Calc., OMe, 22.8%) (compare Irvine, J., 1901, 79, 668).

The authors wish to acknowledge with thanks further grants from the Research Fund Committee of the Chemical Society and the Colston Research Committee.

### CXXXII.—*Determination of the Rate of Hydrolysis of Sparingly Soluble Esters.*

By R. CHRISTIE SMITH and H. A. PATERSON.

THE rate of hydrolysis of esters is most conveniently determined by estimating the amount of free acid formed at successive intervals. With sparingly soluble esters this involves the use either of large quantities of ester solutions, or of smaller quantities, giving relatively larger percentage errors. The use of strong acid (or base) for hydrolysis in order to speed up the reaction and so give increased titrations, brings in its train the difficulty of accurately determining the amount of base (*e.g.*, baryta) necessary for neutralisation of the acid. A method has been evolved which minimises the above difficulties.

In the reaction equation  $dx/dt = kC$  the velocity coefficient can be interpreted as the fraction of the concentration  $C$  which is converted in the unit of time  $dt$ , and, for our purpose, it will be sufficiently accurate to define  $k$  as the fraction of the concentration  $C$  transformed in one minute. If, therefore, the solution is kept with a constant concentration  $C$  of ester, the same amount of ester will be transformed every minute. Hence it will only be necessary to keep the solution with a constant concentration of ester during a sufficiently long period to allow of a reasonable titration being obtained. The most convenient concentration is, of course, that of saturation. Hence if  $x$  c.c. of  $N$ -baryta represent the amount of ester transformed per minute in a 25 c.c. sample, the weight of ester transformed in 100 c.c. is  $0.004 Mx$  g.

In order to test the accuracy with which  $k$  could be determined by this method, propyl acetate, ethyl propionate, and propyl butyrate (see Table I), whose velocity coefficients could also be

determined in the usual way, were chosen. The results do not show such good agreement in the case of propyl acetate as of propyl butyrate, but this is ascribed to the fact that propyl acetate is more soluble, and hence diluted the aqueous layer to an abnormal extent (see below).

TABLE I.

Ester.	$k$ (homogeneous method).	$k$ (heterogeneous method).
Propyl acetate .	0.0063	0.0061
Ethyl propionate	0.0068	0.0071
Propyl butyrate.	0.0039	0.0039

TABLE II.

Ester.	$k$ (by new method).	Solubility (g. per 100 c.c.).
Benzyl acetate .	0.0051	0.234
Benzyl propionate	0.0056	0.078
Phenyl acetate .	0.0046	0.588

The velocity coefficients for the homogeneous reaction were determined in the usual manner. For the heterogeneous reaction of the substances in Table I, 250 c.c. of *N*-hydrochloric acid were shaken with an excess of the ester in a 300 c.c. ground-stoppered bottle in a rotary thermostat at 25°. At intervals, 25 c.c. of solution were withdrawn, 25 c.c. of *N*-sodium hydroxide added, and the excess of acid was titrated with baryta, the amount of ester transformed per minute being calculated from the titre. In the cases of benzyl acetate, benzyl propionate, and phenyl acetate, only 25 c.c. of *N*-hydrochloric acid were placed in the bottle, an excess of ester was added, and, after a given period in the thermostat, the whole was titrated. To ensure greater accuracy, the additions of normal acid and base were checked by weighing. The solubilities of these esters were determined by basic hydrolysis of 25 c.c. of saturated solution. The results are in Table II.

CXXXIII.—*Experiments on the Synthesis of Brazilin and Hæmatoxylin and their Derivatives. Part I. Veratrylidene-7-methoxychromanone and an Account of a New Synthesis of some Benzopyrylium Salts.*

By WILLIAM HENRY PERKIN, jun., JNANENDRA NATH RÂY, and ROBERT ROBINSON.

THE investigation of brazilin and hæmatoxylin by analytical methods, commenced in 1901 (Part I, Gilbody, Perkin, and Yates, J., 79, 1401) and completed in 1909 (Part X, Perkin and Robinson, J., 95, 381), resulted in the demonstration that brazilin has the constitution (I) and that hæmatoxylin is an analogous derivative of pyrogallol. In the course of the work a number of derivatives

of brazilin and hæmatoxylin were synthesised, the more important being anhydrobrazilic acid, brazilic acid, and the lactones of dihydrobrazilinic and dihydrohæmatoxylinic acids (Perkin and Robinson). Brazilinic acid (II) is an example of a derivative containing all the carbon atoms of trimethylbrazilin, and the correctness of the carbon skeleton of (I) was further confirmed by the

synthesis of isobrazilein and of isohæmatein (Crabtree and Robinson, J., 1918, 113, 859; 1922, 121, 1033), substances which contain intact the ring-system of brazilin. There exists, however, no synthetical \* proof of the position of the hydroxyl group in (I), since the production of 3:7-dihydroxychromone, an oxidation product of brazilein (Schall and Dralle, *Ber.*, 1888, 21, 3016), could be explained in a natural manner by several brazilein formulæ and, for example, by that in which the hydroxyl is in the position denoted by an asterisk in (I). Apart from this consideration an obvious interest attaches to the synthesis of brazilin, an interest which is only heightened by the difficulty of the problem and by the probable necessity of devising new methods for its solution. In 1911, Tschitschibabin and Nikitin (*J. Russ. Phys. Chem. Soc.*, 43, 1185) published a note on 7-methoxychromanone (III), and this led two of us to submit a preliminary note (P., 1912, 28, 7) on the experiments which had been made on the same subject with the object of synthesising trimethylbrazilin.

3-Veratrylidene-7-methoxychromanone (IV), m. p. 140°, was described in the note of 1912 and comment was made on its close relationship to trimethylbrazilin. Pfeiffer and Grimmer (*Ber.*, 1917, 50, 911) then announced their intention of attacking the problem of the synthesis of brazilin and its derivatives and selected the method indicated in the above-mentioned note of 1912. These

\* The position assigned to the hydroxyl in (I) is indicated by the fact that tetramethyldihydrobrazileinol yields trimethylbrazilone on oxidation (Engels, Perkin, and Robinson, J., 1908, 83, 1130).

authors reported the preparation of anisylidene-7-methoxychromanone, and in consequence the fact that a nearer relative of brazilin, namely, veratrylidene-7-methoxychromanone, had been prepared was pointed out in a footnote to a paper in this *Journal* (1918, 113, 859). Undeterred by this, Pfeiffer and Emmer (*Ber.*, 1920, 53, 945) proceeded to the preparation of veratrylidene-7-methoxychromanone, m. p. 140°, and stated that they had succeeded in reducing the substance to a dihydro-derivative (V) by means of hydrogen in the presence of platinum black.

The experiments on this subject, interrupted at the time because of other interests, have now been resumed, and in this communication we bring together some observations arising out of work as yet unfinished. The preparation of (V) was one of the primary objects of the investigation, since dehydration to (VI) should be feasible. We are, however, of the opinion, for various reasons, that the product of the catalytic \* hydrogenation of veratrylidene-7-methoxychromanone is 3-homoveratryl-7-methoxychroman (VII) and not the ketone (V) as suggested by Pfeiffer and Emmer (*loc. cit.*).

This result is by no means unique, since Freudenberg (*Ber.*, 1920, 53, 1416) has shown that the pentamethoxychalkone (VIII) is reduced to the related diphenylpropane derivative by hydrogen in presence of spongy platinum.

Further attempts to reduce veratrylidene-7-methoxychromanone to a dihydro-derivative will be made. Our objects in making certain further experiments are explained in the sequel (pp. 947, 948, 950). In the presence of acid condensing agents veratrylidene-7-methoxychromanone (IV) might be expected to undergo internal condensation with formation of isobrazilein salts, readily recognisable on account of the intense green fluorescence which they exhibit. Under several sets of conditions it was, in fact, noticed that substances exhibiting intense green fluorescence could be derived from

\* We employed palladium as the catalyst, but it should be noted that platinum is usually regarded as even more efficient.

veratrylidene-7-methoxychromanone. The yield was usually very small, but when the unsaturated ketone was dissolved in acetic anhydride and anhydrous ferric chloride added, a relatively considerable amount of an oxonium ferrichloride was produced. The new salt was readily purified and exhibited an even more striking fluorescence than isobrazilein chloride trimethyl ether. It has the composition  $C_{19}H_{15}O_5Cl_4Fe$  and is therefore derived from veratrylidene-7-methoxychromanone,  $C_{19}H_{16}O_5$ , by some process of oxidation. In considering this matter it seemed possible that the pyrylium ring, which the salt obviously contained, might be produced, not by modification of the heterocyclic system already present, but by attachment of the oxygen of the carbonyl group to carbon of the veratrole nucleus. The following partial formulæ will serve to make this suggestion clear:

Such a reaction, leading to the formation of a benzopyrylium salt, has not been previously observed, but it is similar, both in principle and in method, to Diltz's synthesis of pyrylium salts (*J. pr. Chem.*, 1916, 94, 53) and it also resembles many methods of preparation of oxazine, thiazine and azine dyestuffs. The simplest analogy is furnished by an observation recently made by Gomberg and Nishida (*J. Amer. Chem. Soc.*, 1923, 45, 190): *o*-hydroxy-triphenylcarbinol in solution above  $100^\circ$  yields 9-phenylxanthane (X), no doubt through the intermediate (IX).

We found support for this view of the reaction in the fact that veratrylidene-5:6-dimethoxyhydrindone (XI) could be similarly oxidised to an oxonium ferrichloride (XII), and several further cases have been discovered.

The process is nevertheless not a very general one and up to the present we have only found it to succeed with the veratrylidene, *o*-veratrylidene or piperonylidene derivatives of cyclic ketones. Thus veratrylideneacetoveratrone and *m*- or *p*-methoxybenzylidene-5:6-dimethoxyhydrindone gave negative results.

#### EXPERIMENTAL.

*m*-Methoxyphenol.—The conditions for the semi-methylation of resorcinol have been studied and the following process has been devised. Potassium hydroxide (40 g.) dissolved in water (100 c.c.) was gradually added to a mixture of resorcinol (110 g.), alcohol (100 c.c.), and methyl sulphate (120 c.c.), which was frequently shaken and cooled in running water. An hour afterwards, an equal quantity of aqueous potassium hydroxide was gradually introduced and finally the mixture was heated on the steam-bath for 45 minutes. The solution was then acidified, extracted with benzene and the separated benzene layer was washed with aqueous sodium hydroxide until nothing more was removed. The alkaline solutions were acidified and again extracted with benzene. This process removes unchanged resorcinol and resorcinol dimethyl ether may be recovered from the first benzene solution. The second benzene extract was dried and distilled, 50 g., b. p. 240–242°, being obtained.

$\beta$ -*m*-Methoxyphenoxypropionic Acid.—This substance was originally obtained from *m*-methoxyphenol in aqueous alkaline solution by interaction with  $\beta$ -iodopropionic acid. The use of  $\beta$ -bromopropionic acid results in rather improved yields, but  $\beta$ -chloropropionic acid is still better. A solution of  $\beta$ -chloropropionic acid (60 g.) in water (225 c.c.) and sodium bicarbonate (45.3 g.) was mixed with one of *m*-methoxyphenol (67.5 g.) in aqueous potassium hydroxide (100 c.c. of 30%), and the liquid heated on the steam-bath for 3 hours. After acidification, the mixture was extracted with ether, and the acid removed from the extract by means of aqueous sodium bicarbonate.  $\beta$ -*m*-Methoxyphenoxypropionic acid (30 g.) and recovered *m*-methoxyphenol (28–30 g.) were ultimately isolated.

We refrain from detailed descriptions of the substances mentioned in the note of 1912 (*loc cit.*), the properties of which have since been placed on record by Pfeiffer and his colleagues.

*m*- $\beta$ -Hydroxyethoxyanisole, b. p. 290°/15 mm., was prepared from *m*-methoxyphenol, sodium ethoxide, and ethylene chlorohydrin in alcoholic solution. In an attempt to replace the hydroxyl group in this substance by bromine with the ultimate object of preparing  $\beta$ -*m*-methoxyphenoxypropionitrile, a curious result was

obtained. The glycol ether (11 g.) was dissolved in benzene and phosphorus tribromide (20 g.) added, causing a copious evolution of hydrogen bromide. The mixture was gently heated in the steam-bath for 2 hours, and the neutral product isolated. This was dissolved in alcohol, and the solution boiled for 3 hours after the introduction of a concentrated aqueous solution of potassium cyanide (5 g.). On addition of water, a solid (6 g.) was precipitated and the substance crystallised from alcohol in long, colourless needles, m. p. 65° (Found: C, 70.1; H, 6.6.  $C_{16}H_{18}O_4$  requires C, 70.1; H, 6.5%). The substance appears to be the ethylene ether of *m*-methoxyphenol,  $MeO \cdot C_6H_4 \cdot O \cdot CH_2 \cdot CH_2 \cdot O \cdot C_6H_4 \cdot OMe$ .

7-Methoxychromanone (III) has been prepared by several methods but, although it is not satisfactory, the original process of dehydration of methoxyphenoxypropionic acid in benzene solution by means of phosphoric anhydride is still the best. Phosphoric anhydride (80–90 g.) was gradually added to a gently boiling solution of methoxyphenoxypropionic acid (30 g.) in benzene (200 c.c.). After heating for 4 hours, the neutral ketone was isolated and purified by distillation. The yield was 6–8 g., b. p. 197°/30 mm., m. p. 56° after crystallisation from light petroleum. The semicarbazone separates from alcohol in glistening plates, m. p. 222° (decomp.).

3-Veratrylidene-7-methoxychromanone (IV).—This substance was at first prepared by condensation of 7-methoxychromanone and veratraldehyde in methyl-alcoholic solution in presence of potassium hydroxide, but the following is a much improved method. A rapid stream of hydrogen chloride was passed for one hour through a solution of methoxychromanone (5 g.) and veratraldehyde (5 g.) in acetic acid (10 c.c.) cooled in a freezing mixture. Next day the deep red solution was filled with a red crystalline mass of the *hydrochloride* of the unsaturated ketone and this was collected and decomposed with crushed ice. The substance was finally crystallised from much methyl alcohol, separating in colourless needles, m. p. 141°. The yield was 5.6 g.

3-Homoveratryl-7-methoxychromanone (VII).—A solution of veratrylidene-7-methoxychromanone (7 g.) in acetic acid (200 c.c.) was mixed with aqueous palladous chloride (30 c.c. of 1%) and agitated in an atmosphere of hydrogen until absorption of the gas slackened. The temperature was then raised to 50–60° and the agitation in hydrogen continued for about 6 hours. Most of the acetic acid was removed from the filtered solution by distillation under diminished pressure, and the residue neutralised with aqueous sodium carbonate. The colourless solid which was precipitated was collected and when once crystallised from methyl alcohol had m. p. 89°. This is the m. p. assigned by Pfeiffer and Emmer (*loc. cit.*)

to the supposed ketonic product of the catalytic hydrogenation of veratrylidene-methoxychromanone. After three or four successive crystallisations from methyl alcohol or from aqueous acetone, the substance is obtained in slender, colourless needles, m. p. 96—97° (Found: C, 72.2; H, 7.2.  $C_{19}H_{22}O_4$  requires C, 72.6; H, 7.0%). The substance dissolves in sulphuric acid to a pale rose solution and is inactive towards reagents for the carbonyl group. We do not go so far as to assert that the products of the hydrogenation of veratrylidene-methoxychromanone in presence of platinum (Pfeiffer and Emmer) and of palladium are identical, although we think it probable that this will prove to be the case.\* We have not been able to isolate any product of the reduction other than that here described and it is noteworthy that, whereas the semicarbazone of the reduction product of anisylidene-methoxychromanone was described (Pfeiffer and Emmer, *loc. cit.*), no proof, other than analysis, was offered of the ketonic nature of the reduction product, m. p. 89°, of veratrylidene-methoxychromanone.

*Di- $\omega$ -6-nitropiperonylisobutyrophenone,*

—Attempts are in progress to introduce the homoveratryl group into 7-methoxychromanone by a direct process and preliminary experiments on the interaction of the sodium derivative of acetophenone and homopiperonyl † bromide have been made. Powdered sodamide (2 g.) was added to acetophenone (6 c.c.) dissolved in dry ether (75 c.c.) and, after the mixture had been occasionally shaken during an hour, homopiperonyl bromide (11 g.) was added to the clear solution. The mixture was heated on the steam-bath for 1 hour, water was added, and ether and acetophenone were removed in

\* It would be anticipated that the m. p. of a chromanone should be higher than that of the related chroman.

† Possibly on account of its close relation to piperonal the alcohol  $CH_2O_2:C_6H_5\cdot CH_2\cdot OH$  has been called piperonyl alcohol, and consequently the amine,  $CH_2O_2:C_6H_5\cdot CH_2\cdot CH_2\cdot NH_2$ , has been named homopiperonylamine. This nomenclature is, however, erroneous and its continuance must necessarily create confusion. The historical case for regarding the group  $CH_2O_2:C_6H_5\cdot$  as piperonyl is overwhelming; thus Ladenburg termed

piperonylacrolein and the words piperonyl, veratryl, and anisyl have been very widely employed to indicate the corresponding substituted phenyl groups. The compound often called piperonyl alcohol is really homopiperonyl alcohol and the base for which the usual name is homopiperonylamine is best termed  $\beta$ -piperonylethylamine. It is obviously undesirable to employ one and the same word to denote two different radicals (compare Robinson and Robinson, J., 1914, 105, 1461; Oberlin, *Arch. Pharm.*, 1925, 9, 10).

a current of steam. The residual yellow oil could not be crystallised but, on nitration in acetic acid solution, it yielded a compound which crystallised from benzene in needles, m. p.  $193^{\circ}$  with sintering at  $175^{\circ}$  (Found: C, 51.5; H, 3.5.  $C_{16}H_{13}O_8N_3$  requires C, 51.2; H, 3.5%). The substance appears to be *dinitrodihomopiperonylamine*,  $CH_2O_2:C_6H_2(NO_2)\cdot CH_2\cdot NH\cdot CH_2\cdot C_6H_2(NO_2):O_2CH_2$ , obtained from homopiperonyl bromide and ammonia followed by nitration. The experiment was therefore repeated under the same conditions with the single exception that ammonia was removed from the ethereal solution by means of a current of nitrogen before introduction of the homopiperonyl bromide. In this case also the product was an oil which gave a nitro-derivative, crystallising from benzene in slender needles, m. p.  $160-161^{\circ}$  (Found: C, 60.4, 60.3; H, 3.9, 4.0; N, 6.0.  $C_{24}H_{18}O_9N_2$  requires C, 60.3; H, 3.8; N, 5.9%). The composition of this substance is in agreement with the hypothesis that it is the ketone figured at the head of this section. We have not yet completed our experiments on the homoveratrylation of methoxychromanone, but it may be mentioned that in the course of the preparation of homoveratryl alcohol a further case of the production of a derivative of cinnamic acid in a Cannizzaro reaction, carried out in the presence of ethyl alcohol, has been observed (compare Perkin and Stoyle, J., 1923, 123, 3174). Potassium hydroxide (30 g.) dissolved in ethyl alcohol (75 c.c. of 98%) was added to veratraldehyde (20 g.) dissolved in the same solvent (25 c.c.). Next day, the crystals which had separated were collected and found to consist of potassium 3:4-dimethoxycinnamate and to yield 7.8 g. of the corresponding acid. Veratric acid and homoveratryl alcohol were isolated from the filtrate in the usual manner.

*2-Bromo-5:6-dimethoxy-1-hydrindone*,  $C_6H_2(OMe)_2\begin{smallmatrix} \text{CO} \\ \diagup \quad \diagdown \\ \text{CH}_2 \end{smallmatrix}CHBr$ .

—A portion (18 c.c.) of a solution of bromine (1 c.c.) in carbon tetrachloride (20 c.c.) was gradually added to 5:6-dimethoxyhydrindone (3.0 g.) dissolved in warm carbon tetrachloride (30 c.c.). After 1 hour the thick paste that had been produced (3.0 g.) was washed with carbon tetrachloride; it crystallised from alcohol in very pale yellow, rectangular plates, m. p.  $157^{\circ}$  (Found: Br, 28.3.  $C_{11}H_{11}O_3Br$  requires Br, 29.5%).

*2-Cyano-5:6-dimethoxy-1-hydrindone*,  $C_6H_2(OMe)_2\begin{smallmatrix} \text{CO} \\ \diagup \quad \diagdown \\ \text{CH}_2 \end{smallmatrix}CH\cdot CN$ .

—This substance was prepared in order to attempt the synthesis of a coumarin derivative by condensation with resorcinol. Such a substance would be closely related to trimethylbrazilin. A mixture of 2-bromo-5:6-dimethoxy-1-hydrindone (3 g.), alcohol (40 c.c. of 95%), potassium cyanide (1.5 g.), and water (20 c.c.) was boiled

under reflux for 3 hours, then cooled, acidified with acetic acid, and extracted with ether. The residue left after removal of the solvent from the extract crystallised from alcohol in clusters of radiating needles (1—1.5 g.), m. p. 174° (Found: C, 66.1; H, 4.8.  $C_{12}H_{11}O_3N$  requires C, 66.3; H, 5.0%). The substance dissolves in dilute aqueous potassium hydroxide to a very pale yellow solution and gives no coloration with alcoholic ferric chloride. On hydrolysis with boiling 50% sulphuric acid, 5:6-dimethoxyhydrindone, identified by conversion into its piperonylidene derivative, m. p. 245°, was obtained. In a subsequent experiment, the proportion of water employed was reduced, and in this case, in addition to the above-described nitrile, a polymeric modification or condensation product of it was obtained. Bromo-5:6-dimethoxyhydrindone (10 g.), absolute alcohol (60 c.c.), potassium cyanide (3.5 g.), and water (5 c.c.) were mixed and then boiled under reflux for 2 hours, water (10 c.c.) being gradually introduced during this period. The product was added to water, and the solid (5 g.) collected. On acidification the filtrate gave 1.5 g. of the normal nitrile. The main product was sparingly soluble in most organic solvents and crystallised from glacial acetic acid in needles, m. p. 256—257° to a red liquid (Found: C, 66.4; H, 5.4%). The substance is insoluble in dilute aqueous potassium hydroxide.

*Ethyl 5:6-Dimethoxy-1-hydrindone-2-carboxylate,*

—A solution of the nitrile, m. p. 174°, described in the last section, in 20 times its weight of absolute alcohol was saturated with hydrogen chloride at the ordinary temperature for 3 hours, then boiled for 10 minutes and added to ice-cold water. The solid which separated crystallised from alcohol in colourless needles, m. p. 138° (decomp.) (Found: C, 63.9; H, 6.3.  $C_{14}H_{16}O_5$  requires C, 63.6; H, 6.1%). This ester gives with ferric chloride in alcoholic solution a transient green and then a blue coloration. We have not yet prepared a coumarin derivative from either the nitrile or the ester by condensation with resorcinol, although a number of trials have been made.

*5:6-Dimethoxy-1-hydrindone-resorcinol,*

—A solution of dimethoxyhydrindone (9.0 g.) and resorcinol (7.0 g.) in acetic acid (35 c.c.) was saturated with hydrogen chloride in the cold, kept for 1 hour, and added to water (150 c.c.). The resulting

clear liquid was neutralised with sodium carbonate; the yellow, crystalline deposit separated from boiling water in silky needles, m. p.  $78^{\circ}$  (Found: C, 67.9; H, 6.0.  $C_{17}H_{18}O_5$  requires C, 67.6; H, 5.9%). A small quantity of a yellow oil was separated in the above process on account of its sparing solubility in hot water. This consists of a substance which crystallises from methyl alcohol in needles, m. p.  $227^{\circ}$ . The by-product has not yet been further examined, nor has the compound, m. p.  $78^{\circ}$ , been characterised by the preparation of derivatives. It is remarkably sensitive to alkalis, being quantitatively resolved into its components, namely, dimethoxyhydrindone and resorcinol, by means of cold aqueous sodium hydroxide. Attempts to prepare an indene derivative by dehydration of this substance were fruitless. It is not a mere molecular compound, since it is not obtained in the absence of a condensing agent.

2:3-[7-Methoxychromeno (4:3)]-6:7-dimethoxybenzopyrylium Ferrichloride,

—Anhydrous ferric chloride (5.0 g.) was added to a solution of veratrylidene-7-methoxychromanone (1.0 g.) in acetic anhydride (25 c.c.) and when the reaction had subsided a further quantity of ferric chloride (3.0 g.) was added. After 10 minutes, the product was added to water (250 c.c.), and a ferrichloride precipitated by addition of a concentrated solution of ferric chloride in hydrochloric acid. The substance (yield almost quantitative) crystallised from acetic acid in crimson, prismatic needles, m. p.  $213^{\circ}$ , exhibiting a blue reflex (Found: C, 43.7, 43.4; H, 3.5, 3.2.  $C_{19}H_{15}O_5Cl_4Fe$  requires C, 43.6; H, 3.3%). Solutions of this salt in all solvents and particularly those in alcohol and acetic acid exhibit an extraordinarily brilliant greenish-yellow fluorescence. The salt is very sparingly soluble in acetic acid and more readily soluble in hot formic acid.

2-m-Methoxybenzylidene-5:6-dimethoxy-1-hydrindone.—This compound was obtained by condensation of dimethoxyhydrindone and m-methoxybenzaldehyde in hot alcoholic solution containing a few drops of concentrated aqueous potassium hydroxide. The yield was practically quantitative and the sparingly soluble substance crystallised from ethyl acetate in pale yellow needles, m. p.  $164-165^{\circ}$  (Found: C, 73.6; H, 5.7.  $C_{19}H_{18}O_4$  requires C, 73.5; H, 5.8%).

Neither this substance nor the isomeric anisylidenedimethoxyhydrindone could be converted into a pyrylium salt by means of ferric chloride in acetic anhydride solution.

3 : 4-Dimethoxystyryl Veratryl Ketone,

—An ethyl-alcoholic solution of equivalent quantities of veratraldehyde and acetoveratrone, together with a few drops of concentrated aqueous potassium hydroxide, was boiled for 10 minutes. The oil then precipitated by water solidified on repeated washing with cold water and aqueous alcohol. The substance crystallised from alcohol in flat, yellow prisms, m. p. 116° (Found : C, 69·3; H, 6·1.  $\text{C}_{19}\text{H}_{20}\text{O}_5$  requires C, 69·5; H, 6·1%). The compound is not changed to a pyrylium salt by the action of ferric chloride in acetic anhydride solution. This fact may be compared with the ready conversion of veratrylidenedimethoxyhydrindone into an oxonium ferrichloride by oxidation with ferric chloride. In the latter case, the carbon atoms in the asterisked positions in the above formula are connected by a methylene group.

2-Veratrylidene-4 : 6-dimethoxycoumaranone,

—A solution of equivalent quantities of veratraldehyde and 4 : 6-dimethoxycoumaranone (Sonn, *Ber.*, 1917, 50, 1265) in five times their weight of acetic acid was cooled in a freezing mixture and saturated with hydrogen chloride. The liquid was filled with a mass of deep red crystals of a hydrochloride in 1·5 hours; these were collected and decomposed by water, giving a bright yellow substance which crystallised from alcohol in needles, m. p. 175° (Found : C, 66·1; H, 4·9.  $\text{C}_{19}\text{H}_{18}\text{O}_6$  requires C, 66·6; H, 5·2%). No pyrylium salt could be isolated from the product of the action of ferric chloride and acetic anhydride on this substance.

2-Veratrylidene-1-hydrindone,  $\text{C}_6\text{H}_4 \left\langle \begin{array}{c} \text{CO} \\ \text{CH}_2 \end{array} \right\rangle \text{C} : \text{CH} \cdot \text{C}_6\text{H}_3(\text{OMe})_2$ .—

An ice-cold mixture of veratraldehyde (4·5 g.),  $\alpha$ -hydrindone (3 g.), and acetic acid (15 c.c.) was saturated with hydrogen chloride and after 3 hours the scarlet hydrochloride was collected, washed with acetic acid, and decomposed with water; the resulting yellow compound crystallised from acetic acid in prisms, m. p. 175° (Found : C, 76·6; H, 5·8.  $\text{C}_{18}\text{H}_{16}\text{O}_3$  requires C, 77·2; H, 5·7%).

2 : 3-Indeno(1 : 2)-6 : 7-dimethoxybenzopyrylium Ferrichloride (formula similar to XII).—Anhydrous ferric chloride (15 g.) was added in portions of about 3 g. during an hour to a solution of

veratrylidene-1-hydrindone (2 g.) in acetic anhydride (35 c.c.). After 2 hours, the dark red mixture was added to a concentrated solution of ferric chloride in hydrochloric acid, and the precipitate was collected, dried, and extracted with acetic acid; the chocolate residue crystallised from absolute formic acid in brownish-red prisms, m. p. 237—238°, twinning characteristically with formation of a symmetrical cross (Found: C, 45.4; H, 3.2.  $C_{18}H_{15}O_3Cl_4Fe$  requires C, 45.5; H, 3.1%). A similar, even more sparingly soluble, ferrichloride may be obtained analogously from piperonylidene-hydrindone.

2 : 3[5 : 6-Dimethoxyindeno(1 : 2)]-6 : 7-dimethoxybenzopyrylium *Ferrichloride* (XII).—Anhydrous ferric chloride (10 g.) was gradually added to a mechanically stirred solution of 2-veratrylidene-5 : 6-dimethoxy-1-hydrindone (Perkin and Robinson, J., 1907, **91**, 1073) (3.7 g.) in acetic anhydride (50 c.c.) cooled in melting ice. After  $\frac{1}{2}$  hour, the vessel was removed from the cooling bath and a further equal quantity of sublimed ferric chloride added. After 15 minutes, the vessel was immersed in water at 40—50° and stirring continued for 20 minutes. Next day, decomposition with aqueous hydro-ferrichloric acid gave a gelatinous precipitate, which was collected and became crystalline on boiling with acetic acid. The substance crystallised from formic acid in deep brownish-crimson needles, m. p. 246—247°, with bluish-green reflex (Found: C, 45.0; H, 3.7.  $C_{20}H_{19}O_5Cl_4Fe$  requires C, 44.9; H, 3.6%). Solutions of this salt in alcohol or formic acid exhibit a phenomenal, greenish-yellow fluorescence. The substance is insoluble in cold acetic acid and sparingly soluble in formic acid.

2 : 3[5 : 6-Dimethoxyindeno(1 : 2)]-6 : 7-methylenedioxybenzopyrylium *Ferrichloride* (formula similar to XII).—Anhydrous ferric chloride (20 g.) was gradually added to a stirred solution of 2-piperonylidene-5 : 6-dimethoxy-1-hydrindone (3.5 g.) in acetic anhydride (50 c.c.) during 2 hours. The product, isolated in the usual manner, was extracted by acetic acid and crystallised from formic acid in hæmatite-red, microscopic prisms, m. p. 270° (decomp.) (Found: C, 43.6; H, 3.0.  $C_{19}H_{15}O_5Cl_4Fe$  requires C, 43.8; H, 2.9%). This very sparingly soluble substance exhibits a vivid greenish-yellow fluorescence in formic acid solution.

2-(2 : 3-Dimethoxybenzylidene)-1-hydrindone,

—This substance was obtained in almost theoretical yield by the methylation of 2-hydroxy-3-methoxybenzylidenehydrindone (Lawson and Robinson, J., 1924, **125**, 207) by means of methyl sulphate and potassium hydroxide in alcoholic solution. It crystallises from

alcohol in pale yellow prisms, m. p. 124° (Found: C, 77·2; H, 5·3.  $C_{18}H_{16}O_3$  requires C, 77·2; H, 5·7%).

2 : 3-Indeno(1 : 2)-5 : 6-dimethoxybenzopyrylium Ferrichloride (formula after XII).—Anhydrous ferric chloride (18 g.) was gradually added to a stirred solution of 2 : 3-dimethoxybenzylidenehydrindone (3 g.) in acetic anhydride (40 c.c.) during 1·5 hours. The product, isolated in the usual manner, crystallised from acetic acid in crimson leaflets or flat needles, m. p. 168° (Found: C, 45·2; H, 3·3.  $C_{18}H_{15}O_3Cl_4Fe$  requires C, 45·5; H, 3·1%). This salt does not exhibit strong fluorescence in any solution. *o*-Veratrylidenehydrindone might have given indeno-8-methoxybenzopyrylium ferrichloride, m. p. 187° (Lawson and Robinson, *loc. cit.*), by hydrolysis of the *o*-situated methoxyl group, but a mixture of the salts, m. p. 168° and 187°, melted indefinitely at about 140°.

2' : 3' : 5 : 6-Tetramethoxy-2-benzylidene-1-hydrindone,

—The coppery-red potassium salt, resulting from the condensation of *o*-vanillin and 5 : 6-dimethoxyhydrindone in alcoholic solution in presence of potassium hydroxide, was methylated by means of methyl sulphate. The product crystallised in glistening yellow leaflets, m. p. 183—184°, from ethyl acetate-methyl alcohol (Found: C, 70·5; H, 5·2.  $C_{20}H_{20}O_5$  requires C, 70·8; H, 5·6%). Anhydrous ferric chloride and acetic anhydride convert this substance into a ferrichloride crystallising from formic acid in brick-red leaflets, m. p. 211° (decomp.). The m. p. of the salt described below is depressed by admixture with this compound, and the salt, m. p. 211°, is therefore, in all probability, 2 : 3[5 : 6-dimethoxyindeno(1 : 2)]-5 : 6-dimethoxybenzopyrylium ferrichloride.

2 : 3[5 : 6-Dimethoxyindeno(1 : 2)]-8-methoxybenzopyrylium Ferrichloride (formula after XII).—A solution of equivalent quantities of *o*-vanillin and 5 : 6-dimethoxyhydrindone in acetic acid was saturated with hydrogen chloride for 2 hours; it was then diluted with water and a ferrichloride precipitated. The latter crystallised from much acetic acid in brownish-red needles, m. p. 250° (decomp.) (Found: C, 45·1; H, 3·6.  $C_{19}H_{17}O_4Cl_4Fe$  requires C, 45·0; H, 3·3%). Solutions of this salt do not exhibit fluorescence.

We wish to thank the Chemical Society for a grant which has defrayed a part of the expense of this investigation.

THE UNIVERSITIES OF OXFORD AND MANCHESTER.

[Received, January 14th, 1926.]

## NOTES.

*Acetyl-o-phenylenediamine and Acetyl-1:2:3-benztriazole.* By

FRANK BELL and JOSEPH KENYON.

THE cumbrous procedure for the preparation of acetyl-*o*-phenylenediamine described by Leuchs (*Ber.*, 1907, **40**, 1085) can with advantage be replaced by the following simplified method. Aluminium amalgam is added to a solution of *o*-nitroacetanilide in moist ether until the yellow colour of the solution is discharged. Owing to its limited solubility in ether, acetyl-*o*-phenylenediamine separates from the solution along with aluminium hydroxide, from which it is extracted by means of boiling benzene. It separates from benzene in small, lustrous plates, m. p. 132°.

On addition of the calculated amount of sodium nitrite to a solution of this compound in hydrochloric acid, there is produced an immediate precipitate of acetyl-1:2:3-benztriazole, which crystallises from alcohol in compact needles, m. p. 51° (Found: CH<sub>3</sub>·CO, 26·7. C<sub>8</sub>H<sub>7</sub>ON<sub>3</sub> requires CH<sub>3</sub>·CO, 26·7%). Acetyl-1:2:3-benztriazole is hydrolysed with extreme ease to give 1:2:3-benztriazole (m. p. 98°), which on acetylation reforms the acetyl derivative of m. p. 51°.—BATTERSEA POLYTECHNIC, LONDON, S.W. 11. [*Received, February 23rd, 1926.*]

---

*Density of Boric Oxide from a Fractional Crystallisation of Boric Acid.* By HENRY VINCENT AIRD BRISCOE, PERCY LUCOCK ROBINSON, and GEORGE EDWARD STEPHENSON.

A PREVIOUS communication (Briscoe, Robinson, and Stephenson, *J.*, 1925, **127**, 155) described a systematic fractional crystallisation of boric acid, involving about 1150 crystallisations. As the analytical method then applied proved useless to detect any differences in the atomic weight of boron resulting from this treatment, two end-fractions of boric acid which were still available were converted into boric oxide glass and the densities of these samples were compared by the flotation method recently described (*idem*, this vol., p. 70). The flotation liquid was the mixture of pentachloroethane and trimethylene bromide previously used having  $d_{4}^{27.00}$  1.79773 and  $d_{4}^{28.45}$  1.79372.

The data and results are as follows :

Origin of Sample.	Flotation Temp.	Density.	Relative Atomic weight.
Head Fraction Series B .....	18.18°	1.79415	10.790
Tail Fraction Series B .....	19.00	1.79445	10.796

In these determinations, the beads of each sample showed rather greater variations in density among themselves than did those derived from the various mineral sources (except sample No. 6) described in the previous communication. Therefore the authors attach little value to the third decimal figure in the present results and consider that these simply serve to indicate, in consonance with the results of a previous investigation on bromine (Robinson and Briscoe, J., 1925, 127, 138), that fractional crystallisation of boric acid has produced no change as great as 0.01 in the atomic weight of boron.

The authors desire to acknowledge a grant from the Department of Scientific and Industrial Research enabling one of them (G. E. S.) to take part in this work.—UNIVERSITY OF DURHAM, ARMSTRONG COLLEGE, NEWCASTLE-UPON-TYNE. [*Received, March 12th, 1926.*]

*A Synthesis of 1 : 2-Dihydroquinaldine. A Correction.* By  
FREDERICK ALFRED MASON.

IN a previous communication (J., 1925, 127, 1032), a description was given of a synthesis of "1 : 2-dihydroquinaldine," having the properties of the substance recorded by R  th (*Ber.*, 1924, 57, 555). As subsequent work (*e.g.*, Meisenheimer and Stolz, *Ber.*, 1925, 58, 2330; K  nig and Buchheim, *ibid.*, p. 2868) has cast doubts upon the validity of some of R  th's results, a re-examination of the present author's product has been made. The melting points of the recrystallised picrates of the "1 : 2-dihydroquinaldine" and of quinaldine were carefully compared and no depression was observed on admixture, so that the product obtained by the author and described as 1 : 2-dihydroquinaldine was in fact a mixture consisting largely of quinaldine itself, and the prefix "1 : 2-dihydro" should accordingly be deleted from the title. From the results of the previous analysis, which agreed almost exactly with the theoretical figures for dihydroquinaldine (0.0882 g. gave 0.2674 g. CO<sub>2</sub> and 0.0605 g. H<sub>2</sub>O : C, 82.7; H, 7.6%. 0.1451 g. gave 12.4 c.c. N<sub>2</sub> at 18° and 754 mm. N, 9.7%) it now seems certain that the product obtained was a mixture of quinaldine and a hydrogenated substance, possibly tetrahydroquinaldine or *isobutylaniline*. This would agree with the work of Jones and Evans (J., 1911, 99, 334), who showed that the so-called "aldol base" from *p*-toluidine gave, on treatment with acids, a mixture of 2 : 6-dimethylquinoline and 2 : 6-dimethyl-tetrahydroquinoline; similar results were obtained with the "aldol base" from *m*-xylydine (compare also Mills, Harris, and Lambourne, J., 1921, 119, 1924).

Owing to the small amount dealt with, attempts to separate the

mixture were unsuccessful; its exact composition can be settled only by further investigation with larger quantities of material.—  
DYSON PERRINS LABORATORY, OXFORD. [Received, March 8th, 1926.]

*The Reduction of Ethyl Dibenzylacetoacetate.* By ELLEN  
SUSAN HILL.

DIALKYL- and diaryl-substitution products of ethyl acetoacetate should, theoretically, be convertible into quaternary hydrocarbons by well-known general reactions; ethyl dibenzylacetoacetate, for example, might be transformed into ethylisopropyldibenzylmethane:

Many attempts to carry out the first of these stages have been made; an alcoholic solution of the ester was treated with sodium, sodium amalgam, zinc and acids, hydrogen and colloidal platinum, amalgamated zinc and acids; and the ester was treated with sodium and amyl alcohol, but the only products isolated were the unchanged substance and an acid, m. p. 89° (see below). The ester was also unattacked by phosphorus pentachloride and therefore could not be reduced indirectly through the dichloro-derivative. Its stability under the conditions noted suggests steric hindrance.

By the action of sodium (twenty times the theoretical) on an ethereal solution of the ester floating on sodium hydroxide solution, two additional products were isolated. One of these was a neutral oil distilling at about 290° and probably dibenzylacetone (C, 84·6; H, 7·2; *M*, 212.  $\text{C}_{17}\text{H}_{18}\text{O}$  requires C, 85·7; H, 7·4%; *M*, 238), and the other an acid, crystallising from light petroleum, melting at 152—153° and probably hydroxyethyldibenzylacetic acid (Found: Ag, 27·6.  $\text{C}_{18}\text{H}_{19}\text{O}_3\text{Ag}$  requires Ag, 27·6%). The yields were so small that the compounds were not fully identified.

In attempting to prepare ethyl dibenzylacetoacetate (m. p. 57°) by the action of benzyl chloride on a methyl-alcoholic solution of sodium methoxide an ester melting at 41° was obtained. This was proved to be *methyl dibenzylacetate* by preparing it from dibenzylacetic acid (m. p. 89°) and methyl alcohol. The acid (m. p. 89°) obtained by the hydrolysis of ethyl dibenzylacetoacetate was proved to be dibenzylacetic acid; it would seem, therefore, that the compound described by Fittig and Christ as dibenzylacetoacetic acid (*Annalen*, 1892, 268, 123) is really dibenzylacetic acid.—UNIVERSITY COLLEGE, NOTTINGHAM. [Received, January 21st, 1926.]

*Synthesis of Naphthathioxins.* By REGINALD CHILD and SAMUEL SMILES.

LESSER and GAD have recently described (*Ber.*, 1925, 58, 2557) experiments on the synthesis of  $\alpha\beta'$ -naphthathioxin; the present note gives the results of experiments made previously with a similar object. Di- $\beta$ -naphthyl ether when heated with sulphur and a trace of iodine at 280° for 3 hours, or when treated with sulphur chloride and aluminium chloride, gave small quantities of  $\alpha\alpha'$ -naphthathioxin (m. p. 165°), which was isolated by means of the picrate. On the other hand, in accordance with the experience of Lesser and Gad, attempts to obtain  $\alpha\beta'$ -naphthathioxin by similar treatment of  $\alpha$ -naphthyl  $\beta$ -naphthyl ether were unsuccessful. Lesser and Gad obtained 4-chloro- $\alpha$ -naphthyl  $\beta$ -naphthyl 2:1'-sulphide by treating a mixture of  $\beta$ -naphthol and 4-chloro- $\alpha$ -naphthol with sulphur chloride; but the substance is readily obtained in quantity from the reaction of  $\beta$ -naphthol with 4-chloro- $\alpha$ -naphthyl 2-sulphur bromide, the latter substance being formed from bromine and the corresponding disulphide in carbon tetrachloride. The corresponding sulphur chloride could not be obtained, owing to the ease with which chlorine displaces sulphur from the disulphide. Treatment of the foregoing  $\alpha\beta'$ -sulphide with dehydrating agents gave a small yield of a substance (m. p. 157°) which from its properties appears to be a naphthathioxin.—KING'S COLLEGE, LONDON. [*Received, February 3rd, 1926.*]

---

*Critical Temperature of Mercury.* By LEONARD ALFRED SAYCE and HENRY VINCENT AIRD BRISCOE.

APPLYING the law of Guldberg and Guye (*Z. physikal. Chem.*, 1890, 5, 374, etc.), that the critical temperature of a non-associated liquid is one and a half times its normal boiling point when both constants are expressed on the absolute scale, to the case of mercury, we should conclude that its critical temperature is 675°. From a brief note in a paper by Traube and Teichner (*Ann. Physik*, 1904, 13, 620) it would appear, however, that this temperature is above 1000°. Further, calculation from surface tension data indicates that it is about 1550° (Journeau, *Bull. Soc. chim.*, 1924, 35, 1293). This figure is so widely different from that given by the Guldberg and Guye law that it seemed advisable to make a further attempt to measure the critical temperature experimentally.

For this purpose, pure redistilled mercury was enclosed in a capillary tube of transparent silica having a bore of 2 mm. and walls 3 mm. in thickness. One end of the tube was sealed off, and

the other was attached to "Hyvac" and mercury diffusion pumps while the mercury was boiled and recondensed several times to free it from dissolved gases. Finally, a portion of the tube 4 cm. long was sealed off, containing a column of mercury 1 cm. long. This silica "bomb" was supported vertically in the middle of a horizontal iron pipe 30 cm. long and 5 cm. in internal diameter, which was heated electrically by a winding of "nichrome" wire. The ends of the pipe were shielded by plate-glass and the bomb was closely observed by means of a telescope. At a temperature above  $1000^{\circ}$ , the bomb burst. Immediately before this occurred, the mercury, although at a bright red heat, was still liquid, the contrast being quite distinct between the opaque liquid and the perfectly transparent vapour.

In view of the above, the experimental determination of the critical temperature of mercury would seem to be a matter of great difficulty. It is suggested, however, that mercury might be enclosed in a very stout-walled silica vessel of considerable size and heated inductively to its critical temperature by high-frequency oscillatory currents circulating in its vicinity. It might thus be possible to heat the mercury to the critical temperature while the silica vessel was so far cooled by radiation and conduction that its strength would be maintained.

We desire to acknowledge a grant from the Department of Scientific and Industrial Research enabling one of us (L. A. S.) to take part in this work.—ARMSTRONG COLLEGE, NEWCASTLE-UPON-TYNE. [Received, February 4th, 1926.]

*Some Organo-silicon Compounds.* By RONALD RUMSEY  
WIDDOWSON.

OF certain organo-silicon compounds described by Hart (*Rep. Brit. Assoc.*, 1887, 661), one, obtained by the action of sodium on a mixture of ethylene dibromide and silicon tetrachloride, is called dichlorosilicoethylene dibromide,  $(\text{CH}_2\text{Br}\cdot\text{CH}_2)_2\text{SiCl}_2$ ; another, produced from trimethylene dibromide in a similar manner, is described as trimethylenesilicon dichloride,  $\text{CH}_2\langle\begin{smallmatrix} \text{CH}_2 \\ \text{CH}_2 \end{smallmatrix}\rangle\text{SiCl}_2$ , and its product of hydrolysis as trimethylenesilicon oxide. A dark brown solid, obtained from a mixture of silicon tetrachloride and *o*-dichlorobenzene, is named di-*o*-diphenylenesilicium,

Although the evidence offered in the paper is by no means convincing, the "compounds" there described are recorded in Beilstein's "Handbuch."

At Professor Kipping's suggestion and under his supervision, the author has repeated very carefully some of Hart's experiments under the same conditions. From ethylene dibromide and from *o*-dichlorobenzene no silicon compounds were formed in appreciable quantities; experiments with trimethylene dibromide were not made. These facts, a study of Hart's paper, and the general results of recent work seem to show that the organo-silicon compounds mentioned above may with advantage be deleted from the literature (compare Bygdén, *Ber.*, 1915, 48, 1236).—UNIVERSITY COLLEGE, NOTTINGHAM. [*Received, January 29th, 1926.*]

---

*Deposition of Metallic Zinc on the Positive Pole of a Simple Voltaic Cell.* By SPENCER ROBERT HUMBY and MICHAEL WILLCOX PERRIN.

SOME observations first made in 1924 seemed to indicate that in simple voltaic cells which were left in action for some time metallic zinc was deposited on the copper plates. A large number of experiments have shown that this is the case.

Zinc and copper dipping into dilute sulphuric acid or zinc sulphate solution were connected together externally as in a simple voltaic cell; after some time the copper became covered with a layer of metallic zinc.

The following pairs of metals were treated in exactly the same way: zinc and platinum, zinc and silver, zinc and lead, zinc and iron, iron and silver, and it was found that zinc was deposited upon platinum, silver, lead, or iron, and iron upon silver. In each case, the more electropositive metal was thus deposited on the more electronegative one.

In Daniell cells, also, after short-circuiting for some days, a deposit was obtained on the copper consisting of both copper (from the copper sulphate solution) and zinc.

In the case of the simple  $\text{Zn}|\text{H}_2\text{SO}_4|\text{Cu}$  cell, zinc was deposited while the liquid in the cell was still acid. In another experiment, the liquid was stirred by bubbling hydrogen through it, but this made no difference to the results. The zinc was deposited slowly and continuously, as was shown by weighing a platinum plate at intervals during the course of the experiment. When the two poles of the cell were disconnected, the zinc was dissolved off the copper provided the solution still remained acid.

The current with a  $\text{Zn}|\text{ZnSO}_4|\text{Cu}$  cell fell to 0.006 amp. almost immediately and then more slowly to 0.0001 amp. in 30 minutes.

Various papers were found bearing on the subject. Odling (*Quart. J. Chem. Soc.*, 1857, 9, 289) states that in several instances

if a metal is immersed in a strong, boiling and rather acid solution of a salt of a more electropositive metal, that metal is deposited out of solution on the first, or more electronegative, metal. Raoult (*Compt. rend.*, 1873, **76**, 156) states that if pieces of gold and cadmium connected together are immersed in a boiling solution of cadmium sulphate or chloride, metallic cadmium is deposited on the gold. The gold may be replaced by copper and the cadmium by zinc or tin with the same results. Smith (*J. Amer. Chem. Soc.*, 1905, **27**, 540) states that sodium and potassium, potassium and barium, and sodium and barium are reciprocally replaceable in their amalgams.

The results so far obtained leave no doubt as to the reality of the phenomenon, but it is hoped that additional data will shortly be ready for publication.—WINCHESTER COLLEGE and NEW COLLEGE, OXFORD. [Received, January 28th, 1926.]

*The System Ammonium Acetate-Acetic Acid-Water.* By RUTH SUGDEN.

IN addition to the acid acetate  $\text{NH}_4\text{C}_2\text{H}_3\text{O}_2$ ,  $\text{C}_2\text{H}_4\text{O}_2$ , a hydrated complex of the composition  $2\text{NH}_4\text{C}_2\text{H}_3\text{O}_2 \cdot 3\text{C}_2\text{H}_4\text{O}_2 \cdot \text{H}_2\text{O}$  has been

described by Berthelot (*Bull. Soc. chim.*, 1864, **22**, 440). At the suggestion of Professor Rivett, isotherms of the ternary system

have been determined at 16° and 25° and a few additional measurements made at 0°. Commercial chemicals (B.D.H., A.R.) were used. Analyses of saturated solutions and wet solids were carried out by the usual ammonia distillation method, a known excess of caustic soda being used from which, by back titration, the total acetate and hence the acetic acid present could be determined. Compositions in the following table are expressed in percentages of components by weight. Water (not quoted) may be obtained by difference.

% Composition of sat. soln.		% Composition of wet solid.		% Composition of sat. soln.		% Composition of wet solid.

\* Signifies metastable.

These figures are plotted in the diagrams, from which it is seen that the existence of the complex 1 : 1 : 0 is confirmed, but that there is no evidence whatever for the existence of Berthelot's compound 2 : 3 : 1 at the temperatures examined.—UNIVERSITY OF MELBOURNE. [Received, February 8th, 1926.]

# ANNUAL GENERAL MEETING,

HELD IN THE CHEMISTRY THEATRE OF THE UNIVERSITY OF  
MANCHESTER ON THURSDAY, MARCH 25TH, 1926, AT 4 P.M.

DR. ARTHUR W. CROSSLEY, C.M.G., C.B.E., LL.D., F.R.S., President, was in the Chair, and drew attention to the fact that this was the first occasion since the foundation of the Society in 1841 on which the Society had held its Annual General Meeting away from London.

The Report of the Council, together with the Balance Sheets and Statements of Accounts for 1925, was presented, and after a statement by the Treasurer, the adoption of the report and accounts was proposed by Prof. H. BRERETON BAKER, seconded by Dr. E. F. ARMSTRONG, and carried unanimously.

## REPORT OF COUNCIL, 1925-1926.

### *I. Fellowship Statistics.*

ON the 31st December, 1924, the number of Fellows was 3963. During the year 1925, 344 Fellows were elected and 10 reinstated, the gross total thus reaching 4317. The number of deaths recorded during the year was 40, as against 45 the previous year. The Council records a considerable falling off in the resignations received, the number being 88 as compared with 121 in 1924. The names of 105 Fellows have been removed from the List of Fellows owing to non-payment of annual subscriptions, and the election of one Fellow (in May 1924) has been declared void, the corresponding figures last year being 107 and 7, respectively. The number of Fellows at the 31st December, 1925, was, therefore, 4083, giving an increase of 120 over the preceding year. Among the Fellows who have died during the past year are Sir Edward Thorpe, who held the office of President from 1899-1901, of Treasurer from 1889-1899 and served on the Council for 40 years in all; Dr. Horace T. Brown, who was Treasurer from 1903-1904, Foreign Secretary from 1907-1913, and served on the Council for 20 years, and Professor F. R. Japp, who was Foreign Secretary from 1885-1891, and served on the Council for 16 years. The Council also mourns the loss of two distinguished Honorary Fellows, Professor Albin Haller (elected in 1908) and Professor Guglielmo Körner (elected 1898), the number of Honorary Fellows now being 24.

An obituary notice of Professor Körner, prepared by Professor J. B. Cohen, appeared in the Journal for December, and a notice of Professor Haller will be published in a forthcoming issue of the Journal. The Council takes this opportunity of recording its

appreciative thanks to those Fellows who kindly prepare for the Journal valuable notices of deceased Fellows.

The congratulations of the Council have been conveyed to Sir William A. Tilden (elected 1st June, 1865) and to Mr. William E. Bickerdike (elected 7th December, 1865), who have been Fellows for 60 years, and to the following, who, during the year, have attained their jubilee as Fellows :

	Elected.					
Alfred Southall	...	...	...	...	...	May 6th, 1875.

Francis S. Earp	...	...	...	...	...	Feb. 17th, 1876.
John M. H. Munro	...	...	...	...	...	Feb. 17th, 1876.

The congratulations of the Society were conveyed to Professor B. Brauner on the occasion of the celebration of his 70th birthday held in Prague in May.

## II. *Changes in Officers.*

The Council has received with deep regret the resignation of Dr. Arthur W. Crossley from the office of President, owing to reasons of ill-health. The Council, in placing on record its warm appreciation of his eminent services and untiring devotion to the affairs of the Society, desires to express its best hope that his recovery may be speedy and complete.

## III. *Publications.*

The Journal for 1925 contains 2986 pages, of which 2902 pages are occupied by 409 memoirs and 32 notes, the remaining 84 pages being devoted to Obituary Notices, one lecture, the Report on International Atomic Weights, the Report of the General Meeting, and the Presidential Address. The volume of the preceding year contained 363 memoirs and 31 notes, occupying 2605 pages. The number of papers published in the Journal for 1925 is a record, the previous largest number being 400 memoirs and 11 notes, occupying 3258 pages of the Journal for 1923.

During 1925, 479 papers were considered by the Publication Committee; of these, 37 were declined.

The average interval between the dates of receipt and of publication of papers was 13 weeks in 1925 and 17 weeks in 1924.

A large amount of work is done willingly and efficiently by Referees, and the Council desires to place on record its appreciation of their services. The Council also desires to express its thanks to Professor Wynne for again seeing the August number of the Journal through the press, thus enabling the Editor to take some holiday. It feels, however, that the arrangements for editing the Journal are far from satisfactory so long as the work remains in one pair of hands. Under present conditions the Editor, in the absence of voluntary assistance, would be debarred from a holiday, and, in the event of accident or illness happening to him, there is no one to take over the editorial work until his return to duty. This matter is receiving the attention of the Council.

#### IV. *Library.*

During 1925 there were 6994 attendances in the Library as compared with 6652 in 1924, 4746 of these being made by Fellows of the Society, and 2248 by members of contributing Societies, while the number of books borrowed was 4950 as against 4509 the previous year. The Library has been increased by the addition of 265 books, 609 volumes of periodicals, and 163 pamphlets, the corresponding figures last year being 265, 560, and 164, respectively. The Library now contains 30,011 volumes, consisting of 9066 books and 20,945 bound volumes of periodicals.

In 1925 £1799 2s. 3d. was expended on the Library, towards which £681 15s. was contributed by the kindred Societies. The Council desires again to express its appreciation of the substantial help received from the contributing Societies. The assistance thus given facilitates progress towards the establishment of a complete chemical library.

The urgent need for additional space for the Library has been mentioned in recent reports, and the necessity for a workroom for cataloguing and repairing books is hardly less urgent. For the moment the question of Chemistry House is in abeyance, so that relief in that direction is unlikely in the near future. It has been decided to provide further shelf space for books by lining the north and east walls of the Council Room with adjustable steel bookshelves and erecting a cantilever gallery. The consent of His Majesty's Office of Works having been obtained, the work will be put in hand without delay. It is estimated that the cost will be about £250, and that the shelf space thus provided may be

sufficient to meet the demands of the Library for three, or perhaps four, years. In this connexion it will be necessary to remove the portraits of the Past Presidents now in the Council Room. These will be contained in a portfolio accessible to Fellows, and the names of the Past-Presidents will be inscribed on oak panels which will be placed on the wall in the Meeting Room.

Arrangements have been made during the year by which readers can obtain photostatic copies of printed matter in the Library. Considerable use has been made of the facilities thus afforded.

#### *V. General.*

The society was represented by a number of Fellows at the meeting held at the Royal Institution on June 16th to celebrate the discovery of benzene by Faraday. On behalf of the President, who was unavoidably prevented from attending as official representative, Sir William Pope presented an Address of Congratulation. Professor C. S. Gibson, Mr. A. J. Greenaway, and Sir William Pope attended as delegates of the Society the Fifth Congress of Applied Chemistry held in Paris in September, and Professor H. E. Armstrong gave an oration in honour of Chevreul at the Celebrations held in the same city a month later; while Professor J. B. Cohen was the Society's representative at the Celebrations of the 11th centenary of the foundation of Pavia University held in Pavia in May. At the invitation of the General Council of Medical Education and Registration, the Council appointed the President and Foreign Secretary to represent the Society at the Conference held in February to discuss general questions relating to the proposed revision of the British Pharmacopœia. Professor C. S. Gibson, Sir William Pope, and Professor J. F. Thorpe were appointed to represent the Society on the Federal Council for 1926; while Professor J. W. McBain and Professor J. C. Philip were reappointed for a further term of two years on the Editorial Board of the "Journal of Physical Chemistry."

The Society has continued to be represented on the Bureau of Chemical Abstracts by Professors C. S. Gibson, G. T. Morgan, J. F. Thorpe, and W. P. Wynne. During the year the Bureau's proposals for the change of the format of the abstracts in pure chemistry were accepted by the Council, and accordingly from January, 1926, onwards, "British Chemical Abstracts" is appearing in two sections dealing respectively with papers in pure and applied chemistry, in double-column quarto format, and without overlap in respect of the papers abstracted. These arrangements make possible the preparation of a single annual index covering the abstracts in both sections, and this index will be supplied (without

additional charge) to all who receive the "A" section or the "B" section or both. Fellows of the Chemical Society, who are not members of the Society of Chemical Industry, but who desire to receive the "B" abstracts, can obtain them for £2 2s. per annum.

The Anniversary Dinner was held at the Hotel Victoria on March 26th, 1925, Dr. Arthur W. Crossley, President, in the chair. The company present numbered 240.

This year, for the first time in the history of the Society, it has been decided to hold the Annual General Meeting and the Dinner elsewhere than in London, and arrangements have been made for both to take place in Manchester—the meeting in the University and the Dinner at the Midland Hotel. It is hoped this innovation will commend itself to country members, and that the attendance will be such as to justify the Council in holding the Annual General Meeting at other provincial centres from time to time.

The Special Lecture this session was delivered on February 11th in the Chemistry Theatre of University College, London, by Professor J. Barcroft, who chose as his subject "Hæmoglobin." Instead of arranging for an additional Special Lecture, the Council decided to try the experiment of holding informal lectures given by Fellows of the Society, and two such lectures have been arranged. The first, by Professor R. Robinson, who lectured on "Recent Researches on the Structural Relationships of some Plant Products," was held in the rooms of the Society on November 26th at 6 o'clock, instead of the usual hour of 8 p.m.; the second lecture will be delivered by Professor W. E. S. Turner on April 29th at 6 p.m.

The large attendance at the lectures indicates that they are appreciated, and the Council desires to express its warm thanks to those who place their services at the disposal of the Society in this connexion.

The hope expressed in the last Report that the difficulty in awarding the Harrison Memorial Prize might be overcome by an agreement with the Committee which promoted the memorial, to vary the terms of the Trust Deed by the omission of the latter part of Clause 9, has not yet been realised.

The Council has made a grant of £100, thus completing the £300 promised, towards the cost of publishing the "Annual Tables of Constants," and has contributed £50 towards the cost of the Scientific Exhibit at the British Empire Exhibition, 1925. By means of the Russian Fund, which was created in September 1921 to grant relief to Russian Men of Science and their dependents, the Council has been able to afford assistance to Madame Mendeléev. A letter of thanks from Madame Mendeléev appeared in the

Proceedings for 1926 (p. 2). The Russian Fund, which reached a total of £400 4s. 10d., has been closed, the balance of £7 7s. 10d. having been transferred to Publications Fund Account.

JOCELYN THORPE,  
*Treasurer.*

The List of Fellows, which, owing to the call for economy, was not published in 1924, was printed in August, 1925, and issued to those Fellows who made application.

In accordance with the decision of the Council, copies of the Presidential Address, entitled "Universities as Centres of Chemical Research," delivered by Professor W. P. Wynne on March 26th, were distributed amongst Members of Parliament, various Government Officials, and educational bodies.

The attention of the Council has been directed to the use by Fellows of the letters "F.C.S." in advertisements. The Council deprecates the use of the letters in this connexion, since they do not denote a qualification and such use is misleading to the public.

Applications for Research Grants aggregating £1644 have been received during the year, and Grants amounting to £758 10s., as recorded in the Proceedings (see pp. 93 and 148), have been allotted. Since the total sum for which application was made far exceeded that available for distribution, prior consideration has been given to applications made by Fellows.

VI. *Financial.*

The balance representing excess of income over expenditure for 1925 is £466 4s. 3d. The income of the Society has increased by £1208 6s. 8d. over that of 1924, in spite of the fact that the admission fees (£528 in 1924) have not been available, and that there has been a diminution in income from advertisements (£25 3s. 7d.), from invested funds (£37 4s. 11d.), and from miscellaneous receipts and sales (£138). The source of the new income is to be traced to the decisions of the Council, reached in 1923 and in 1924, to charge an increased price for the Journal, Abstracts, and Annual Reports to the public, and to charge Fellows for the Annual Reports; also, for the first time there has been a substantial income from the Publications Fund. The total obtained under these heads during the year has been £6112 8s. 8d., as against £4522 17s. 10d. for 1924 (during which year some of the effects of the changes were beginning to be felt), and £3799 17s. 6d. for the previous year, that is, before the changes came into operation.

The expenditure side of the account shows that the cost of the Journal has increased by £223 12s. 3d., despite the fact that there has been a saving of £125 16s. on the preparation of Authors' copies. The cause of this increase is the enlargement of the Journal by 288 pages due to the publication of 409 memoirs in place of the 363 published in 1924. The cost of the Abstracts has increased by £394 17s. 8d., due to the number of pages in 1925 being 468 higher than in 1924. There is, however, no overlapping in the payment of editorial salaries, and for this reason a saving of £113 9s. 9d. has been effected. Judging by these figures it is evident that there is still an upward tendency in the curve representing the world's annual output of published chemical research, and that the apex of the curve has still to be attained. At the same time there seems to be no immediate prospect of the cost of printing being materially decreased and, until the curve flattens, the Society will have to meet a constantly rising expenditure.

Among the other items on the expenditure side it will be noticed that the administration expenses have increased by £190 2s. 7d., due, mainly, to an increase in the item for miscellaneous printing and stationery of £125 0s. 6d. It will be seen, however, that the cost of printing the List of Fellows has been more than met by a saving of £133 1s. 4d. in the cost of the Annual Reports.

The total market value of the invested funds of the Society is £40,474 10s. 5d., an increase of £1,709 3s. 4d. over the figure for 1924 despite the depreciation of trustee stock to the extent of £852 on the General Purposes Account and the sale of £662 7s. of 3½% Conversion Stock, value £500, from the Research Fund Account.

The outlook for the future is fairly promising because, during the year 1926, the full interest on the Pedler bequest will become available; moreover it is to be expected that increased receipts will be obtained from outside sales of publications. On the other hand, the Society will be faced with an increased expenditure due to the scheme for the superannuation of the staff, and also to the cost of fitting the Council Chamber with bookcases in order to meet the requirements of the library. Next year's balance will depend on the cost of the Journal and Abstracts, and it is to be hoped that the scheme of co-operation which has led to the founding of the Bureau of Chemical Abstracts will enable a saving to be made by the elimination of the overlap between the "A" and the "B" series.

*Publications Fund.* In the last report of Council it was stated that, notwithstanding the generous response by Fellows who had contributed £1434 17s. 1d. to the Publications Fund, if the Fund were to be made really effective it would be necessary substantially to increase it. With this object in view it was decided to issue an appeal to Manufacturers, and as a result the Publications Fund now stands at £4067 17s. 4d. Of this, £2166 was received from Manufacturers and other firms connected directly and indirectly with the Chemical Industries of the country and £100 as a grant from the Birmingham University Research Fund. The income derived from the Publications Fund, together with Subscriptions received during the year under review, amounts to £622 13s. 10d. This sum, in which are included £350 from the Government Publications Grant of the Royal Society, and £80 the income from the residue of the estate of the late Sir Alexander Pedler, has helped to meet the expenses of publication. It is anticipated that between £4000 and £5000 bequeathed to the Society by Sir Alexander Pedler will be made over to the Society during 1926; the Publications Fund will then have a capital sum of close upon £9000.

*Special Publications Fund.* In 1918, a Committee of Chemists was formed to prepare and publish chemical bibliographies and works of reference in the English language, and funds were collected. The scheme was abandoned, but funds amounting to £1896 8s. 4d. collected by this Committee have been handed over to the Society on the understanding that they would be used "for the purpose of promoting chemical publication, but not for the purpose of defraying the cost of the Society's ordinary publications." The Council accepted the funds on the conditions stated, and a Special Publications Fund has been created, the sum of £1600 being invested in Conversion Loan.

*Memorial Lectures.* During the year Vol. I of the Memorial Lectures has been reproduced by a phototype process and is sold

to Fellows at 9s., post free, and to the Public at 10s. 6d. The publication of this volume is being financed by means of the Special Publications Fund.

*Staff Superannuation Scheme.* Another matter which has received the serious consideration of the Council has been the necessity for making some provision towards the Superannuation of the Staff. A contributory scheme of insurance based upon a 10 per cent. premium of the salaries received by the Staff, and payable at death, or on retirement, has been instituted, 5 per cent. being contributed by members of the staff and 5 per cent. by the Society. It is realised, however, that the sums thus accruing on the retirement of the beneficiaries will be inadequate, and accordingly a Pensions Fund has been created with a view to amplifying the amounts received from the insurance policies. The general funds of the Society will thus be relieved from any sudden call they may have to face, and Fellows have been invited to contribute to the Fund.

*Sales of Publications.* The price to the Public of the "A" Abstracts in Pure Chemistry for 1926 has been increased from £2 10s. to £3 10s., and the price of the Journal and Abstracts together has been increased from £5 to £5 10s. to the Public, and from £4 5s. to £4 15s. to Fellows who require extra copies. In order that the Abstracts in the new format may reach the Fellows in as good condition as possible it has been decided to issue them flat and in envelopes.

*Advertisements.* It is hoped that with the increased facilities which the "A" Abstracts in the new format afford for displaying announcements, the income of the Society derived from advertisements will show a considerable increase in the forthcoming year.

A vote of thanks to the Auditors (Profs. J. F. Spencer, A. J. Allmand, and J. S. S. Brame) for their services, was proposed by the Treasurer, seconded by Prof. F. L. PYMAN, and carried unanimously.

Prof. H. B. DIXON proposed a vote of thanks to the Treasurer, Secretaries, Foreign Secretary, Council, and Committees for their services during the year. This was seconded by Dr. ALFRED RÉE and adopted, acknowledgment being made by Sir WILLIAM POPE.

On the motion of Prof. R. ROBINSON, seconded by Dr. D. C. HENRY, Prof. A. J. Allmand, Prof. J. S. S. Brame, and Dr. G. W. Monier-Williams were elected Auditors for the coming year.

Prof. T. S. PATTERSON then moved the following resolution :

"In view of the fact that the publication in the Proceedings of the Chemical Society of a list of titles of papers which have been received but not published and which—either because the Publication Committee considers them unsuitable or because the author

may be unable to accept alterations suggested by the referees or by the Publication Committee, or for any other reason—may not be published, is very prejudicial to the subsequent publication of these papers elsewhere and, by disclosing the fact that such work is in progress, unfair to the author, besides involving the Society in unnecessary and unjustifiable expense at a time when all possible economy should be exercised, this meeting recommends that the practice of publishing such a list be discontinued.”

This was seconded by Prof. F. J. WILSON and, after discussion, was put to the meeting, and declared lost.

The following resolution :

“That this meeting, being of opinion that the position of the Chemical Society would be strengthened and the membership increased by the institution of local sections, recommends the Council to take such steps as would render practicable the institution of local sections where they might be desired ”

also proposed by Prof. T. S. PATTERSON and seconded by Prof. F. J. WILSON, was discussed; on its being put to the meeting it was declared lost.

THE PRESIDENT then delivered his address, entitled “The Co-operation of Science and Industry.”

A vote of thanks to the President for his services in the chair during the past year, and for his address, requesting him to allow the address to appear in the Journal, was proposed by Prof. W. P. WYNNE, seconded by Prof. W. H. PERKIN, and carried with acclamation. The PRESIDENT acknowledged the thanks and proceeded to read the report on the election to vacancies on the Council, announcing that Prof. H. Brereton Baker had been elected President. Prof. Baker then took the chair and continued the reading of the report :

*Vice-Presidents who have filled the office of President.*—H. E. Armstrong; Arthur W. Crossley; Percy F. Frankland; W. H. Perkin; Alexander Scott; W. P. Wynne.

*Vice-Presidents who have not filled the office of President.*—J. B. Cohen; A. J. Greenaway; James C. Philip; Sir Robert Robertson; R. Robinson; N. V. Sidgwick.

*Treasurer.*—Jocelyn F. Thorpe.

*Secretaries.*—T. Slater Price; C. S. Gibson.

*Foreign Secretary.*—F. G. Donnan.

*Ordinary Members of Council.*—H. Bassett; D. R. Boyd; O. L. Brady; H. V. A. Briscoe; A. E. Dunstan; F. A. Freeth; F. W. Gamble; R. Whytlaw Gray; J. Kenyon; B. Lambert; T. S. Moore; T. J. Nolan; K. J. P. Orton; R. H. Pickard; B. D. Porritt; F. L. Pyman; G. Stubbs; F. J. Wilson.

## PRESIDENTIAL ADDRESS.

Delivered at the ANNUAL GENERAL MEETING held in Manchester on March 25th, 1926.

By ARTHUR W. CROSSLEY, C.M.G., C.B.E., LL.D., F.R.S.

THIS is the first occasion on which the Chemical Society has departed from a custom, which has persisted since its foundation in 1841, namely, that of holding all its official meetings at its premises in London. The opinion has often been expressed that our provincial members do not have a sufficient say in the management of the Society's affairs, and certain alterations of Bye-Laws have recently been made, which materially affect this state of affairs. When the suggestion was made to the Council that every alternate Annual Meeting should be held in the Provinces, it was unanimously accepted and it is by virtue of that decision of the Council that we meet to-day in Manchester.

It seems particularly appropriate that our meeting should be in this Institution and in this lecture theatre; for through the Professors who have taught here and who have also been Presidents of the Chemical Society there are very close ties with us, and I am confident that I may record the most grateful thanks of the Society to the University of Manchester for granting permission for us to assemble here to-day.

The first professor of chemistry in the Owens College was Edward Frankland (1851—1857), who was President of our Society from 1871—1873. For the twenty-nine succeeding years, 1857—1886, he was followed by Henry Enfield Roscoe, who was President of the Chemical Society in 1880—1882. It was my privilege to be one of the later students of Sir Henry Roscoe, and I have often heard him lecture in this room. He was truly a remarkable teacher and one who had a very unusual hold and influence on his students. He was not a polished lecturer from the point of view of delivery, nor because he gave deep-seated discourses into abstruse chemical problems, but he was a lecturer who had the faculty of interesting his students in a marked degree, in consequence of which they became anxious to learn for themselves. That, to my mind, is the essence of real teaching.

Roscoe was followed in 1886 by Harold Baily Dixon, who occupied the Chair for thirty-seven years, namely, until 1923, and who was President of our Society during the period 1909—1911. My main student years were spent under his direction, but since he is here with us to-day, I will only say of him that he is as young as ever,

still hale, hearty, and active. Long may he remain so! There is, however, one very special reason why we may to-day offer him our warmest congratulations, inasmuch as he was elected a Fellow of our Society in 1876 and has therefore attained his Jubilee of Fellowship.

Two other past Presidents of our Society have also been Professors in this University: Professor W. H. Perkin, who was Professor of Organic Chemistry from 1892—1912 and our President for the period 1913—1915, and Sir William Pope, who was Professor of Applied Chemistry from 1905—1908 and our President from 1917—1919. To them also we would express our sincere wishes for long-continued health and activity.

*The Co-operation of Science and Industry.*

It is a simple economic fact that since this country does not produce a sufficiency of foodstuffs to feed its population, it must manufacture goods and sell these in foreign markets at a profit, in order to purchase the food which is necessary to sustain life. The more the population grows, the more of our manufactured goods must be sold abroad, if our existence is to continue. It follows from this fact that the maintenance of our industries is a national necessity, and they must not only be maintained on the same standard as in the past, but we must always be attempting to reach a higher efficiency, in order to cope with foreign competition. There was a time when Great Britain, as the pioneer of industrial development, could afford to select her own pace and her own methods, for she alone was in the field. The results obtained, largely without the aid of science, were indeed astonishing, but they came as a result of the breaking of new ground. Virgin soil may give wonderful crops for a few years, but to take from it continually and give nothing to it spells, as everyone realises, ruination, and in order to maintain the harvest it is necessary to nurture the soil or to manure it.

British industry worked on virgin soil in the past, and has worked it well-nigh to starvation point, owing to the lack of appreciation of the importance of science generally from the point of view of our national welfare. Numberless examples of the importance of science to industry and to the general welfare of mankind have been and are being constantly brought to our notice, and the years 1914—1918 gave signs that the nation had at last realised that science and scientific method were our only hope. Yet the lesson then apparently learnt seems to have been forgotten, because as a nation we still fail to realise that all real industrial progress is the result of the application of scientific facts and data and that those

who fail to utilise science to the full must inevitably fall behind in the race of nations which is now in progress.

Instead of being, as in the past, almost the only industrial nation, we now realise that other peoples have become industrialists, to whom we have given all our past experience. But they have forged ahead owing to their full appreciation of the possibilities of science in its application to industrial problems; from being the teachers in the past, we have now become pupils, and not very apt or willing pupils at that. We do not seem able to forget our unprecedented and unopposed success in the past; we think the same methods should still lead to success now and in the future, and we waste much precious time in wondering why our industries are not as prosperous as they used to be.

We can scarcely look for more new raw material within the country other than brains, in which respect we have good reason to think that our raw materials are at least equal in quality to those of any other country. Our brains must be used to resuscitate our industrial soil, which must be nurtured or manured, and new scientific facts and data are the nourishment which must be given if industry is to continue to be a profitable undertaking; if we are to be, I will not say as successful as we were in the past, but if we are to hold a place amongst the foremost nations of the world, or if our existence as a nation is to continue.

An anonymous author writes\* as follows in the *Round Table* under the heading "British Industry and the Future":

"It is not only in the actual processes of manufacture that science can be used, but in the whole conduct of business, from the purchase of raw materials and the distribution of machinery, to the training and selection of labour, transport and sales. All these problems are more or less solved by a business that pays its way, but in too many cases rule of thumb and antiquated methods make the yield much poorer than it might be. For the higher branches of management there is little or no systematic training attempted. . . . In an age of super competition nothing but the best-equipped brains will be able to stand the pace. . . . Modern industry is as complex and difficult a profession as any. Its leaders need as thorough and prolonged an intellectual training as the doctor or the lawyer."

If a country can manufacture goods of superior quality, of constant novelty or of exceptionally high performance, at reason-

\* Several quotations in this paper are from an article entitled "British Industry and the Future," to be found in the September 1925 number of the *Round Table Review*; also from a pamphlet "What Price Progress", published by the "Chemical Foundation," New York, 1925.

able prices and keep on doing so, other countries are compelled to buy from it. Science is the modern key to such a situation and new discoveries in science are essential to maintain the industrial position of this country; in fact, science is the sentinel that must be posted at the door of every business house with the main object of preventing loss from want of knowledge. If we look round, surely nothing can bring greater hope to us than the realisation of the many comforts we enjoy as the result of research—electric light, the telephone, the telegraph, wireless, the internal combustion engine, to mention only a few of the more obvious.

But on one point let there be no doubt; although science should bring great hope to all for the future, it gives no hope whatever for less strenuous efforts, but rather the reverse. Science of all taskmasters is the hardest, the most uncompromising, the most severe, punishing relentlessly any slack or slovenly work done in her name and exacting to the uttermost limit faithful and untiring devotion, if she is to reveal her secrets.

It is always interesting to know the opinions of successful men on such matters, and Mr. Filene, an American business magnate, writes in his book, "The Way Out," as follows :

"This period will ultimately witness a ruthless weeding out of 'the businesses that do not go beyond mere price cutting and 'wage slashing. The survivors will be the businesses in which 'waste has been conquered and scientific method introduced."

Again the American wood alcohol industry has recently suffered a severe check as the result of a new scientific discovery, and in commenting on the fact a celebrated American professor of chemistry says :

"American manufacturers have failed, on the whole, to understand the need for research to keep their industries at the front. 'The backwardness of the manufacturer in this respect only reflects 'that of the general public in this country. The principal trouble 'here, in comparison with Germany, France, and England, is that 'we do not appreciate to the same extent the significance of science 'to the present day civilisation. . . . The whole thing will have its 'value if it is appreciated by American manufacturers and the 'public, as an object lesson of our backward-looking attitude 'towards research."

This writer is evidently of opinion that the general appreciation of the importance of research is greater in this country than in America. Although I have no personal knowledge of America, I do not think this can be possible, nor does the writer in the *Round Table* who, in comparing the trade possibilities of this country and America, points to many of the immense initial trade advantages

possessed by America, and then adds : " If, in addition, they obtain a lead in the application of science to industry it is difficult to see how we can hope to compete with them."

It is not only research that is needed in this country, but research on well-ordered and organised lines. If the suggestion made at the first meeting of the British Association had been carried into effect it is probable that the general appreciation of the importance of science in this country would now have been widespread : but as it is, research has been allowed to be carried out by the individual on his own lines and in accordance with his own fancies, without in any way attempting to produce organised effort for the general welfare of the nation ; and the pure research worker has been left to himself to become " a member of a priesthood which prides itself on its detachment from worldly things, a priesthood which refuses admission to any who bear the taint of hope of material gain."

Yet despite this splendid isolation of the pure research worker, what a glorious record of important discoveries is his and how much his country might have benefited if some few of them had been put to industrial use here, instead of becoming milestones in the development of foreign industrial capacity.

It was not until 1914 that any real attempt was made to organise the scientific workers of this country, with what results everyone knows and we have to thank some unknown persons whose ideas led, in July, 1915, to the establishment of an Advisory Council to make recommendations and proposals for :

I. Instituting specific researches.

II. Establishing or developing special institutions or departments of existing institutions for the scientific study of problems affecting particular industries and trades.

III. The establishment and award of Research Studentships and Fellowships.

From this suggestion has developed the Government Department of Scientific and Industrial Research, which in the short time it has existed has done more for the organisation of scientific effort than has ever before been done in this country.

Professor Wynne in his Presidential Address last year spoke in no uncertain terms of the benefit which had accrued to research students as the result of research grants made by the Department, and I need not refer further to item III above. Those who are interested in the other activities of the Department will do well to study somewhat carefully its annual report for the year 1924—1925. Under item I above are included such important problems

as researches connected with fuel, building materials, illumination, adhesives, forest products, foods and cold storage, and many others which have been initiated as a result of co-ordination of research in Government Departments by a series of co-ordinating Research Boards. And under item II come the National Physical Laboratory, the newly-established Chemical Laboratory, the Geological Survey and Museum of Practical Geology, the British Museum Laboratory and Industrial Research Associations.

Many of the difficulties of applying science to an industry as a whole were evidently fully appreciated by the Committee of the Privy Council, and under the title "Impediments to Industrial Research" the following words appear in the Report of the Committee for 1915-1916\* :

"Our experience up to the present leads us indeed to think that the small scale on which most British industrial firms have been planned is one of the principal impediments in the way of the organisation of research, with a view to the conduct of those long and complicated investigations which are necessary for the solution of the fundamental problems lying at the basis of our staple industries. What, for instance, is the exact nature and constitution of the cotton fibre, of rubber or of the resins? How does the structure of an alloy depend on its chemical composition and on its mechanical and heat treatment? . . . These are questions which none but the greatest of individual firms or a big combination of firms could venture to attack."

Yet the initial difficulties seem to have been overcome with great skill and Research Associations have been formed by specific industries, on the principle that the Department would provide money in definite proportion to the amount raised by the industry and would continue these grants for five years. In the case of the cotton industry, the subscriptions from the trade are regulated by the number of spindles or looms in a mill or by the declared capital of the company, and are on a unit principle. Since nearly 90 per cent. of all the firms in the industry are members of the Research Association, and also owing largely to generous help which has been afforded by the Cotton Trade War Memorial Fund Committee, the annual income of this Association is for the next four years approximately £54,000. It has therefore been possible to establish laboratories wherein "the fundamental problems lying at the basis" of the industry can be attacked, for which purpose organised and co-operative research is absolutely necessary. It is true that there are many purely botanical, chemical, or physical

\* Report of the Committee of the Privy Council for Scientific and Industrial Research for the year 1915-16, page 25.

problems to be solved, but fundamental research directed towards the general advancement of this industry more often than not means the close co-operative efforts of botanist, chemist, and physicist, and where results are forthcoming, further co-operation with technical men and practical works experience become essential.

Undoubtedly, organised research has been carried on in the past by some firms or industries—the results achieved allow us to make this deduction; but the information gained has naturally remained the property of the firms concerned and does not touch the national programme of scientific work. The aim of the Department's scheme is to advance the industry as a whole.

The grants made by the Department were originally for five years, in which time it was hoped that the Associations would have done so much for their trades that further Government help would not be necessary. But the First Report of the Committee of the Privy Council (page 30) contains these words: "The shortest period in which any considerable results can be expected is five years, while results so considerable as to affect the whole industry cannot be looked for in less than ten years' consecutive work." It has now been proved that five years is too short a time in which firmly to establish such an enterprise, which necessitates the selection of a scientific staff, the building of laboratories, and the collection of a library, together with other research facilities. The British Cotton Industry Research Association was founded in 1920, its laboratories were opened in March, 1922, and it is only now, six years after its creation, that the Association is really getting into intimate contact with the trade, which is recognising that science is capable of rendering assistance. It may appear to some that progress from the point of view of the trade has been slower than it should have been and it is just possible that more work of immediate use to the trade might have resulted, if those responsible for the foundation of the Association had not decided that the large fundamental problems lying at the basis of the industry were to be the main objects of inquiry. But the founders made a wise decision, for although initial advances may have been slow, future progress will be greatly accelerated by the better understanding of these fundamental problems.

The idea of these Research Associations and the plan on which they have been brought into being seem to me to be the only possibility for the general introduction of science and scientific method into some of our large industries, and the work of the Department in this direction is destined to prove of immense value to the trade of this country, indeed it would not appear too much to say that the whole concept is one of the utmost national importance. The

movement must lead ultimately to greater trade efficiency, to the expansion of trade, and to greater employment both of scientific and industrial workers.

Further, the movement has led to the increase of the number of research workers in laboratories connected with individual firms, and will lead to the larger employment of scientists in works, to establish scientific control, and to form the intelligence departments which will search into the results obtained and endeavour to apply them to industrial progress.

But the Department's scheme has none the less been severely criticised, largely by those who are always willing to pour forth destructive criticism, without attempting to supply anything in the nature of a constructive policy.

Sympathy has often been expressed for me in my supposed efforts to divest my surroundings of Departmental red tape, which, as my well-wishers put it, must stifle any freedom of action relative to research. I can only say that I have not encountered any of this flaming cord. Naturally an Association receiving money from public funds must be required to conform to certain rules and regulations, but these have not been in any way irksome, nor have they in the least interfered with research progress. On the other hand, I am glad to have this opportunity of acknowledging the great help which the Association has received from the Department on all and every occasion on which such help has been sought. One of these aids, which is becoming of increasing importance, is the Department's Information Bureau, which not only serves as a clearing house for research information relative to this country, but is taking on a much wider scope.

It has been frequently urged that it is undesirable, not to say wrong, to devote public money to industrial research, which should be supported entirely by the trade concerned. There is, I think, a very good answer to this criticism. Truly successful research is rarely without benefit to mankind at large and one need not do more to emphasise this point than refer to the life work of such a man as Pasteur. As regards industrial research, it may safely be said that the fruits of such research are always for the public benefit. It has been estimated, for example, that the research work of the General Electric Company of America is saving the American nation at least a billion dollars a year in the matter of electric light.

Those industrialists who found research laboratories with the avowed intention of investigating the fundamental problems of their industries, of ascertaining all there is to be known about the materials which they use, do so perhaps mainly in the hope that

their businesses will thereby be expanded, as the result of the introduction of new or the improvement of old materials and processes. They further realise that this must lead to greater employment, both industrial and scientific, for scientifically controlled production means methodically certain production, with less expense of mental effort and therefore more of the latter for devotion to other work. But they take a chance, for no one can assure them that results of value will be obtained in any stated period. When, however, results are forthcoming, the public, which has staked nothing, gets the benefit every time, whether it be in the way of electric light, artificial silk garments, or more skilful medical treatment. Why, then, should not the public contribute to the cost of research from the results of which they benefit so largely?

But no matter how much criticism is levelled at the Department of Scientific and Industrial Research, it still remains a fact that its activities have led to an organised effort to bring science and industry together, an effort which has already been crowned with distinct success and will lead to a great future, if all those interested will look at the movement in the true national spirit and do what they can to support and further it. For in reality it is a distinct step towards the organisation of the immense research power of this country.

If, however, the results of research are to be effectively applied, it is absolutely necessary that industry should meet science at least half-way. It is useless for the industrialist to complain that he does not understand scientific papers and that they must be put into everyday language, so that he *can* understand them. It is not to be expected that every industrialist can be a trained scientist, but he can at least guard himself by employing trained scientists in his business, thus establishing the position of the man of scientific training in industrial management. The position could not be more clearly stated than in the following words of the Prime Minister, when speaking in the House of Commons in the summer of 1925 :

"No one will assert that British industry can be saved by science alone, but it is none the less true that until scientific methods and scientific men can take their place in industry and an equal place with the administrator and the financier, British trade will never be strong enough or resilient enough to meet the shocks that it is bound to meet as the years go by, or to meet the sudden and unexpected changes which will always arise in international trade."

Reference has just been made to the immense research power possessed by this country. Are there not other ways in which this power can be put to the nation's benefit? Cannot we so organise

ourselves that at all events some portion of this vast research force is utilised in the solution of some of the problems which are vital for our welfare? In foreign countries much of the research energy of the Universities and higher Technical Institutions is directed by the Professor, himself in the closest contact with the heads of some great industry, towards the solving of important technical problems. Immediate solution is not looked for, but gradually a mass of new information is forthcoming, which in very many cases has led to results of the greatest importance, in regard to the elimination of waste, the utilisation of what have been regarded up to the time as waste products, and the discovery of new materials of commercial value. Frequently this means that a young scientist is sent into a works to watch his laboratory experiments gradually translated into manufacturing possibilities and hence the Professor and also the works authorities have opportunity of judging in which direction his future capacity lies, whether solely for pure research or for the application of science to works problems, etc.

Could not funds be found from somewhere to provide for the training in research method of those who are willing to undertake work on one of the many urgent national problems?

Cannot facilities be provided for sending trained men of science at an early point in their industrial career, to study the industrial methods of other countries?

Neither science alone nor industry alone can set any such ideas in motion, it is only by the honest and hearty co-operation of both sides that any success will be gained.

Is there any amongst us who can truthfully say, These are matters which do not interest or affect me and towards the solution of which I can add nothing of value? Surely, as a result of the simple fact with which I opened my remarks, we are all, without exception and no matter what our every-day work is, ultimately dependent for our existence on the success of our great industries, and although there may be some slight indication of trade improvement, the present situation is sufficiently serious to warrant every thinking man making it the principal national thought for the time being.

Someone has said that the Britisher is a confirmed individualist, from which fact his failures and his successes have arisen; but is it not time that we brought ourselves to realise that there is much unselfish and co-operative national work to be done? The never-ending search for new knowledge is the exacting price which must be paid for survival under modern industrial conditions.

There is another important aspect of the situation which I should like to consider for a few moments: as a teacher, or at all events one who, if not active at the present, has spent a large portion of

his life in the teaching of chemistry, I would ask if we are satisfied that we are doing all in our power to train up a body of young chemists, who will be able to fill the openings which industrial life offers and will in future offer always in increasing numbers, provided we continue to progress. I have given much consideration to this question, especially during the past six years, and I am bound to say that I do not think a wholly positive answer can be returned to the question. One often hears it urged as a serious fault of British manufacturers trading in foreign markets that they supply goods which they "think should be required" by the said markets without troubling to ascertain whether the purchasers have any tastes, desires, or special requirements of their own or whether their natural surroundings render desirable modification of goods made for this country, whereas our competitors do make the necessary inquiries and are constantly reaping the benefit. I rather think the same accusation might legitimately be brought against the teachers of chemistry in this country, who might be considered to be providing chemists who have had the training which the teachers "think should be required" by industry, without troubling to inquire whether industry has any special needs of its own, whether industrial surroundings demand special consideration, or whether one industry differs in its requirements from another. It is granted that such inquiries would demand more than a bowing acquaintance with any special industry. Is it not, however, the duty of the teacher to make such inquiries as equally, in my opinion, it is the duty of the industrialist to make known his requirements to the teaching profession?

It needs but little consideration of the question to reveal the fact that industry requires chemists with broadly differing lines of training, according to the special branch they are going to take up. To my mind, our present training is much too stereotyped, leading to the production of one type of man only. The system produces many extraordinarily good men of this type, but it leaves out of consideration the fact that there are many differing types of men who are not all capable of showing their best qualities as a result of one set method of training.

Take, for example, the industry with which I am connected, namely, the cotton industry; here the chemist has to deal with a biological entity, and if he has not had a training in some biological subject and cannot think from the biological standpoint, much of his time and of his employers' time will be wasted, for it is hopeless to look upon the cotton hair as a definite "substance" from the chemist's point of view.

Among the various types of chemists required by industry is

the research worker pure and simple, who will be free to devote his abilities solely to the advancement of knowledge and who need not of necessity have any business qualifications or adaptability for applying his knowledge to industrial problems. He may be the true specialist in some branch of his science.

A second type of chemist, quite as rare as the true research worker, quite as important in industry, and yet possessing an entirely different outlook of mind, is the man who can apply new scientific data to industrial development and can convert laboratory experiments into industrial operations. Then there is the process chemist, whose duty is not the furtherance of abstract knowledge, but the careful scientific control of works processes. He again is a most important type, for there are few industries in which better technical results could not be obtained by more careful scientific control. One of the main requirements from such a man is his capacity to do, or to supervise, accurate analytical work, requiring frequently a high order of attainment as an analyst, a qualification not always demanded by our present examination system. As a fourth type may be mentioned the chemical engineer, probably more wanted in this country than any of the other types.

Now, are we doing our best for our future chemists or for industry by putting them all, together with future school and university teachers, through the same courses of study? Personally I do not think that we are. I shall probably be met by the criticism that there is only one chemistry and therefore there can be but one way of teaching it. Here I disagree, because I feel that the present system leads to the production of narrow specialists, who have not a wide outlook on science generally. In most chemistry schools, especially those of the newer universities, the Honours chemistry course extends over three years, and although classes in physics and mathematics may be a part of the curriculum, this does not of necessity imply any real absorption of these sciences. I am a firm believer in a broad general training in, say, three sciences before the student proceeds to specialise in any one of them; the system, in fact, which used to prevail in the University of London and is still in vogue in a few of our Universities.

Moreover, I do not think the present method of examination is giving us the desired information about candidates or is enabling them to realise what is before them in the future. Far too much is expected from them in the way of book work and far too little in the way of accurate straightforward chemical manipulative skill. Here is what a friend wrote to me the other day, when calling my attention to a really capable young chemist: "My recommendation

is only based upon the possibility of your happening to need a pair of well-trained and capable hands, backed by a mind that is naturally endowed with the scientific curiosity which leads to research. I dare say that, like myself, you have often found that sound scientific training and even brilliant chemical knowledge is sometimes acquired in a University, without the acquisition of any ability to use the hands for sound accurate quantitative work, partly because in some of the University laboratories the value of manipulative skill is not appreciated, and partly because nowadays such an immense amount of theoretical work has to be crowded into the college course that there is little time for the humble utilitarianism of routine analytical operations, though the accurate acquisition of facts is not less important than the projection and co-ordination of the inquiry on which they bear."

I agree with these sentiments entirely and can say with certainty that much has been done to make industry sceptical of the value of trained chemists by the fact that Universities have sent out into the world as first class honours graduates men who could write reams on ill-digested facts concerning molecules, atoms, and sub-atoms, but who had no competency whatever for conducting a straightforward piece of ordinary analytical work. By all means let us give our students a good theoretical grounding and, provided this foundation is sound and on broad lines, the good men will be able to build for themselves upon it, in accordance with the necessities of their future occupations.

I could not attempt to trace here the training that a chemical engineer should be put through, but I do think that everyone going into industry should at all events have some slight knowledge of the subject. Might it not reasonably be made a third subject for a pass degree? I do not by this mean to imply that such a training would be adequate for anyone who wished to become a full-fledged chemical engineer, but it would at all events help a young man going into industry to bridge over the chasm, which exists at present, between the laboratory and works operations. I have often seen a look of astonishment and blank dismay come over the face of a young chemist when he has been shown for the first time a working drawing of a piece of chemical plant. There is certainly no reason why every future industrial chemist should not be taught sufficient of machine drawing and design to enable him to read these drawings with ease.

It must, of course, be granted that there is much, very much, concerning industrial chemistry which cannot be taught in University laboratories and can only be learnt in the works itself, but I think it should be possible, with more co-operation between industrialists

and teachers, to make the learning considerably easier than it is at present.

If it be admitted that our training of future industrial chemists is not all that could be desired, can the blame for this state of things be placed on the teachers only? This question can undoubtedly be answered by an unqualified negative, and others may be asked, for example, What have industrialists done to co-operate with the teaching profession in the training of young chemists? Have industrialists offered any slight advantages to students during their training, or have they in any way made clear their wants, and have they helped as far as possible in making their wants practical possibilities? It would appear that little has been done in any of these directions, and the idea is still prevalent among many industrialists that "the young man who grows up with the business will acquire all the knowledge he needs."

In these circumstances it is an encouraging pleasure to record the fact that the Managing Director of the British Dyestuffs Corporation forwarded in July, 1925, for the information of your President, a copy of a letter which had been addressed to Professors at the various Universities, pointing out that the progress of the synthetic organic chemical industry in Britain depends so largely on the achievements of British chemists, both within and without the industry, and is a matter of such national importance that the most sympathetic co-operation is necessary between the Universities, Technical Schools, and the industry. The letter then invites co-operation in several ways, such as advising the Corporation of likely students for research departments or works processes; giving early notice of laboratory researches likely to have an industrial application; allowing students to carry out researches in conjunction with the Corporation, etc. Finally came the information that the question of permitting a limited number of students to gain works experience with the Corporation during the long vacation was receiving sympathetic consideration, so sympathetic, in fact, that the suggestion materialised and I believe some fifteen students were given, during the summer vacation of 1925, the opportunity of acquiring knowledge in the works of the British Dyestuffs Corporation. The result from the students' point of view was an unqualified success and can scarcely have been a failure from the point of view of the Corporation, since this body is again granting similar facilities to students this summer. The warm thanks of all interested in the training of industrial chemists may be given to the Corporation for this example of the co-operation which is so greatly needed, and for so definitely disproving what in the past was frequently stated to be an impossibility, owing to the dis-

organisation of works practice that it would cause, and also to the danger of works secrets leaking out. If such difficulties have arisen in the present case, it is obvious that the Corporation is willing to face them in view of the importance of the whole question.

In his address last year Professor Wynne directed attention to the desirability of such experience being made possible for students, and stated that in Sheffield the problem had been faced and solved, since it is now the custom for intending graduates in Metallurgy to spend part of the long vacation in certain of the steel works in Sheffield, to be welcomed there and to be placed under foremen to do such work as may be suggested. Now we have the proof that such a state of affairs is not an impossibility in chemical works, and it is to be hoped that the important example set by the British Dyestuffs Corporation will be largely followed by other firms.

Much has been heard recently of the necessity of co-operation between employer and employed, but there is at least as much need for co-operation between business men and teaching institutions regarding educational matters. No one can afford in the interest of our national welfare to say that he has no interests in education, for it is an essential part of the life-work of everyone.

This nation possesses, in addition to others, two most powerful assets which individually have reached great heights. I refer to practical industrial experience and scientific research capacity. If these two forces can be linked together, if the exponents of each can be brought into intimate contact and will in every way possible heartily co-operate with one another, then there is no reason to be pessimistic about the future, for the possibilities such a co-operation opens out are unlimited.

And now, in conclusion, I would express to the Officers, Council, and Fellows of the Society my great appreciation of their kindness to me during my term of office and my deep regret that I have not been able to complete the usual period of two years. I can only say that my interest in the Society has not waned and that I hope in the future to be able still to be of service to the Society.

I should like to add a very special word of thanks to the permanent officials of the Society with whom I have now worked uninterruptedly for 21 years: to Mr. Carr and to Mr. Clifford my sincere thanks are due for the willing and pleasurable way in which they have co-operated with me: and I should also like to thank Sergeant Holland for the share which he has taken in helping me with the work of the Society.

## OBITUARY NOTICES.

## JOHN YOUNG BUCHANAN \*

BORN FEBRUARY 20TH, 1844; DIED OCTOBER 16TH, 1925.

JOHN YOUNG BUCHANAN was born in Glasgow on February 20th, 1844. He was the second son of Mr. John Buchanan of Dowanhill and the elder brother of the Right Hon. T. R. Buchanan, M.P., who represented Edinburgh in Parliament for many years. He was educated at the Glasgow High School and the University of Glasgow, where he graduated in Arts in 1863. His attention had been turned to Chemistry, and he proceeded to study this science on the Continent, spending several years in Germany at the Universities of Marburg, Bonn, and Leipzig, and going on in 1867 to Paris, where he worked in the laboratory of Würtz, a master for whose scientific genius and personal kindness he always cherished a warm admiration.

Shortly after his return to Scotland Buchanan was appointed Assistant to Professor Crum Brown, then recently established in the Chair of Chemistry in the University of Edinburgh, and in 1870, on Crum Brown's nomination, he was elected a Fellow of the Royal Society of Edinburgh.

When the voyage of H.M.S. *Challenger* was planned for the purpose of investigating the physical and biological conditions of the great ocean basins, it was decided that one representative of the physical sciences should be charged with all matters concerning physics, chemistry, and geology, except such hydrographical and meteorological observations as had been assigned to the naval officers. Buchanan was chosen for this comprehensive post by the Circumnavigation Committee of the Royal Society, who had prepared the programme of scientific work. His selection was due largely to his skill and resourcefulness in devising and making apparatus, his reputation as a practical chemist, his knowledge of mineralogy, and his interest in all natural phenomena. The wisdom of the choice was fully justified. Five years were entirely occupied by the *Challenger* work; the preparations for the cruise, and the fitting up of a chemical laboratory in the small space available on board, taking up several months before the ship sailed in December 1872, and the completion of work in hand occupying a longer time after the ship returned in June 1876.

Throughout those years Buchanan's mind was bent on the practical

\* Reprinted by permission from the *Proceedings* of the Royal Society of Edinburgh.

problems arising in the study of sea-water; but he took full advantage of the many opportunities for excursions into little-known lands when the ship was in port, and he acquired a love of travel that never left him.

He returned to Edinburgh and set up a private laboratory, in which he carried on research on his own account. The possession of ample means made it unnecessary for him to seek any professional appointment, and he continued to spend much of his time at sea. He made investigations on the west coast of Scotland and on the lochs of the Great Glen in his steam yacht, the *Mallard*; and he took part in several voyages of the cable-laying ships of the Silvertown Company on the west coast of Africa and across the Atlantic, mastering the new methods of sounding by wire, which superseded the clumsy processes of the *Challenger*.

In Edinburgh he entered into the remarkable revival in the study of physical geography and kindred sciences which was a feature of the eighth decade of the nineteenth century, and he took a share in establishing the Ben Nevis Observatory, the Scottish Geographical Society, and the Scottish Marine Station. He contributed a large quantity of material for the equipment of the Physical and Chemical laboratory of the original Marine Station at Granton in 1884, and the writer of this notice had many opportunities there of profiting by his instruction in the arts of observing and recording. In 1887 the Royal Society of Edinburgh awarded the Keith Prize to Buchanan for his work in chemical oceanography, and in London the Royal Society elected him a Fellow.

Buchanan was on terms of friendship with Professor Robertson Smith, who encouraged him in the study of physical geography, and helped to persuade him to accept the lectureship in Geography in the University of Cambridge in 1889. Buchanan was given the Cambridge degree of M.A., and took rooms in Christ's College, where Robertson Smith was already established. He resigned the lectureship after holding it for four years, but Christ's College continued to be his home for twenty years, and in his will he left substantial proof of the regard he entertained for it. On leaving Cambridge, Buchanan took up house in London; but he was much abroad, frequently visiting South America, where he had property in the Argentine, and staying at continental resorts, where he had many friends, some of them in very high positions. Kindred tastes cemented a close friendship with Prince Albert I. of Monaco, and he spent much time as the Prince's guest on shore and afloat, making many cruises in the Mediterranean, the Atlantic, and to Spitsbergen in the Prince's yachts, which were splendidly equipped for oceanographical research.

The outbreak of war in 1914 was a blow from which Buchanan never recovered. He had been on terms of personal friendship with the Kaiser and other distinguished Germans, while his old scientific associations with France had been strengthened by his membership of the governing body of the Oceanographical Institute, founded by the Prince of Monaco in Paris. In real distress of mind, Buchanan gave up his London house and betook himself to Havana, in the West Indies, until hostilities ceased.

His last work was the preparation of three volumes, published by the Cambridge University Press, containing reprints of those of his papers which appeared to him the most worthy of preservation. To these he prefixed very copious analytical Tables of Contents, with comments and criticisms often of great interest. The volumes were: *Scientific Papers*, vol. i.—*Oceanographical*, published in 1913; *Comptes Rendus of Observation and Reasoning*, in 1917; and *Accounts Rendered of Work Done and Things Seen*, in 1919.

After his return to London in broken health, the isolating shadow of old age fell on him, and he withdrew more and more from the society of his remaining scientific friends. He died at the age of eighty-one, on October 16th, 1925.

Buchanan's scientific work was directed to the elucidation of practical problems presented to him during the voyage of the *Challenger*. He did not care for theoretical deductions or comprehensive generalisations. He seemed to work mainly for the satisfaction of his own mind, for once a definite result was obtained the problem lost its driving power; and only a portion of the notes which he amassed, with a care and precision that can only be described as meticulous, was ever worked up for publication. He used to say that he loved work but hated writing; still, the number of his published papers exceeds one hundred.

On the *Challenger* most of his time was filled by a routine prescribed by the Circumnavigation Committee, but the tedium was lightened by flashes of discovery. One was the fact of large concretionary deposits of manganese peroxide produced by chemical action of sea-water on minerals. Another was the discovery that the gelatinous substance found on all preserved deep-sea deposits, which Huxley had taken for a primeval organism and named *Bathybius Haeckeli*, was really a precipitate of calcium sulphate thrown down from sea-water by the addition of alcohol.

The short stay of the *Challenger* in Antarctic waters raised the question of the formation and melting of sea ice, on which Buchanan worked with great keenness for several years, producing a series of valuable papers on "Ice and Brines," in which he worked out the chemical and thermal changes accompanying the freezing of saline

solutions and the temperature at which pure ice melted in them. This led to a further series of calorimetric researches on "Steam and Brines."

Another subject raised on the *Challenger* and settled in a shore laboratory, was the compressibility of glass and other substances under the pressure of the deep sea, ranging up to 5 or 6 tons per square inch. The apparatus invented for this purpose was handed over to Professor P. G. Tait, and used by him in determining the pressure corrections of the *Challenger* thermometers.

Buchanan's most important contribution to the *Challenger* Reports was a memoir on the "Salinity of Ocean Water," in which he published the first complete map of the world-wide distribution of surface salinity, the main features of which have been fully confirmed by later investigators.

His work on the Telegraph ships resulted in a study of continental slopes and oceanic shoals, which had scientific as well as practical value. One of his few general papers was a suggestive survey of Similarities in the Physical Geography of the Great Oceans, contributed to the Royal Geographical Society in 1886. In Limnology he was the first to prove that vertical circulation set up by the wind produced a winter temperature of the deep water in a lake far below the maximum density point.

The work of Buchanan was that of a pioneer breaking new ground, and it was his fate, which he recognised and perhaps resented, to make observations of fundamental importance, which were lost sight of under the superstructure raised by others whose names are better known to the scientific public. All he did was original work in the fullest sense. He owed nothing to other workers. He insisted always on going to the fountain-head, preferably by direct observation, for all data, and on handling such data in the way most likely to ascertain their true relationships even if that required difference from recognised authorities.

His character exhibited singular sincerity, and a kindness which he did nothing to advertise. Although to acquaintances his manner may often have seemed cold and distant, his nature showed a very warm and friendly side to the few congenial comrades of his choice.

H. R. M.

---

### GIACOMO LUIGI CIAMICIAN.\*

BORN AUGUST 27TH, 1857; DIED JANUARY 2ND, 1922.

GIACOMO LUIGI CIAMICIAN was the son of Giacomo Ciamician and Carolina Ghezzeo and was born at Trieste, where his father's family,

\* Translated by Sir Wm. J. Pope.

*G. Ciurcian*

[To face p. 996.]

of Armenian origin, had not been long established. The family claimed descent from the great 18th-century historian of the Armenian people, Michele Ciamician.

Ciamician received his secondary education in his native Trieste, where Prof. Augusto Vierthaler initiated him into chemistry; he then studied at the Polytechnic and the University of Vienna, devoting himself principally to Chemistry under Professors Barth and Weidel. While still a student he busied himself enthusiastically and with no little insight upon biological and physical investigations and published several papers of importance, thus laying the foundation of that broad appreciation of physical and biological science which became so evident in his later scientific work and which set the stamp of character on his future triumphs. In 1880 he became a Doctor in Philosophy in the University of Giessen and in the same year was appointed assistant under Stanislaw Cannizzaro in the Institute of General Chemistry of the University of Rome. While in Rome, where he remained until 1887, he was appointed to a Readership, and in this capacity delivered, first, courses of lectures on spectroscopy and, later, on the nitrogenous organic compounds. In 1887 he was chosen in competition for the post of Professor of General Chemistry in the University of Padua, and in 1889, again competitively, he was elected into the corresponding chair in the University of Bologna; here he remained until his death, giving two courses, those of general and inorganic chemistry and of organic and biological chemistry.

The scientific work of Ciamician can be classified in six large groups:

1. *Various Chemical and Physical Investigations carried out between 1877 and 1880.*

This group comprises ten memoirs which deal particularly with spectrum analysis, and also with the resins and the composition of Dippel's oil; it treats of work done in the Polytechnic and the University of Vienna before its author proceeded to his Doctor's degree. The contributions to spectroscopy are of the greatest interest, presenting as they do a comparative study of the spectra of homologous elements which belong to the same group in the periodic system. Ciamician foresaw much that has been since firmly established by more modern methods; he affirmed the spectroscope to be the instrument destined to elicit information concerning atomic motion, and declared that analogous elements of the natural system have analogous structures. These conclusions were far in advance of their time, and it is small wonder that even Mendeléev and Wm. Ostwald judged them as fanciful.

## 2. *The Study of Pyrrole and Allied Compounds.*

This group includes about eighty papers published between 1880 and 1905; therein are described many derivatives of pyrrole with the details which establish the chemical character and behaviour of this base. The aromatic nature of pyrrole and its analogies with the phenols are here developed; these are questions of prime importance in connexion with this group of compounds and later became fundamental to the study of chlorophyll and hæmatin. The reduction products of pyrrole, pyrrolylene, and more especially of pyrrolidine, prepared for the first time in 1885, call for particular mention in that these groupings form part of the nuclei of such important alkaloids as hygrine, nicotine, cocaine and atropine, and of the proteins.

The results of these investigations were collected in a monograph "*Il Pirrolo e i suoi Derivati*," published in 1888, which gained for its author the Royal Prize of the Accademia dei Lincei. Ciamician gave a masterly review of the whole subject in an address to the Deutschen Chemischen Gesellschaft "*On the Development of the Chemistry of Pyrrole during the last Quarter of a Century*," in 1904 (*Ber.*, 1904, **37**, 4200). Amongst the work done in this field should be noted the discovery and utilisation of tetraiodopyrrole or *iodol*, which has found considerable therapeutic use as a substitute for iodoform. To be remarked also is the preparation from pyrrolidine of butadiene, a hydrocarbon which later became so important in connexion with the synthetic manufacture of indiarubber. Meyer and Jacobsen ("*Lehrbuch der organischen Chemie*," 1920, **2**, 147) refer to this group of investigations in their statement—"Das eigenartige Verhalten der Pyrrol-Körper wurde besonders durch eine grosse Reihe von trefflichen Untersuchungen beleuchtet, welche man dem italienischen Forscher Ciamician und seinen Schülern verdankt."

## 3. *Researches on Certain Vegetable Components.*

Thirty-seven papers are devoted to this subject and appeared between 1888 and 1899. The constitutions of a number of organic compounds of vegetable origin were established by these investigations. The work on apiole, and the conversion of safrole and eugenol into their isomerides, which was vital to the industrial manufacture of heliotropin and vanillin, here call for mention; so also does the study of the components of the Coto and similar barks, of pseudo-pelletierine and the constituents of the essential oil of celery, in which the constitution of the aromatic principle, sedanolid, was elucidated. This was one of Ciamician's finest pieces of work; it

preceded that of Willstätter, who developed with such success, and in a variety of directions, the line of investigation so well marked out and defined by Ciamician.

#### 4. *Researches on the Chemical Action of Light.*

Forty notes and nine memoirs were published between 1900 and 1915 on this subject, which was developed into the first systematic study of the behaviour of organic substances towards light.

These researches on the action of light were initiated by Ciamician at Rome in 1886 by his investigation "On the conversion of quinone into quinol by light" and "On the action of light on nitrobenzene in alcoholic solution." They were resumed actively in 1900 and carried on until 1915 in conjunction with Dr. Paolo Silber, who had collaborated in most of Ciamician's work since 1882. The war interrupted this partnership, which is one of the longest, the most fruitful, and the most disinterested joint efforts in chemical scientific investigation. In the course of this work the following photochemical reactions were discovered: the reciprocal reduction and oxidation of alcohols and carbonylic compounds such as aldehydes and ketones, the reduction of aromatic nitro-derivatives by alcohols and aldehydes, the polymerisation of unsaturated compounds and their isomeric changes—this was extended also to the oximes—the hydrolysis of open- and closed-chain ketones, and also of *cyclohexanone* and its derivatives, of menthone, of camphor, and of fenchone, the condensation of hydrogen cyanide with ketones and aldehydes, the aldol condensation of alcohols and ketones, and the synthesis and autoxidation of  $\gamma$ -diketones.

The earlier portions of this series of studies were summarised in a brilliant lecture "On the Chemical Action of Light," delivered before the French Chemical Society in 1908. The later publications on photochemistry treat of the autoxidation of organic acids and of ketones, of bases such as piperidine and nicotine, and of the reduction of copper salts by acetic and benzoic aldehydes. As of especial interest in connexion with autoxidation may be noted that of the *cyclohexanones*, which yield dicarboxylic acids and the corresponding ketones by opening of the ring, and that of oleic acid, in which the double bond is broken, giving a series of lower fatty acids and providing an explanation of the occurrence of rancidity.

During his researches on light as a chemical agent, Ciamician acquired the conviction that the future of organic chemistry lay in its application to biological chemistry and that the more the chemist makes his methods approximate to those of natural pro-

cesses the better he will succeed in elucidating the secrets of nature. Ciamician was never interested in making new compounds for their own sake; he held in horror those substances which only figure in Beilstein, and his work followed no fashion, but was always directed towards the solution of fundamental problems. Plotnikov, impressed by the mass of work carried out by Ciamician and Silber since 1900, has stated that this year marks the basic date in the history of photochemistry.

#### 5. *Researches on Vegetable Chemistry.*

This group of studies is described in nine notes and twelve memoirs and was initiated by Ciamician in 1908 in collaboration with his assistant, Dr. Ciro Ravenna, now Professor of Agricultural Chemistry at Pisa, and was continued until a few months before his death. The problem involved was that of the origin and the functions of the vegetable glucosides and alkaloids.

These investigations constitute a broad and happy attempt to elucidate the functions and mutual transformations of the substances contained in the living plant; its most valuable result has been the synthesis of glucosides by introducing the aromatic compounds concerned into the plant. Thus, salicin is formed as a result of inoculating growing maize with salicyl alcohol. Further, on introducing nitrogenous substances, and especially amino-acids, into plants which produce alkaloids, the production of the latter is increased: thus, asparagine increases the formation of nicotine in the tobacco plant. In another series of experiments, the influence of certain organic substances on the germination and development of plants was studied with a view to ascertaining the function of the alkaloids. From all this work it appears to be indicated that such accessory products as alkaloids, produced in the living plant, are not excretory products, but exercise a function which may be similar to that of the hormones in animals.

Ciamician summarised his work and its conclusions in an elegant and lucid address "On the Biological Significance of Alkaloids in Plants," delivered in October, 1921, at the meeting in Trieste of the Italian Association for the Advancement of Science. This was the last occasion on which he spoke in public, and he concluded the account of this very beautiful piece of synthetic work by stating—"The conclusion deduced from what we know at present, is that the plant practises a chemistry corresponding to that practised in the laboratory, but does so by means infinitely more simple than ours, although with objects similar to ours. The plant organisation is less differentiated than that of animals, and volitional manifestation is less developed, but amends are made

by the exercise of a highly perfected chemical technique; the plant consciousness is a chemical consciousness."

6. *Memoirs and Notes on Physical Chemistry.—Addresses and General Discourses.*

The first work of Giacomo Ciamician was on physical chemistry, and he continually followed the development of this science; indeed, he made notable contributions to it by a few but fundamental papers. The note "On a Lecture Experiment for Demonstrating Raoult's Law," and that "On the Theory of Electrolytic Dissociation," in which he was perhaps the first to advance the idea of complexes formed between the ions and the molecules of the solvent (*i.e.*, solvates of the ions), are worthy of remark. Again, the paper "On the Relations between the Chemical Constitution and the Property of forming Solid Solutions of Organic Compounds" was the starting point of fruitful investigations in his own laboratory and culminated in the classical work of Bruni on solid solutions. The note on "Considerations on the Nature of Chemical Affinity and of the Valency of the Atoms," published with Padoa in 1918, came early in the introduction into our science of the electronic constitution of the atom, and some of the views put forward are really profound and merit further development now that the secrets of atomic constitution seem in the main unveiled. Ciamician's point of view in the treatment of questions of general interest was a very admirable one. In his inaugural address on "Chemical Problems of the New Century" in 1903 he showed a real gift for the dignified but at the same time efficient popularisation of science; this power was still further developed in a lecture on "Problems and Objects of Modern Organic Chemistry," given at Vienna in 1907, in those on "Organic Chemistry in Organisms" at Parma in 1908, and on "The Co-operation of the Sciences" at Naples in 1910, and, lastly, in his magnificent discourse on "The Photochemistry of the Future," read at New York in 1912 before the 8th International Congress of Applied Chemistry. In this sparkling address he developed many fundamental conceptions which have been taken up in numerous later well-known utterances by others; he insisted on the need for setting plants to work, so that we may conserve, so far as may be possible, our natural wealth of fossil fuels, which is really small, and of applying photochemistry in desert regions to the utilisation of the solar radiation.

"On the arid earth," he says, "will spring up industrial colonies without soot and without chimneys: forests of glass tubes and greenhouses of all sizes will rear themselves before the sun, and in this transparent apparatus will proceed those photochemical

processes of which the secret and the monopoly are at present held alone by the plant, but which human industry will learn how to wrest from it. That knowledge will be usefully applied in quite new ways, because whilst nature is incapable of haste, humanity can act more speedily; if, in some distant future, the moment arrives when fossil carbon becomes exhausted, it will not entail the death of civilisation, for life and its amenities will endure so long as the sun shines." He took up this argument again, and in a form which appealed to a larger public, in his article on "Chemical Industry without Carbon," published in the "Nuova Antologia" in 1917.

Amongst other writings of Ciamician which call for special mention are those devoted to the memory of Stanislao Cannizzaro and of his intimate friend Augusto Piccini, and the discourse, pregnant with thought, delivered at the celebration of the 70th birthday of Guglielmo Koerner.

The vast output of scientific work of outstanding merit produced by Giacomo Ciamician has been very briefly summarised in the above pages; it appears the more remarkable by contrast with the penury of his laboratory, which made his work a real struggle. He was an incomparable master in the laboratory and the lecture theatre and a great stimulus to energetic work. His numerous pupils now fill the most important chairs of chemistry in Italy and hold high the renown of Italian chemistry; amongst them may be mentioned Angeli, Magnanini, Plancher, Garelli, Bruni, Mascarelli, Ravenna, Boeris, Cambi, Barbieri, Padoa, and Ciusa, together with Zanetti and Rimini, who have passed away. He initiated and vigorously inspired much original work which did not come strictly within his own field; thus arose the investigations of Bruni, Garelli, and Padoa. Himself indefatigable, he inspired in all a noble enthusiasm for assiduous work. His lectures, to which he devoted himself like an apostle, were models of elegance, of precision, and of vivacity, as well as in the choice of experiments; they were one of his great passions, and it was always for him a sad day when he could not appear before his class, which welcomed him with growing applause, repeated at the close of the lecture. Against the advice of his friends and students, and when already attacked by fever in November 1921, he wished to commence his courses in general and in organic chemistry; immediately afterwards he was laid aside by the insidious malady which took him from us.

Giacomo Ciamician was a member of practically all the Italian Academies and scientific bodies, as well as of a large number of foreign societies. He had been President of the Italian Society for the Advancement of Science and of the Italian Association for Pure and Applied Chemistry; he was an honorary member of the

English, French, German, and American Chemical Societies, and a foreign member of the French Academy of Sciences. He was an honorary LL.D. of the University of Glasgow and an honorary member of the Royal Institution of Great Britain. He did not seek dignities, but he was a Cavaliere dell' Ordine del Merito civile di Savoia and a Chevalier of the Legion of Honour. After 1910, he worked actively as a member of the Italian Senate. He had a distaste for militant politics, but nevertheless his voice did not fail the Senate when questions arose which concerned education or the chemical industries; his principles were broadly liberal and he was greatly attached to his native Trieste. Immediately after his graduation he left Vienna, although he could have found there an ample career and ample means for carrying out his work, and came to Italy. At the death of Professor Weidel, an occasion offered for his election as Professor in Vienna with honours, means of work, and emoluments far greater than those he enjoyed in Italy; notwithstanding his gratitude to his former teacher, Professor Lieben, he never thought for a moment of abandoning Italy.

During the war he devoted his great abilities with much self-sacrifice but with juvenile enthusiasm to the work allotted to him; this work was arduous and intense and, whilst without doubt valuable to our country, undermined his already shaken constitution. Towards the end of the war he was smitten by two great sorrows, first, the death of his mother and later that of his dearly-loved sister, Carolina, the wife of Professor R. Nasini. The last great pleasure of his life was to witness the liberation of his native Trieste. Trieste had always held him in affection and esteem as one of the elect of her sons, and decided on his death that the Via degli Armeni, in which is the house of his aunts on the mother's side where he passed his youth and which he made his home when in Trieste, should be renamed the "Via Giacomo Ciamician." On the house in which he was born, 21 Via S. Martiri, the Municipality has placed a bronze medallion with his portrait and an inscription by the well-known patriot and scholar, Senator Attilio Hortis.

Ciamician was of a benign and fine presence; his blue eyes expressed his great kindness and revealed the simplicity of his nature; he was easily moved to anger, but incapable of harbouring offence. He had a genius for friendship and lavished a noble affection upon his intimate associates; he was simple and upright in private life and a model of the civic virtues. His mind was open to all the great modes of intellectual expression; amongst the arts he loved above all that of music, and in this, even in musical Bologna, he was considered as one of the highest authorities. The Queen Margherita held him in affection and enjoyed his thoughtful

and animated conversation; he had friendships amongst all the chief chemists of his day, more particularly with Emil Fischer, who several times proposed him for the Nobel prize, with Albin Haller in France, and with Henry E. Armstrong.

Bologna was proud to look upon him as one of her citizens and followed anxiously the vicissitudes of his last illness, an insidious malady from which so rapid an end was not to be foreseen. He passed away quietly in the arms of his brother-in-law, Professor R. Nasini, and of his nephew, Dr. A. G. Nasini, and surrounded by his relatives from Trieste; most of his former students had collected in Bologna to be present at the end. They took part in the last solemnities when he was laid to rest on a cold and bright January day; to the accompaniment of Beethoven's funeral march, as Ciamician had wished, the great procession passed among the mourning populace through the streets of the old turreted city he had loved so well.

A memorial stone has been placed by his students on the house which he had always occupied, No. 3 Via Guido Reni. In a short time the new Chemical Institute will be inaugurated; Ciamician had devoted much of his activities to this project and its execution and hoped much from its future. It will carry on its façade the inscription "Istituto Chimico Giacomo Ciamician." An honour worthy of the great man of science.

RAFFAELLO NASINI.

---

### SAMUEL HENRY DAVIES.

BORN SEPTEMBER 19TH, 1870; DIED MAY 9TH, 1925.

SAMUEL HENRY DAVIES was born at Liverpool on September 19th, 1870, the son of Richard Davies, pharmacist. He received his early schooling in Liverpool, and was then for four years at the Friends' School at Sidcot in Somerset, where he already showed a keen interest in chemistry. He studied successively at University College, Liverpool, and Owens College, Manchester, and graduated B.Sc. at Manchester in 1890 (M.Sc. in 1893), winning a scholarship which took him to Heidelberg. Here, under the direction of Victor Meyer, he carried out a research on "Alkyl and Acetyl Sulphides," which was published in the *Berichte* in 1892, and a minor research with Emil Feith on the "Action of Hydroxylamine Hydrochloride on Acetomesitylene."

After returning to England Davies held university posts as demonstrator first at Manchester and later at Leeds, and won the esteem of professors and students. His professor at Leeds says: "I never parted with a demonstrator more reluctantly, for

he was an excellent teacher full of life and go, ready to take up and carry out any promising new plans of instruction."

In 1893 Davies was appointed the first head of the chemical department at the new Battersea Polytechnic; into the organisation of this department he threw himself with whole-hearted and characteristic energy. Here he remained until in 1896 he was appointed chemist to Rowntree and Co. at the Cocoa Works, York. This post he held for more than twenty-five years, during which the original small laboratory with one assistant grew under his direction to a finely-equipped department with a staff of fifty.

Davies was a man of the widest human sympathies and his work at York did not end with his duties as chemist but covered a varied field; he lived a very full life both in the works and in the city. He took the keenest possible interest in the welfare of the workers and in their various clubs and social activities, devoting much time in the earlier days to the swimming, rowing, and football clubs.

In 1907 Davies married Miss Edith M. Oliver and about this time was elected a member of the York City Council, on which he represented Castlegate ward for nine years. He was a strenuous advocate of the feeding of necessitous school children and of a clean milk supply and was the author of pamphlets published by the York Health and Housing Reform Association.

Much of Davies's work for the firm could not be made the subject of publications, but in 1904 he published (with McClellan) a paper on the amount of fat contained in cocoa beans of different origin and in 1912 (with J. S. Bainbridge) a valuable paper on "The Essential Oil of Cocoa." He directed much attention to the general problems of factory working, and papers published in 1903-1904 on the "Relative Efficiency of Insulating Media" embody the results of detailed research on the comparative value of materials used for covering steam-pipes. He also wrote on factory ventilation and lighting and devised a simple and rapid method for the estimation of carbon dioxide in the atmosphere.

On behalf of Rowntree and Co. Davies made journeys in many countries, notably in South America and the West Indies; he returned to the West Indies several times in connection with the development of Rowntrees' estates. He always maintained his interest in these islands and was a prime mover in establishing the Technical College in Trinidad, of which he was appointed a governor.

Davies was a member of the Fell and Rock Climbing Club and, an enthusiastic lover of mountains, spent many summer holidays in the Tyrolean Alps.

From 1919 Davies suffered from ill-health and after a break-

down in 1922 relinquished his full time duties at the cocoa works, but was still retained by the firm as consultant. He built himself a new home and a laboratory at Jordans in Buckinghamshire, where he intended to continue research work, but his health broke down completely and he passed away on May 9th, 1925.

Davies possessed an unusual charm of manner and disposition and was beloved by a wide circle of friends; excellent chemist as he was, chemistry was to him but one means of approach to his fellow men. A writer in the *York Gazette* says of him: "When S. H. Davies saw something to be achieved which could bring gladness and essential prosperity into the lives of his neighbours, he sought for this with his whole soul and strength, however strong and influential the forces against him," and one who worked with him in his later years rightly described him as "gentle and charitable, indulgent to others, severe to himself and unwearying in service to friends." His was a noble nature and we who knew him are sorrowful that he has left us so soon.

REGINALD BROWN.

### WILLIAM HENRY DEERING.

BORN DECEMBER 19TH, 1848: DIED SEPTEMBER 5TH, 1925.

WILLIAM HENRY DEERING was the youngest son of W. Deering of Gravesend. He received his early education at the City of London School and in 1864 entered the College of Chemistry as a student under Hoffman. After short periods as assistant to Sir Benjamin Brodie at St. Bartholomew's Hospital and with William Odling at Oxford, in 1867 he joined the staff of Sir Frederick Abel, Chemist to the War Department, at the Royal Arsenal, Woolwich. He spent the rest of his life, until his retirement in 1909, in the Government service, becoming himself Chemist to the War Department in 1905.

Like that of many other civil servants, Deering's work was unknown to the general public, but he played no small part in the application of chemical science to military materials which showed so remarkable a development towards the end of last century. Although the introduction of cordite is associated with the name of Sir Frederick Abel, the fundamental researches which led to its adoption in the British Service necessarily depended on his assistants, and of these Deering and his colleague, the late William Kellner, were mainly responsible for the work. It is sufficient testimony to the thoroughness and completeness of their labours that, in spite of continuous efforts to improve upon it, the cordite of to-day is substantially the same as that introduced into the Service in 1889.

In addition to his work on cordite, Deering was called upon, in the course of his long service, to deal with a large variety of chemical and physical problems in connexion with explosives and other military stores. He carried out much important investigation in perfecting electrically-fired detonators for use in the field.

As regards contributions to the literature of their profession, scientific officers of the public service suffer from certain disabilities. It frequently happens that their more important work is of a confidential nature, or, if not, that it is published in the form of a report by the Head of the Department, in which the part played by individuals is not shown. To these facts, coupled with Deering's marked distaste for publicity, is due the relatively small number of papers under his name. Perhaps the most important are those (with Abel) on the conditions in which carbon exists in steel (J., 1883, 43, 303) and (with Kellner) on the measurement of pressure by the crusher gauge (*Proc. Roy. Soc.*, 1895, 57, 404). But he also contributed papers to the Society's *Journal* on water analysis and on lead salts, and to other journals on mineral oil and certain fatty oils. He was responsible for the article on "Explosives" in the first edition of Thorpe's "Dictionary of Applied Chemistry" and received a medal for a lecture on the same subject before the Royal Society of Arts.

Deering's knowledge of chemical literature was encyclopædic. He remained a student throughout his career and had an exceptionally retentive memory. There were few subjects upon which he could not, without hesitation, refer an inquirer to the more important papers dealing with them. In the laboratory, his work was characterised by meticulous care. He took nothing for granted, satisfied himself at every stage of the accuracy of his work, and eliminated or evaluated every possible source of error. He was a good linguist, speaking French and German fluently. He had also a working knowledge of Italian and the Scandinavian languages.

Inclined to be somewhat impulsive and outspoken, and intensely disliking insincerity of any kind, it was only those who knew Deering well who could realise his kindness of heart. He was incapable of an ungenerous act, and appreciated the work of his humblest assistant.

Deering lived for his work, and the Companionship of the Imperial Service Order, conferred upon him in 1906, was an inadequate recognition of a life of really devoted service to his country.

Deering married, in 1905, Isabel, daughter of Thomas Cowie of Blackheath. Upon his retirement, he moved to Devonshire and, after some years of failing health, died at Torquay on September 5th, 1925.

A. V. E.

## FRANCIS ROBERT JAPP.

BORN FEBRUARY 8TH, 1848: DIED AUGUST 1ST, 1925.

FRANCIS ROBERT JAPP, a member of a family of Dutch origin, whose name was well-known half a century ago in the eastern districts of Forfarshire, was born in Dundee on 8th February, 1848, the youngest son of James Japp, minister of the Catholic Apostolic Church in that city. His earliest education was obtained in the town of his birth, in part at the High School there; but in 1861, at the age of thirteen, he was sent to St. Andrews, the reputation of which as an educational centre stood then, as now, very high. After three years spent at the Madras College, he entered the University as a student in the Faculty of Arts.

The course of study for the Arts degree extended, at that time, over four winter sessions of five to six months each (there were no summer sessions), and the subjects studied were Latin, Greek, Mathematics, English, Logic and Metaphysics, Moral Philosophy, and Natural Philosophy. While at St. Andrews, Japp contracted a lifelong friendship with John Masson, essayist and author of "Lucretius, Epicurean and Poet."

After graduating M.A. at St. Andrews, Japp entered the University of Edinburgh in 1868 as a student of law; but his period of study at Edinburgh proved to be a short one. In the summer of 1869 his health broke down and he was compelled to relinquish his legal studies and to reside abroad, at Pau and at other health resorts. For two years, from the spring of 1871 to the spring of 1873, Japp resided in Germany, at Göttingen, Berlin, and Heidelberg; and although, during a portion of that time, he attended lectures on International Law and on German Literature, he had, even then, abandoned his intention of prosecuting the study of law. The record of the following two years will be more interesting if told in Japp's own words, communicated to the writer in a letter some years ago: "In the spring of 1873, I returned to England and spent the time partly in London, partly in Scotland. I had by this time taken up the subject of chemistry, in which I had always been interested. In the autumn of 1873 I returned to Heidelberg and began the study of that subject under Bunsen. I was then twenty-five years of age, and my friends, who had long despaired of my ever taking up anything seriously, regarded this last step as the crowning folly of a hopeless career. In 1875 I graduated Ph.D. at Heidelberg (only *insigni cum laude*). I was anxious to get all examinations behind me as soon as possible and, I fear, rather hurried matters. The Heidelberg Ph.D. at that time required no 'dissertation' and was rather a worthless degree;

Yours sincerely,  
F. R. Japp.

[To face p. 1008.]

there was no practical examination—merely an ‘oral’ of two hours. I stayed with Bunsen until the end of the summer semester, 1876, devoting the winter semester to the separation and preparation of various rare elements and the summer to a rather impossible piece of research which Bunsen had suggested and which led to no result. I also heard lectures by Hermann Kopp, on the History of Chemistry; by Hermann Quincke, on Physics; and by Blum, on Mineralogy. Contemporaries of mine in Bunsen’s laboratory were John Gibson, J. E. L. Shadwell, C. Loring Jackson, W. F. Hillebrand, T. H. Norton, F. P. Treadwell, Charles Otto Trechmann, Hans Jahn, and Siegmund Gabriel.”

From Heidelberg Japp proceeded to Bonn to work in the laboratory of August Kekulé, who had, some years previously, been appointed to the Chair of Chemistry in the University and had attracted to his Institute large numbers of young chemists of different nationalities. Whether the young Scottish chemist felt, as did van ’t Hoff, that the laboratory of Kekulé was a sacred temple to be entered only with feelings of reverence and of awe, we cannot say; but the Memorial Lecture on Kekulé, delivered by Japp in 1897, bears, in its every line, clear and eloquent testimony of the esteem and admiration which he felt for his new teacher, who, although no longer at the height of his physical power, preserved his mental faculties unimpaired and could still inspire work of unsurpassed excellence. It was in the palatial laboratory at Bonn that Japp, under the more immediate guidance of G. Schultz and of Anschütz, first entered on that course of chemical investigation which he pursued with such wholehearted devotion and success for over thirty years. Among Japp’s contemporaries at Bonn were P. Phillips Bedson, Henry Forster Morley, Richard Taylor Plimpton, and Shadwell.\*

\* The writer is indebted to Geheimrat Professor R. Anschütz for the following reminiscences of Japp’s period of study in Bonn:

“Japp wohnte in Bonn mit seiner Mutter in einem Haus in der Kölnstrasse im Nordosten Bonns weit weg von dem in Poppelsdorf gelegenen chemischen Institut. Das beschränkte stark seinen Verkehr mit seinen Studiengenossen, die er nur im Laboratorium sprach; von studentischen Kneipereien hielt er sich fern. . . .

“Damals war Gustav Schultz Kekulé’s Privatassistent und ich Vorlesungsassistent. . . . Soweit es meine Arbeiten für Kekulé gestatteten, arbeitete ich mit Schultz über das Phenanthren. Japp schloss sich an uns an und wir lernten im persönlichen Umgang die liebenswürdigen Eigenschaften des um einige Jahre älteren Fachgenossen schätzen, der nicht nur die deutsche Sprache völlig beherrschte, sondern sogar einen ausgesprochenen Sinn für den deutschen Volkshumor an den Tag legte. . . .

“Da Gustav Schultz und ich unsere Arbeitsplätze neben Kekulé im Privatlaboratorium hatten, so brachte es Japp’s Entschluss mit uns zu

In 1878, Japp returned to Scotland and continued his research work in the laboratory of Professor Crum Brown, Edinburgh. Later in the same year he was chosen by Professor (later Sir) Edward Frankland, out of a large number of candidates, to take charge of the Research Laboratory which was then being established at the Normal School of Science, South Kensington, and to devote his whole time to the supervision of the research students. In 1881, when the Science Schools were reorganised by the Science and Art Department, Japp was promoted to the rank of Assistant-Professor in what was then called the Royal School of Mines and Normal School of Science, and which, at a later date, became the Royal College of Science. Here, under E. Frankland and later under T. E. Thorpe, who succeeded to the Chair of Chemistry in 1885, Japp continued to direct the work of research in, as well as to lecture on, organic chemistry. Although recognised as a brilliant research chemist, Japp felt that he was adversely affected in his candidatures for a Chair by his lack of experience in the conduct of a general laboratory, and in 1889, on the departure of P. F. Frankland to occupy the Chair of Chemistry at Dundee, Japp requested and was given a share in the teaching work of the large laboratories. Unsuccessful in his candidature for the Chairs at Leeds in 1885 and at Dundee in 1889, Japp was appointed to the Chair at Aberdeen in 1890, in succession to Thomas Carnelley.

The twelve years spent in London constituted, perhaps, the "Golden Age" of Japp's scientific life. Filled with an enthusiasm for research, Japp not only found his work at the Normal School (and Royal College) of Science for the most part congenial and satisfying, but he also greatly enjoyed participating in the active scientific life which found its focus in the Chemical Society, at the meetings of which he was often a conspicuous figure. In the discussions which there took place, as the writer is informed, "opportunity arose for his revealing, not only his dry humour, but also his profound knowledge of chemical literature and a width of classical and philosophical reading altogether beyond the range of the attainments of the great majority of his contemporary

---

arbeiten mit sich, dass er mit Kekulé genauer bekannt wurde, als es sonst geschehen wäre. Kekulé fand bald Gefallen an Japp's immer bedächtiger aber stets klarer Art sich in der Unterhaltung über wissenschaftliche Fragen auszusprechen.

"Als im Jahre 1878 die Stelle eines Demonstrator der organischen Chemie am Royal College in London bei Frankland zu besetzen war, bewarb sich Japp darum, unterstützt durch ein ausgezeichnetes Zeugnis von Kekulé, und Frankland gab ihm vor anderen Mitbewerbern den Vorzug. Wie mir Japp später mitteilte, habe Frankland besonders unsere Beweisführung der Konstitution des Phenanthrens gefallen."

chemical colleagues." Japp valued also the personal contacts with the leaders and fellow-workers in chemical science which residence in London made possible. On the other hand, Japp's scientific accomplishments, his well-stored and cultured mind, and his remarkable personality won the admiration, regard, and esteem of his fellow-chemists, and he was early called to serve on the Council and the Publication Committee of the Chemical Society. Although, to the great regret of his many scientific friends, Japp seldom, after his departure in 1890, re-visited London or took part in the gatherings of chemists elsewhere, one could not fail to note how, in later years when settled at the northern University, he sometimes looked back with something of wistful yearning to the inspiration and stimulating fulness of life which the Metropolis offered to the scientific worker.

While at the Royal College of Science, Japp gathered round him a large number of able and enthusiastic students, and research was prosecuted with great activity. About half the total number of scientific papers which Japp published, either independently or in collaboration, appeared during his London period.

During this period, also, Japp contributed to the advancement of chemistry by the publication, in collaboration with E. Frankland, of a text-book of Inorganic Chemistry which was "constructed on those principles of Classification, Nomenclature, and Notation which, after an experience of nearly twenty years, have been found to lead most readily to the acquisition of a sound and accurate knowledge of elementary chemistry." The composition of the book was mainly the work of Japp, and the more theoretical sections, such as the chapter on the Atomic Theory, are excellent examples of clear and well-reasoned exposition. Owing, doubtless, to the adoption of Frankland's constitutional formulæ and nomenclature, which did not find favour with contemporary chemists, this work did not have the circulation which it deserved.

Japp also collaborated with Frankland in the preparation of a new edition of the latter's "Lecture Notes on Organic Chemistry."

From the Royal College of Science Japp proceeded, as has been noted, to the University of Aberdeen. He was, perhaps, fortunate in the date of his appointment, for it fell on the eve of a very great and rapid development of the University, marked, not only by the erection of imposing buildings and an increase in the number of its teachers, but also by a renewed activity in literary and scientific investigation. In all this progressive movement the Chemistry Department, under Japp's guidance and enthusiasm, played a notable part.

Until 1896, the Chemistry Department of the University of

Aberdeen was housed in a series of four or five small rooms, badly lit and badly ventilated, which afforded accommodation of a very inadequate character for only two or three advanced students working at one time. Two of the rooms, in which the classes in practical chemistry for medical students were held, were fitted with a circular table without sink and without water-supply other than that contained in a jug placed on the narrow working bench. In these rooms even the most primitive arrangements for the extraction of fumes were wanting, so that when fifteen or twenty students were vigorously boiling off excess of aqua regia, the figure of Japp, seated on a stool in the centre of the space enclosed by the circular work-bench, could be only faintly discerned through a mist of acid vapours.

With such accommodation at his disposal, it was clear that it would be impossible to build up a school of chemistry of any importance, and Japp therefore set about the task of arousing public opinion and of stimulating the University authorities to a recognition of the claims of chemistry to more adequate accommodation. His reward came at last, and in 1896, with the carrying out of a scheme of University extension, Japp found himself installed in laboratories which, at that time, could be regarded as palatial, but which, in the space of thirty years, have become inadequate for the requirements of the present day.

Development, however, took place in directions other and more important than towards new buildings. Previously, the work of the Chemistry Department had consisted, almost entirely, in the teaching of elementary chemistry to medical students, but soon after Japp's installation as Professor at Aberdeen, a Faculty of Science was instituted, courses of instruction leading to the degree of B.Sc. were introduced, and a school of advanced chemical study rapidly grew up. It must, indeed, be regarded as not the least important and valuable of Japp's contributions to the advancement of chemical science that, in an area where there had previously existed no school of advanced chemical training or tradition of chemical study, he created a vigorous school of chemical instruction and research from which there has issued a succession of chemists, many of whom occupy important academical and industrial posts in various parts of the world.

While at Aberdeen, Japp delivered, each year, two courses of lectures, one on elementary inorganic chemistry and one on organic chemistry; and it must be confessed that as a lecturer to young Scottish students, perhaps the most testing audience for any lecturer to address, Japp fell somewhat short of achieving complete success. It may be that he did not sufficiently bear in mind that

the great majority of the students attending his elementary class came to him entirely ignorant of chemistry or were hearing his lectures, not from choice, but under the compulsion of regulations; and it may also be that he was, temperamentally, somewhat out of touch with the mind of the average young student. As a consequence, the generous appreciation of which the Scottish student is capable sometimes degenerated, unfortunately, into an irritating disturbance or even a boorish noisiness. This behaviour on the part of his students was a constant source of annoyance and worry to Japp, and even told adversely on his health. On one occasion, when the disturbance was more than usually bad, Japp was roused to protest. Halting in the course of his lecture, he gazed on his students for a few moments and said: "Gentlemen, I have been a member of four Universities—London, Edinburgh, St. Andrews, and Aberdeen—and I find that the higher the latitude the lower the breeding."

For his comparative lack of success with his elementary class, his success as a lecturer on organic chemistry to advanced students in science must have been some compensation. In this case, the lecturer was dealing with a branch of chemistry to which he had devoted his life and he was in the presence of a serious body of students to whom he gave of his best. Drawing on his wonderful knowledge of the subject and brightening, here and there, the intricacies of a problem in constitution with a touch of personal reminiscence, Japp revealed to his students the main features and course of development of organic chemistry in a manner which, to the student, was most impressive and showed Japp's mastery of detail, clearness of thought, and accuracy of language.

In all his teaching, whether in the lecture room or in the laboratory, Japp was intolerant of haziness of thought and slovenliness of manipulation; and the high standard of clear thinking, accurate expression, and neatness of experimental work which he set for himself and demanded of his students did not fail to make an inefaceable impression on his pupils.

It was, however, in the research laboratory that Japp was most at home and at his best. With the help of a research assistant, maintained by means of a grant from the Royal Society, and in later years with the assistance of his own graduate pupils, Japp was enabled to maintain, although in somewhat diminished volume, his output of research work. During his tenure of the Chair at Aberdeen, upwards of forty papers were published by Japp in collaboration with his private assistants or research students. Although the last paper to bear his name appeared in 1905, Japp continued to inspire and direct the research work of members of

his staff; and, with a modesty approaching almost to self-depreciation, he frequently effaced himself in order that his reputation and seniority might not deprive his younger colleagues of any credit to which they might be entitled. This self-effacement was exhibited, not only in connexion with the publication of research, but also in connexion with the organisation and development of the teaching work of his Department.

Although always jealous of the interests of his Department and active in its development, Japp took no prominent part in University politics or in the general work of administration. Nor did he take much part in the life of the various University Societies. "Whenever they" (the officials of the societies) "came to me for an address, I used to give them a sovereign, which I have no doubt was infinitely more acceptable." This, of course, was not the case, and one cannot but regret, from the point of view of the students, that Japp refrained from making use of the opportunities which offered of impressing on a larger body of the students something of his own remarkable personality, of imparting to them something from his great store of scientific and literary lore, and of encouraging in them the cultivation of the wide and philosophic outlook which he himself possessed. Japp, however, had little of the missionary spirit and no great love for the platform or the market place; and he preferred to share the treasures of his mind chiefly with those who were associated with him in research or had the good fortune to enjoy his friendship.

Commencing, as Japp did, his career as a chemical investigator in the laboratory of Kekulé, who, to quote from the Memorial Lecture, "brought an intellect of incomparable power and subtlety to bear on problems so abstruse, so remote from the everyday thoughts and interests of mankind, that the vast majority even of educated persons have never heard either of the problems or of the man who did so much to solve them," it is, perhaps, not surprising that Japp's research work was by no means "popular." It concerned itself at no point with problems of everyday experience or of immediate industrial importance, but dealt with many difficult problems of chemical constitution which required for their solution greater chemical acumen and a more profound knowledge than is the case with many investigations which make a more direct appeal to the lay mind. Endowed with a very retentive memory, Japp took to heart, and passed on to his pupils, the counsel which Liebig gave to Kekulé: "If you want to be a chemist, you will have to ruin your health; no one who does not ruin his health with study will ever do anything in chemistry nowadays." The *Journal of the Chemical Society*, the *Berichte*, and

the *Annalen* were Japp's constant companions, and the *Jahresbericht* formed his holiday reading. As a result he acquired an incomparable knowledge of organic chemistry which, together with a great capacity for accurate and laborious experimental work, the power of clear thinking and reasoning, and a highly developed "chemical instinct," enabled him to solve successfully many obscure problems of chemical constitution. Japp, moreover, was imbued with the spirit of the true scientific investigator intent only on eliciting the truth, without thought of personal ambition or material gain.

The raw materials of almost all of Japp's research work were phenanthraquinone, benzil, and benzoin; and from a paper (J., 1897, 71, 123) which may almost be regarded as the *apologia* of his scientific life one learns that the main objects of the systematic study of the condensations of the ketones and keto-alcohol mentioned were the synthesis of cycloids and the comparison of the properties of ortho-diketones of the aromatic series with those of the  $\alpha$ -diketones or keto-alcohols of the aliphatic series. As he pointed out: "At that time, Ladenburg's 'prism' formula could still be seriously put forward as a satisfactory expression of the reactions of benzene; and in this formula the ortho-carbon atoms are not directly united. Every condensation, therefore, which bore out the foregoing analogy" (between aromatic and aliphatic  $\alpha$ -diketones) "was a fresh argument against the 'prism' formula. Indeed, it is cumulative evidence of this character, rather than any definite disproof, that has caused the 'prism' formula to be withdrawn from discussion."

It may be remarked that some of Japp's earlier investigations (e.g., J., 1880, 37, 410; 1882, 41, 146), which were undertaken partly with the object of throwing light on the constitution of phenanthraquinone itself, supported Graebe's peroxide formula; later work, however (e.g., J., 1883, 43, 27), furnished a very strong argument in favour of Fittig's formula, which was subsequently always employed.

The success with which the main object of Japp's research work, the synthesis of cycloids, was realised, is well seen from the following list of the various classes of compounds formed in different condensation processes:

*Oxazoles*.—1. By the interaction of  $\alpha$ -diketones with aldehydes and ammonia (J., 1880, 37, 669; 1881, 39, 225). 2. From benzoin and nitriles (*ibid.*, 1893, 63, 469).

*Iminazoles*.—1. *Ordinary (secondary) Iminazoles*.—From  $\alpha$ -diketones, aldehydes, and ammonia (*ibid.*, 1882, 41, 146, 157, 323; 1886, 49, 464; 1887, 51, 552, 557). 2. *Tertiary Iminazoles and*

*Quaternary Ammonium Compounds.* From  $\alpha$ -diketones and primary amines of the formula  $R \cdot CH_2 \cdot NH_2$  (*ibid.*, 1895, 67, 32).

*Furfurans.*—By the action of hydriodic acid on the condensation products of  $\alpha$ -diketones with ketones (*ibid.*, 1890, 57, 662).

*Indoles.*—By the condensation of benzoin with primary benzenoid amines (*ibid.*, 1894, 65, 889).

*Azines.*—By the action of ammonia (1) on benzoin and (2) on  $\alpha$ -diketones (*ibid.*, 1886, 49, 828; 1887, 51, 98).

To the above series of compounds one may also add *lactones*, *pyrrolones*, and *pyrroles*.

In addition to the foregoing classes of compounds, all of which are heterocyclic, a number of pentacarbon ring compounds were also synthesised. Chief among these are *anhydracetonebenzil*, obtained by the condensation of benzil with acetone (J., 1885, 47, 21); *anhydracetonebenzilcarboxylic acid*, by the condensation of benzil with acetonedicarboxylic acid (J., 1897, 71, 139); and two isomeric *anhydrobenzil-lævulic acids*, by the condensation of benzil with lævulic acid (J., 1897, 71, 144).

For the most part, the superstructure of Japp's synthetic work was founded on a new reaction which he discovered, the condensation of ketones with aldehydes in presence of ammonia, and on his use of caustic potash as a condensing agent. The careful investigation of a large number of such condensation reactions and the elucidation of the constitution of the compounds produced in these reactions or prepared as derivatives therefrom, not only formed a very important and valuable contribution to synthetic organic chemistry, but also enabled Japp to elucidate the constitution of important compounds prepared by other investigators. Thus, by condensing benzil with benzaldehyde in presence of ammonia, lophine was obtained, and the constitution of this compound, first prepared by Laurent and by Fownes, was thus

shown to be 
$$\begin{array}{c} C_6H_5 \cdot C \cdot NH \\ | \\ C_6H_5 \cdot C \cdot N \end{array} > C \cdot C_6H_5.$$
 By the reduction of lophine, amarine, 
$$\begin{array}{c} C_6H_5 \cdot C \cdot NH \\ | \\ C_6H_5 \cdot C \cdot NH \end{array} > CH \cdot C_6H_5,$$
 is formed (J., 1882, 41, 323; 1900, 77, 608).

Further, condensation of benzoin with benzonitrile under the influence of concentrated sulphuric acid showed that Laurent's benzilam (Zinin's azobenzil) is triphenyloxazole; and the oxidation of anhydracetonebenzil to desyleneacetic acid and the reduction of this acid to  $\beta\gamma$ -diphenylbutyric acid, which was found to be identical with Zinin's pyroamaric acid, established the constitution of the latter. By other condensations, also, important light was thrown on the constitution of glyoxaline, 
$$\begin{array}{c} CH \cdot NH \\ | \\ CH - N \end{array} > CH,$$

glycosine,  $\begin{array}{c} \text{CH}\cdot\text{NH} \\ | \quad \diagup \\ \text{CH}-\text{N} \end{array} > \text{C}=\text{C} < \begin{array}{c} \text{NH}\cdot\text{CH} \\ | \quad \diagdown \\ \text{N}-\text{CH} \end{array}$ , and lepiden (tetraphenylfurfuran).

Whilst the scientific investigations to which reference has just been made established Japp's reputation as a chemist of the first rank, the address which he delivered as President of the Chemistry Section of the British Association in 1898 made a wider appeal, and showed that he was not a mere specialist with his interests confined within the bounds of his own narrow branch of work, but that he interested himself also in the more fundamental problems of science and of life.

In that address, Japp emphasised the importance of the discoveries in stereochemistry because they furnish a reply "to the most fundamental question that physiology can propose to itself—namely, whether the phenomena of life are wholly explicable in terms of chemistry and physics; . . . or whether, on the contrary, there are certain residual phenomena, inexplicable by such means, pointing to the existence of a directive force which enters upon the scene with life itself, and which, whilst in no way violating the laws of the kinetics of atoms, determines the course of their operation within the living organism." His whole address was an argument, based on the results of stereochemical investigation, in favour of the doctrine of vitalism as revived by the younger physiologists; and in it his purpose was to show that "living matter is constantly performing a certain geometrical feat which dead matter, unless, indeed, it happens to belong to a particular class of products of the living organism and to be thus ultimately referable to living matter, is incapable—not even conceivably capable—of performing."

The argument may be briefly summarised. Although in nature most asymmetric compounds occur in one of the optically active forms only, it is found that when it is attempted to synthesise such a compound from symmetric substances the product of the synthesis is always inactive. As Pasteur said: "Artificial products have no molecular asymmetry; and I could not point out the existence of any more profound distinction between the products formed under the influence of life and all others." The inactive forms, however, obtained by chemical synthesis can be resolved into the two oppositely active isomerides by means of enzymes, moulds, etc., and even, in some cases, by crystallisation. Since the racemic sodium ammonium tartrate could be resolved into the active forms by the symmetrically acting process of crystallisation, and these active forms could be separated by hand, it was thought that "the barrier which M. Pasteur had placed between natural

and artificial products" was thereby broken down; and this was undoubtedly the view held by the majority of chemists.

But had it? Japp intimated in his address that he had for some time held a contrary opinion, and he again asked the question which had also previously been posed by Crum Brown: "Is not the observation and deliberate choice by which a human being picks out the two kinds of crystals and places each in a vessel by itself the specific act of a living organism of a kind not altogether dissimilar to the selection made by *Penicillium glaucum*?" This question Japp discussed and answered in the affirmative. The artificial, racemic compound, certainly, had been resolved into the active forms by the symmetrical process of crystallisation, but these two forms had not thereby been *separated* from each other; both active forms were present side by side. Their separation "requires the living operator, whose intellect embraces the conception of opposite forms of symmetry, to separate them." . . . "Conscious selection here produces the same result as the unconscious selection exercised by the micro-organism, the enzyme, or the previously existing asymmetric compound." Pasteur had himself pointed out that "to transform one inactive compound into another inactive compound which has the power of resolving itself simultaneously into a right-handed compound and its opposite, is in no way comparable with the possibility of transforming an inactive compound into a *single active* compound. This is what no one has ever done; it is, on the other hand, what living nature is doing unceasingly before our eyes." Here then is the conclusion to which, from a consideration of the facts of stereochemistry, Japp arrived: "The production of single asymmetric compounds, or their isolation from the mixture of their enantiomorphs, is the prerogative of life. Only the living organism with its asymmetric tissues, or the asymmetric products of the living organism, or the living intelligence with its conception of asymmetry, can produce this result." And further: "I see no escape from the conclusion that, at the moment when life first arose, a directive force came into play—a force of precisely the same character as that which enables the intelligent operator, by the exercise of his will, to select one crystallised enantiomorph and reject its asymmetric opposite." The action of such a directive force, moreover, involves no violation of the law of the conservation of energy.

An address on such a subject as that selected by Japp could not fail to provoke discussion, and its arguments were, indeed, assailed by Karl Pearson, Fitzgerald, Herbert Spencer, and others. All their criticism, however, was successfully met, and failed to force a retreat from any of the positions which had been taken up.

That the work which Japp accomplished for chemistry was appreciated by the scientific and academic world is shown by the honours of which he was made the recipient. As early as 1885, he was elected a Fellow of the Royal Society; from 1885 to 1891, he was Foreign Secretary, and from 1895 to 1899, Vice-President of the Chemical Society; in 1891, he was awarded the Longstaff Medal, the highest mark of appreciation which British chemists can show, for his researches in organic chemistry; in 1898, he was President of the Chemistry Section of the British Association; and from 1901 to 1904, he was Vice-President of the Institute of Chemistry. In 1888, the University of St. Andrews conferred on Japp the Honorary Degree of LL.D., and he was similarly laureated by the University of Aberdeen in 1915.

A sketch of Japp's scientific achievements, however, gives a picture of but half the man; for in him we find one who, although a specialist who won for himself high distinction in a relatively narrow field of scientific study, nevertheless appreciated and loved literature and art. A linguist of ability, the literatures of England, Germany, France, and Italy were accessible to him in the language of their authors; and while possessing a familiar knowledge of all that is best in the literature of our own country, his acquaintance with the literature of Germany, of France, and of Italy was such as might be envied by many who have taken up the study, not of science, but of letters. On many occasions an apt quotation or literary allusion gave point to an argument or brightened a conversation.

In his speech, as in his writing, Japp's language was always clear and accurate, and if he did not compose with rapidity he did so with exceeding care; and his writings were models of lucidity, logical development of an argument, and accuracy of expression.

Japp's interests extended, also, into the realm of Art, especially of music. A musician of cultivated taste, he possessed not only executive ability as a pianist but also a thorough knowledge of musical theory and a wide acquaintance with musical compositions. It was to him a great pleasure, relaxation, and recreation to spend an evening, in the company of music-loving friends, in discussing the compositions of his favourite composers or in performing their works.

Unskilled in the art of self-advertisement and indifferent to the world's estimates of eminence or wisdom, Japp looked upon the general activities of the world and the impatient hurrying of men with a certain Olympian detachment and philosophic calm; and the petty annoyances which were laid upon him by the jealousies or inconsiderateness of lesser minds he bore with amiable

resignation. He was slow to form conclusions, but his judgment, whether of men or of opinions, was sound and could be relied on with confidence. He was himself the soul of honour and devoted to truth.

A product of the old *régime* in Arts in the Scottish Universities which, whatever its defects, cultivated width of view and diversity of outlook, Japp looked out on life through many windows, and to know him was in itself a liberal education.

In 1914, Japp retired from the Chair of Chemistry at Aberdeen and resided at first at Acton and later at Richmond, where he died. The closing years of his life were saddened by the loss of his son, who died, in 1920, while on the threshold of a promising career, from an illness contracted while on military service. In 1921, Japp's health broke down and he had to undergo an operation from which he never fully recovered; and in his last years, failure of eyesight deprived him of the companionship of books.

In 1879, Japp was married to Elizabeth Tegetmeyer, of Kelbra-Kyffhäuser, a small town near Nordhausen, by whom together with two daughters he is survived.

---

### FRANCIS JONES.

BORN 1845; DIED OCTOBER 22ND, 1925.

FRANCIS JONES was born in Edinburgh in 1845 and was educated at the Edinburgh Institute and the University. He went to Heidelberg to work under Bunsen, and here he met Roscoe. On returning to England he became one of Roscoe's two assistants in the great work on the atomic weight of vanadium. For Roscoe he always expressed great admiration, but it was a disappointment to him that no acknowledgment of his help appeared in the great paper. He used to say, with a whimsical smile: "I was only referred to as Analyst A or Analyst B, I forget which." On the retirement of Dr. Marshall Watts, Jones was appointed chemistry master at the Manchester Grammar School. The High Master was then F. W. Walker, one of the few non-clerical headmasters at the time. Realising, as few of his confrères did, the possibilities of science as a means of education, he gave Jones a free hand, and success came at once. Scholarships at the older universities were offered for science, and Manchester secured a very large number. In 1879, no fewer than thirteen of these coveted distinctions were won by Manchester boys, probably a record for the science side of any school. There was no extra preparation for scholarship boys, either in physics or in chemistry. Both Jones and

John Angel, the physics master, believed in letting boys teach themselves and each other, and, beyond the formal lectures and a little instruction in the chemical laboratory, the masters left the boys to work out their own salvation. To a modern schoolmaster, the liberty allowed to the Science Sixth would seem incredible. Many an afternoon would be spent in the Manchester Free Library, or in the ever-delightful quietude of the fifteenth-century library of the Chetham Hospital near by.

Besides Jones's personality, what affected us boys most was seeing him always at work on research. Many of those who have since given their lives to original investigation, owe most of the impetus which has driven them on, to the work on boron hydride which they watched in progress. The complete destruction of a large charcoal stove in which boron trioxide was being heated with magnesium, and the carrying off of R. L. Taylor, Jones's collaborator, to the infirmary, were incidents which made an impression never to be effaced on those of us who saw it.

In the new laboratory at the top of the main block of buildings, Jones had at last a place worthy of himself. His special pride was a very large and well-ventilated draught cupboard. In this the writer attempted, in its first week, the isolation of the still unknown oxide of bromine. About 15 c.c. of liquid monoxide of chlorine were mixed with a quantity of dried silver bromide, and not only was all the frame work and glass shattered to pieces, but the 3-inch slate bed was broken. All Jones said, when he contemplated the wreckage, was: "Well, it was what it was made for."

He died, at the age of 80, on October 22nd, 1925. His memory will always be cherished by his old pupils, who were also his friends. No schoolmaster had an influence like his on the making of a chemist.

### EDMUND KNECHT.

BORN JANUARY 29TH, 1861; DIED DECEMBER 8TH, 1925.

EDMUND KNECHT was born in Liverpool. His father, Gustav Knecht, B.Sc. (London), was a man of exceptional gifts as a schoolmaster, and his mother a Lancashire woman of singular charm. When Edmund was ten years old, the family settled in Southport, where his father conducted a school with much success for several years. From here the family, consisting now of three daughters and two sons, moved to the neighbourhood of Zurich, where a residential school was started on a largish estate. But the responsibilities and worries attendant thereon were too heavy and the

Knechts finally moved into Zurich itself. Edmund by this time was of an age to enter the University. He had natural leanings towards engineering, in fact his manipulative and mechanical skill was very marked. It was, however, his quick perception and interest in chemistry which attracted the notice of Victor Meyer, then Professor at Zurich University, and he induced Knecht to take up the study of this branch of science. At the age of twenty-one Knecht secured his Ph.D., his thesis being concerned with the homologues of resorcinol, and ultimately he became assistant to Victor Meyer. At this time Knecht saw a good deal of Sandmeyer, and the two remained all their lives the closest of friends.

Knecht soon after (1883) was offered the post of Head of the Chemistry and Dyeing Department of the Bradford Technical School which he occupied until, in 1890, there came a call to the Manchester College of Technology, in which institution he was actively engaged for the remainder of his life, as Professor of Tinctorial and Technological Chemistry, or as Associate Professor of Applied Chemistry of the University of Manchester. During a considerable portion of these thirty-five years Knecht was hard at work most days, including three evenings a week as well as Saturday afternoons. His influence on the students was remarkable both in the laboratories and in the lecture room. Few men of his time had so great a gift of inspiring their students with enthusiasm for their subject. Not only at home, but throughout the world, there must be thousands who have had the benefit of his tuition and his influence, and who regarded him with the utmost esteem both as a teacher and for his genial human qualities. His interest in his students did not stop with the conclusion of their academic career. He was wonderfully successful in finding them suitable posts, keeping track of them afterwards, and maintaining an interest in their future. Many are the chemists who would not hesitate to ascribe largely to Knecht's influence whatever success they have attained.

When the Society of Dyers and Colourists was formed in 1884, Knecht was appointed Editor of the Journal (1884—1893), which position he afterwards shared first with C. Rawson (1893—1899) and later with Professor W. M. Gardner (1899—1925). A large number of members assembled last year to commemorate the fortieth year of Professor Knecht's editorship and to make a handsome presentation to him subscribed to by his admirers, resident in all parts of the world.

The editing of the monthly journal just referred to claimed Knecht's close attention, but despite this he published in 1889 in conjunction with Benedict, "Chemistry of Coal Tar Colours," then

in conjunction with Christopher Rawson and Dr. R. Lowenthal that very widely-known text-book, "A Manual of Dyeing," unique of its kind; another treatise, "The Principles and Practice of Textile Printing," was published in conjunction with J. B. Fothergill. Yet another publication is entitled, "New Reduction Methods in Volumetric Analysis," by himself and Eva Hibbert. Many of the new analytical methods described in this volume have been widely adopted in chemical works at home and abroad. The methods are specially applicable to the rapid volumetric estimation of a great variety of substances including iron, sugar, and many dyestuffs. Two editions of all these books have been printed. Knecht was a contributor of many articles to the "Encyclopædia Britannica" as well as to Thorpe's "Dictionary of Chemistry."

Knecht's original research work is recorded in some 120 papers in the *Journals* of the Society of Dyers and Colourists, the Chemical Society, and the Society of Chemical Industry, the *Berichte*, and elsewhere. An enumeration of the titles of all of them appeared in the first-mentioned journal in June, 1925, and February, 1926. His contributions to our knowledge of chemistry range over an extraordinarily wide field. Many are closely connected with industrial, others again with pure chemistry. The major part of his researches was in relation to the chemistry of dyes, to the theory of dyeing, and to the application and manufacture of dyes. But as a glance at the titles of his many papers will show, he gave particularly close attention to all matters connected with the chemical and physical properties of textile fibres, especially cellulose and its derivatives, and he published interesting researches on the constitution of soot, and French and American rosin.

Knecht's system of volumetric analysis by the use of titanous salts, originally only intended to be applicable to the estimation of organic dyestuffs, has been so widely extended as to cover analysis of a great variety of other organic, as well as inorganic, substances. The extraordinarily wide applicability of these methods of volumetric analysis are regarded by some as being of such great importance as even to overshadow his brilliant work on dyeing and the chemistry of cellulose.

Knecht's memory was prodigious and, having read widely, he kept himself well up to date in all that touched upon the chemistry of dyes and of dyeing and of textiles. In these domains he was a perfect walking encyclopædia and could refer one, with unflinching trustworthiness, to almost any source of information upon which one desired enlightenment.

Knecht's modesty was characteristic of so many truly great men; his heart was absolutely in his work, with little or no thought of personal advancement or financial benefit to himself.

The circle of his friends and admirers was a very wide one, although he was not much given to indiscriminate social activities. Probably he felt these might interfere too much with his always strenuous work.

As years advanced, Knecht's zeal and enthusiasm for his research work seemed to grow keener and more intense. This was true up to within a few weeks of his death. He then underwent two serious operations. From the effects of these he had not quite recovered when in December, after two months spent in Switzerland, he returned home in very trying weather conditions, as a result of which he quickly succumbed to an attack of bronchitis and, his heart being unable to withstand the further strain, he breathed his last at Marple in the county of Cheshire, where he had made his home for so many years.

I can say without hesitation that I have rarely come across a man who so well deserved the esteem and affection and gratitude of a great body of chemists. A host of them owe to Edmund Knecht that sound basis of scientific thought and enthusiasm for their subject without which so little can be accomplished that is truly worth while in the domain of chemistry. He did his best in his own special sphere of activities and none will deny that his best was very good.

ALFRED RÉE.

---

### WILLIAM ROBERT LANG.

BORN 1870; DIED NOVEMBER 20TH, 1925.

THE late William Robert Lang was a graduate of the University of Glasgow (B.Sc. 1890, D.Sc. 1899) and resigned the lectureship in Organic Chemistry there to become Professor of Chemistry in the University of Toronto. He was a Fellow of the Chemical Society (1897) and a member of the Institute of Chemistry and was elected Fellow of the Royal Society of Canada in 1911.

One of Dr. Lang's first activities in Canada was the promotion of a Canadian Section of the Society of Chemical Industry, of which he was the first Chairman. His scientific interests lay chiefly in the application of chemistry to industrial problems, and his monograph on the chemical industries of the Dominion (*Trans. Can. Inst.*, 1905) formed the basis of the "Directory" published by the Canadian Government in 1921. Many other papers in the chemical journals bear his name, or the names of his students.

From 1889 until the day of his death, Dr. Lang was actively connected with the forces of the King. In Glasgow, his birthplace (1870), he served with the Lanarkshire Royal Engineers (Volunteers); the year of his arrival in Canada he was gazetted to the Second Field Company Canadian Engineers, which he commanded as Major (1902) and Lieutenant-Colonel (1912); at the coronation of King George V in 1911 he commanded the Canadian Infantry there present. On the outbreak of war in 1914 he was appointed to the Canadian General Staff, assumed the duties of Officer in Charge of military instruction for Military District No. 2, and became O.C. the University of Toronto contingent of the C.O.T.C. In 1917 he was gazetted Colonel, and in the following year was G.S.O. (1) Coast Defence in the Maritime Provinces at Halifax N.S.

At the close of the war, Colonel Lang resumed command of the reorganized C.O.T.C. contingent, and resigned the professorship of Chemistry to direct the Department of Military Studies newly established in the University of Toronto; to the excellence of his work in this capacity high tribute was paid by Major-General MacBrien, Chief of Staff of the Canadian Militia, and a very keen critic, when at last year's inspection he said: "This is the largest O.T.C. inspection I have ever seen—and also the best."

Dr. Lang died very suddenly on November 20th last; the military funeral was preceded by a service at the University.

W. LASH MILLER.

---

### FRANK GEORGE POPE.

BORN NOVEMBER 13TH, 1867; DIED OCTOBER 29TH, 1925.

FRANK GEORGE POPE was born on November 13th, 1867, the son of George Campion Pope and Teresa Pope. He received his early education at Haberdashers' School and afterwards proceeded to Finsbury Technical College with the intention of becoming an engineer. This intention was not realised, as he went to the Peoples' Palace Technical Schools as a demonstrator in the Chemical Department. At that time, East London College had not been thought of, and it was necessary to deal, not with matriculated students working for a degree, but with boys of 12 to 15 years of age belonging to a large day school and to spend four nights a week on evening classes, principally attended by junior works chemists and elementary teachers. Luckily, no classes were held on Saturdays.

When I first met Pope one evening in February, 1894, he was running a practical class of the stamp usual in those days and

trying to do some research in the store-room, as he had no private bench of his own at which he could work. The next month we joined forces and started a firm friendship which only ceased with his lamented death last October. Had it not been for his help, kindness, and extreme loyalty, my earlier days at the People's Palace would have been very different. Pope could manage boys; not being used to them, I could not. His methods were summary but just, and many an old boy must remember the penalties exacted for not taking down notes properly during lecture. Whilst boys had to work hard and keep the peace when in class, once the week's work was done, Pope would play cricket with them on Saturdays and for years attended the annual camp of Day School boys on the South Coast.

Pope very soon joined in some work that was interesting me; this was kept going at odd times between classes and, on Saturdays, we often met about 2 p.m. and went on until 10. Our earliest joint publications were concerned with fluorones, the "abnormal hydrates" formed by hydroxyazo-compounds and one or two new hydrazines. The fluorones especially interested Pope and he returned to their study in later years, his work (partly with H. H. Howard) and that of Kehrman clearing up many doubtful points.

In the later 'nineties, the nucleus of East London Technical College was formed with a number of day boys who had finished their three or four years' course and could be put on to more advanced work; in this way, a supply of research assistants was at last assured. Meanwhile, Principal Hatton was striving for the establishment of an East London College. Such a college has now been a school of the University of London for some years past.

A good knowledge of organic chemistry and great interest in the subject, together with a genial disposition, made Pope an excellent teacher. After an advanced organic lecture, he would come with the class into the laboratory, walk to a blackboard, start asking questions, expound views, and make the students show what they did or did not know.

From 1915, until the chair of chemistry was filled by the appointment of Professor Partington, Pope acted as head of the Chemical Department, and the College authorities made him an Assistant-Professor. He had been a Reader in the University for some years. The burden during the war was considerable and the subsequent work heavy, as East London College, like other institutions, suffered from a surfeit of students.

During a well-earned holiday in 1922, peritonitis supervened on food poisoning and after an operation in Switzerland it was some months before Pope returned to England. For a time, he con-

tinued his work at East London College, but it was evident that his health was broken and he had to retire in 1923. His old students and colleagues made him a presentation at the Old Students' Association dinner in January, 1925. This was the last College function he attended. After further months of illness, he died on October 29th, 1925.

Pope was beloved by his pupils and colleagues. Students who shirked or exhibited too much conceit had reason to regret their faults, but anyone who desired aid found in him a ready helper. Like many other chemists, he enjoyed out-door life and it was a delight to sit with him on a Surrey hill, not bothering about the time of lunch or the return train to London.

He married Adelaide, daughter of Harold Field Downer. She and a married daughter survive him to mourn his loss. His old students and former colleagues remember a very unselfish friend to whom they owed many a debt for uniform kindness and consideration. No one realises this more fully, or holds his memory in deeper affection, than the present writer.

J. T. HEWITT.

### CHARLES ETTY POTTER.

BORN JANUARY 5TH, 1880 : DIED SEPTEMBER 13TH, 1925.

CHARLES ETTY POTTER was born on January 5th, 1880, at Melsonby, near Darlington, at which place his father was headmaster of the Wesleyan school. An early aptitude for school work enabled him to gain a Flounder's scholarship with which he entered the North Eastern County School at Barnard Castle, and a successful school career was terminated by the winning of a North Riding scholarship tenable at the Yorkshire College. In his studies at Leeds, Potter's attention was directed to the physical sciences, and after graduating as B.Sc. of Victoria University in 1900, he pursued a post-graduate course in applied chemistry under Professor H. R. Procter in the leather industries department. In the development of various social activities at the Yorkshire College, Potter took a very active part, and the students' scientific, debating, and other societies were indebted in no small measure to his energy, enthusiasm, and determination.

On leaving the Yorkshire College in 1901, Potter accepted a post on the research staff of the Wellcome chemical research laboratories, where, for some years, in collaboration with Dr. F. B. Power and Dr. H. A. D. Jowett, he was engaged in the investigation of problems connected for the most part with complex organic compounds. Three papers published in the *Journal* of

the Chemical Society conjointly with H. A. D. Jowett, namely: "Preparation and Properties of 1:4(or 1:5)-Dimethylglyoxaline and 1:3-Dimethylpyrazole" (J., 1903, **83**, 464), "The Constitution of Chrysophanic Acid and of Emodin" (*ibid.*, p. 1327), "The Constitution of Barbaloin" (J., 1905, **87**, 878), indicate the nature of the work on which he was engaged. The *Pharmaceutical Journal* affords a record of other work with which Potter was associated during this period.

In January, 1906, Potter was transferred to a position in the analytical department at the Dartford works of Messrs. Burroughs Wellcome and Co., but towards the end of the same year he decided to take up teaching work. For a short time he was engaged at the Abergele Council school, but his chief teaching work was done at the Heckmondwike Secondary school where for 10 years he was engaged in teaching chemistry, physics, and mathematics and was responsible for the organisation of courses of instruction in physical science adapted to the requirements of a scheme of home training for girl pupils. For the greater part of this period he was also in charge of evening chemistry classes at the Batley Technical College. Early in 1916, he obtained an appointment as research chemist with Messrs. Levinstein, Ltd., at Blackley, Manchester, which position he retained after the amalgamation of Messrs. Levinstein with British Dyes, Ltd., and at the time of his death he was in the service of the British Dyestuffs Corporation, Ltd. As a member of the staff of the technical research department in this concern Potter was not only associated with the laboratory research work on colouring matters, but with problems incidental to large-scale production; he also held a position of considerable responsibility in connexion with the engagement and welfare of chemical assistants in the technical departments. He took a keen interest in the activities of the Manchester sections of the Society of Chemical Industry and the Institute of Chemistry, and served on the Committee of the latter for a period of three years.

Many of his Yorkshire friends had an opportunity of meeting him at the annual meeting of the Society of Chemical Industry at Leeds in July, 1925. Those who took part in the excursion to Huddersfield were particularly impressed by the lively and illuminating manner in which Potter explained certain of the processes carried on in the works of the British Dyestuffs Corporation. Towards the end of the same month he became seriously ill as the result of an insect bite on the scalp, and, in spite of every attention, died in the Manchester Royal Infirmary on the 13th September, and was buried in the grounds of St. Margaret's church at Prestwich on September 16th. He left a widow and three sons of school age.

For information relating to Potter in the period subsequent to his University studies, the writer is much indebted to Mr. F. H. Lees, the Head of the analytical department of Messrs. Burroughs Wellcome and Co. Potter is described by him as an enthusiastic worker, exhibiting unusual initiative and resourcefulness in overcoming the difficulties inseparable from original research. His cheerful disposition never deserted him under the most trying conditions and his relations with his colleagues were of the most cordial kind. He always strove to uphold the traditions of his Alma Mater and often became eloquent in insisting upon how much he was indebted to his chemical teachers at Leeds. The characteristics portrayed in this description would appear to have been retained in undiminished measure in the later period of his life, and his fellow chemists deplore the loss of a colleague whose integrity and sincerity were universally acclaimed.

H. M. DAWSON.

---

#### ROBERT LLEWELLYN TAYLOR.

BORN NOVEMBER 21ST, 1851; DIED NOVEMBER 8TH, 1925.

ONE of the pioneers of the teaching of science in this country and a man of high scientific attainments, R. L. Taylor passed away at his home in Whalley Range, Manchester, after a sudden heart attack. He will be sadly missed by many friends and associates, who welcomed a meeting with Taylor as one of their real pleasures. Always enthusiastic in the pursuit of chemical knowledge, of a cheery and kindly disposition, he carried a warm atmosphere about with him.

Taylor was born at Sabden in the Pendle Hill district and as a boy he attended the village school there. At fourteen years of age, he was employed at the print works at Sabden, of which his father was the manager. His parents originally intended that he should learn the business of a calico printer and during four years he spent the daytime in this way. In the evenings he studied the science of chemistry and fitted up a disused room in the works as a chemical laboratory. The course which he followed was no easy one, for he had no teacher, but it was at the same time a fine training ground, because it enabled him to understand the difficulties of others when in later years he became a teacher. After his four years' work at Sabden, he was appointed lecturer's assistant to Dr. A. W. Williamson, Professor of Chemistry at University College, London. Here Taylor made the most of the fine opportunity which presented itself of acquiring skill in experimental and research work. In 1872 he was appointed assistant master in the

chemical laboratory of the Manchester Grammar School and in this position his teaching ability soon made itself manifest. Taylor was associated with Mr. Francis Jones at the Grammar School in the discovery and investigation of boron hydride and the work was published in the *Journal* of the Chemical Society. In 1878, Taylor became teacher of chemistry and physics under the School Board and later he became organising master and inspector of science classes to the Manchester Education Committee. The work from 1880 to the date of his retirement under the superannuation act in 1919 involved both day and evening class duties. In spite of this, he managed to find time for many original investigations and his pupils could realise that they were receiving not merely book lore, but first-hand knowledge from one who worked for the love of science. His research was not made easy by the possession of a well-equipped chemical laboratory and he was always grateful for the encouragement of friends and for the assistance afforded by the loan of some simple piece of apparatus. The records of some of his work appear in the *Transactions* of the Chemical Society, in the *Journal* of the Society of Dyers and Colourists, and in the *Memoirs* of the Manchester Literary and Philosophical Society. They embrace a very exhaustive study of bleaching powder and its action in bleaching, the action of bleaching powder on various natural colouring matters, the effect of light on solutions of bleaching powder, a comparison of the bleaching action of hypochlorous acid and chlorine, and a method for the determination of chloric acid and chlorates. In 1911 he was awarded the research medal of the Worshipful Company of Dyers. In earlier years, Taylor introduced a method for the separation of cobalt and nickel and carried out work on a higher oxide of cobalt and on white ferrous ferrocyanide. His chemical text-books are widely known and include "Analytical Tables for Chemical Students," "Chemistry for Beginners," "The Student's Chemistry," and "Chemistry for Evening Continuation Schools." In 1922 Taylor issued and edited a small book, entitled "Bleaching Powder and its Action in Bleaching," embodying his original memoirs on the subject of bleaching powder.

Many distinguished scholars owe their first inspiration to the teaching and guidance of Taylor. In addition to his scientific attainments, he was able in his leisure hours to provide entertainment for old and young by his lectures and demonstrations such as those on soap bubbles and methods of obtaining a light. With a lively party of boys he would explore the wonders of Castleton, the beauties of Ingleton, and the mysteries of Whalley. His interest in the subject of sound extended still further his love of

Yrs very truly  
F. S. Thompson

music and he conducted an orchestra in the Central High School in Manchester.

There is a vacant place in the Manchester Literary and Philosophical Society, of which he was a member of the Council. He was a member of the Chemical Society from January 1874 until the date of his death.

[The late] EDMUND KNECHT.

### SIR EDWARD THORPE.

BORN DECEMBER 8TH, 1845; DIED FEBRUARY 23RD, 1925.

IN the death of Sir Edward Thorpe, which took place at Whinfield, his residence at Salcombe, South Devon, on February 23rd, 1925, in his eightieth year, the Chemical Society lost a former President, whose membership extended over 54 years, and who during this period served the Society as Member of Council, Vice-President, and Treasurer for ten years, from 1899—1909. The record of Sir Edward Thorpe's activities and achievements in chemistry is a full and varied one. Successively he filled with distinction and success the Chair of Chemistry in three institutions. He was appointed to the Andersonian College, Glasgow, in 1870, having as forerunners Birkbeck, Gregory, and Graham, "an honourable and distinguished ancestry," of which he was justly proud. Then in 1874 Thorpe was appointed Professor of Chemistry in the newly-founded College at Leeds, the Yorkshire College of Science, as it was at first styled, the second of those provincial colleges which owed, in no small measure, their formation to the stimulus which the success of Owens College, Manchester, had given to the movement for the provision of university education in the provinces. This appointment must have appealed especially to Thorpe, himself a first and one of the best products of the provincial university college, affording, as it did, opportunities of putting into practice the system of educative work of which he had had experience in the years spent at Owens College. At that time (1873) Owens College had just emerged from its temporary housing to occupy the first block of buildings on the present site of the University of Manchester. Thorpe was fortunate in having as colleagues men so distinguished as Green, Miall, and Rücker, with whom he laid the foundation and traditions of an institution from which the University of Leeds has grown. When in 1885 Thorpe resigned the post at Leeds to become the successor of Sir Edward Frankland at the Royal College of Science in London, he had the satisfaction of seeing the Yorkshire College housed in new and appropriate buildings, with well-designed and equipped chemical

laboratories and lecture theatres. In the year 1894 he was appointed the Director of the Government Laboratories and was responsible for their design and equipment. Shortly before his retirement, in 1909, he accepted the invitation to resume the Professorship of General Chemistry at the Imperial College of Science and Technology, which had been formed by the amalgamation of the Royal College of Science and the City and Guilds Institute at South Kensington. This position he finally resigned in 1912.

The discharge of the duties of these various positions, and the demands made on his time and energy in the building up of a new college at Leeds, did not prevent Thorpe from maintaining a steady output of scientific investigations and research. Furthermore, throughout his life, he maintained a literary activity; the volume of collected essays on Historical Chemistry, the memorial lectures on Kopp, Victor Meyer, Cleve, and Thomson, as also the articles on scientific worthies contributed to *Nature*, constitute examples of the highly valuable additions made to chemical literature and afford illustrations of the clearness in style and the extensive knowledge which characterised his writings. Thorpe's interest in the history of chemistry is shown by the selection of subjects for addresses. At the Leeds Meeting of the British Association in 1890, Priestley, Cavendish, Lavoisier, and *La Révolution Chimique* formed the subject of the address delivered to Section B (Chemistry) on that occasion; and again, ten years later, he selected for the Presidential Address to this society "The Progress of Chemistry in Great Britain and Ireland during the Nineteenth Century." Further, among other valued contributions to chemical literature are the biographies of Priestley, Davy, and of his teacher, Roscoe.

In more prosaic fields, mention should be made of his text-book of Inorganic Chemistry, published in two volumes, the text-books of quantitative and qualitative analysis, and of the monumental work, "The Dictionary of Applied Chemistry," the preparation of a new and enlarged edition of which occupied him to within a few weeks of his death.

Thomas Edward Thorpe, the son of George Thorpe, a Manchester merchant engaged in the cotton trade, was born on December 8th, 1845, at Barnes Green, Harpurhey, near Manchester. His early education he received at the Manchester Diocesan School (Hulme Grammar School), and in 1863 he entered Owens College as a student in the Chemical Department under Professor Roscoe. Here he remained for four years, acting for the greater part of this period as private assistant to Roscoe, taking an active part in the photochemical researches, the investigation of perchlorates, and in the classical work on vanadium, which ultimately resulted in

assigning to this element its true position in the classification of the elements. In the obituary notice of Sir Henry Roscoe, Thorpe has given an account of much of the work of this period, and in connection with the vanadium investigation he wrote: "It was the writer's privilege to assist in the early stages of this investigation, and it fell to his duty to carry out the various experiments which eventually served to establish the composition of the oxides of vanadium, the true nature of its volatile chlorides, the existence of hitherto unknown oxychlorides, and of the mononitride which Berzelius regarded as the metal, and lastly to fix its real atomic weight and to show that it was apparently 16 units below that assumed by Berzelius on the mistaken supposition that vanadium compounds were analogous in composition to those of chromium."

In connexion with the photochemical researches, Thorpe journeyed in 1866 to Pará on the Amazon, and in the autumn of 1867 he made a long series of observations under a cloudless sky at Moita, near Lisbon, concerned with the relation between the sun's altitude and the chemical intensity of daylight. It was on the return journey from Pará that he made a series of determinations of the carbon dioxide present in the air over the ocean, and succeeded in establishing a constancy in the daily and nightly proportion of 3 volumes of carbon dioxide per 10,000 volumes of air, thus confuting the conclusions drawn by Lewy, who maintained that the proportion of carbon dioxide in the air over the ocean exhibited a diurnal and nocturnal variation. In recognition of this work Thorpe was awarded the Dalton Scholarship in Chemistry.

Mr. J. Kentish Wright of Nottingham, a fellow student and life-long friend of Thorpe, has furnished the writer with the following recollections:

"I first came into intimate association with Thorpe (then universally known as Tom Thorpe) in the year 1865 when we were both students at Owens College, Manchester, and were elected joint Secretaries of the Students' Union. Previous to this I had only known him slightly, as he was entirely a 'science' student, and I was entirely an arts student; as far as I remember, we never attended the same lectures but were constantly meeting on union matters; we soon found we had many tastes and interests in common. He was widely read in modern literature and had a very keen appreciation of Dickens and Thackeray, and we had many talks as to our favourite novels. His distinguishing characteristic was his extraordinary vitality and energy, which he put into whatever he was occupied with, and which enabled him to excel in whatever he undertook. Of his eminence in science I was then and am now unable to judge, but the distinction he attained is sufficient

evidence of this. He was, moreover, a skilful writer of popular sketches and verses, which appeared in the Students' Magazine, and was the author of a very interesting account of the rubber gatherers of South America.

"He had a very strong sense of humour and love of fun, was an excellent story-teller, and could enjoy a joke against himself.

"He was an ardent sportsman and lover of athletics, and took a very active part in originating the boat races, which were rowed on the Irwell between the Science and Arts students. These were started in 1864 and continued for many years. He coxed and coached the Science boat, and on one occasion, although of small stature, he rowed bow in that boat.

"He was also a keen cricketer and a useful bat, playing regularly for the college eleven.

"About this time he introduced me to the young lady (Miss Emma Watts, daughter of Dr. John Watts) to whom at that early age he was engaged and to whom he was devoted the whole of his life. They were married in 1870, at the Manchester Cathedral, and I was present as one of his groomsmen. Lady Thorpe is now living at his beautiful home at Salcombe, South Devon.

"In later years his great pleasure was yachting, and he has written several books describing his cruises. It was soon after he went to Glasgow (about 1871 or 1872) that he bought a small cutter yacht and invited me to go with him on a cruise to the Hebrides. I was terribly disappointed that I could not accept, but subsequently I had reason to congratulate myself. Thorpe sailed the yacht up to Skye and anchored off the coast there—but the wind got up in the night—the anchors dragged and the boat was driven on the rocks and became a complete wreck. There was a small dingy and in this Thorpe and his brother-in-law, Harry Watts, and the two men forming the crew managed to reach the shore. If I had been there, in all probability the dingy would not have carried all and there would have been a tragedy. They spent the night shivering on the rocks, and in the morning found themselves in the most desolate part of Skye—eight miles from the nearest house.

"Although our paths diverged in after life, we kept up our friendship to the end of his life by correspondence and occasional visits. It was always an unfailing delight, when we met, to recall the old days and to tell over again the old stories and reminiscences. The last time I saw him was in the year 1921, when he stayed a few days with me on his road to Edinburgh for the British Association Meeting. Thorpe told me an amusing story about Lloyd George, whom, by the way, Thorpe much resembled in stature and

appearance, and for whom he was often mistaken. Lloyd George, when Chancellor of the Exchequer, wished to put a tax on petrol or other spirits used for motors, and sent for Thorpe, who was then Government Chemist, to obtain the proper word to comprise petrol, benzoline, paraffin, and anything else used for that purpose. Thorpe disapproved of the proposed tax, and determined not to help Lloyd George. He said, 'There is no one in England knows more about it than I do, and I can't find a word, and if I can't, no one can.' Lloyd George jumped up and ran to Thorpe and seized him by the lapels of his coat and shook him vigorously, saying, 'Look here, you can help me and you've got to help me—you can help me and you've got to help me.' Thorpe went away quite won over by Lloyd George's fascination and powers of persuasion. He spent a sleepless night pondering the problem, and with the dawn there flashed across his mind the phrase 'Motor Spirit,' which was accepted and has been in use ever since."

In *The Old Owensian Journal* for May, 1925, appeared an appreciation of Sir Edward Thorpe from the pen of the late Francis Jones, who wrote as follows :

"It was my good fortune to make the acquaintance of T. E. Thorpe in 1866 when I returned from Bunsen's laboratory in Heidelberg to become private assistant to Professor Roscoe in the Old Owens College in Quay Street.

"The Professor told me that he had obtained from the copper works at Alderley Edge a large quantity of a residue containing about 2% of vanadium, and he wished to make an investigation of the properties of that rare element and its compounds. He asked me to work at this along with T. E. Thorpe, who had been a senior student of the College, and I was soon after introduced to him. Thus began a lasting friendship between us, and for many months we worked together on what was to both a most fascinating research. We soon found out that what Berzelius considered metallic vanadium was really the lowest oxide, and this involved the lowering of its combining weight to 51.2. It was impossible to work in daily association with Thorpe without being attracted by his unfailing cheerfulness, genial humour and intimate knowledge of chemistry. The results obtained in the investigation were communicated by Roscoe in a paper read before the Royal Society. Our close association ended in 1867, when Thorpe went to Bunsen's laboratory, and soon after (1870) he became Professor of Chemistry in the Andersonian Institution in Glasgow, but we continued to meet from time to time and kept in touch with each other by correspondence.

"He helped me greatly in 1911 when I started a movement to

celebrate the centenary of Bunsen's birthday by sending an illuminated address and wreaths to the Pro-Rector of Heidelberg University, Professor von Duhn, who requested Bunsen's successor, Professor Theodor Curtius, to acknowledge the address and wreaths which were forwarded to Heidelberg in time for the celebration of the anniversary on March 31st, 1911.

"Professor Curtius wrote: 'The address will be framed and find its place in the Bunsen Room of the Chemical Institute with the picture and other mementos of the Master.' Thanks to Thorpe's help twenty-three former students of Bunsen's added their names to the address; these included Henry E. Roscoe, 1852—1855, Alex. Crum Brown, 1861—1862, W. Marshall Watts, 1865, Francis Jones, 1865—1866, T. E. Thorpe, 1867—1870, C. A. Burghardt, 1870, W. Carleton Williams, 1871—1872, J. Grossmann, 1872—1873, Arthur Schuster, 1872, Arthur Smithells, 1883, and G. H. Bailey, 1884—1885.

"I last saw Thorpe when he was President of the British Association in Edinburgh, when he was unfortunately unable, owing to illness, to be present at most of the meetings."

As has been already mentioned, Thorpe obtained the Dalton Scholarship in Chemistry and then proceeded to Heidelberg to study under Bunsen. The following is an extract from a letter published by Sir Henry Roscoe in his Autobiography from Thorpe in which he describes incidents of his arrival at Heidelberg and his reception by Bunsen:

"Well, in the autumn of '67 I set out for Germany, fortified with much good advice, and bearer of sundry presents from you and yours to Bunsen—among them a copy of *The Times* containing an account of a 'horrid murder' (you remember the dear old man's amiable weakness for 'horrid murders'), a small consignment—I think from Mrs. Roscoe, your mother—of potted shrimps (another amiable weakness), and above all some magnificent specimens of potassium and sodium (calculated to go straight to his heart) from Mather's works at Patricroft. Sonstadt had worked out Caron's process for the manufacture of magnesium, and there was what we then considered a great demand for the metals of the alkalis.

"After a leisurely journey up the Rhine—I remember seeing the white-coated Croats in garrison at Mayence—I found myself in Heidelberg and lost no time in presenting myself to Bunsen, armed with the copy of *The Times*, the potted shrimps, and the precious box containing the alkali metals. Although it was still vacation time, Bunsen had returned to work. I was ushered into the little room you know so well, overlooking the Wrede Platz. The great man—great physically as well as intellectually—rose from

the table at which he was writing—I see him now—and motioned me to the sofa. He evidently was not unprepared for my coming—I suppose you must have informed him. I duly presented your letter of introduction and, after answering his many tender inquiries concerning you, moved up my heavy battalions. I received a momentary check, however, for owing partly to his slight deafness but much more to my imperfect knowledge of German, he moved across to the sofa the better to hear me and sat down on my hat! I at once brought *The Times*, the potted shrimps, and the alkali metals into action. The ‘horrid murder’ he would read at bedtime: the potted shrimps would certainly be appreciated in the morning: and we prepared ourselves for the alkali metals. The servant was called to unpack the box, when to my consternation he produced a bottle—I remember it was an old pickle-bottle—partially filled with naphtha, at the bottom of which were a few tablespoonfuls of a bright shining rather mobile fluid. I had given the Geheimrath such a glowing account of the size of the sticks of the two metals that I was simply speechless with astonishment and felt indeed rather like an impostor. I had never realised so vividly before the possibility of the transmutation of metals. ‘Well,’ I said at last, ‘potassium and sodium were certainly put into the bottle before I left home, but what is there now is uncommonly like quicksilver.’ ‘No,’ said Bunsen, who was holding the bottle, ‘it is not quicksilver. Feel the weight of it!’ The fact was that our old friend Heywood, who had been ordered by you to pack the specimens at the time in separate bottles, perceiving that both could be got into one bottle, had, with the charitable idea of not encumbering me with too bulky a package, placed the two metals together, with the untoward result I have indicated. Chemical combination between solids is not of frequent occurrence, but that it is possible under certain circumstances has never been forgotten by me. I had no knowledge at the time of the existence of the fluid alloy—nor had Bunsen—which, perhaps, is not very creditable to us, since it is actually mentioned by Davy. As an historical fact, I believe the first so-called potassium isolated by Davy was fluid at ordinary temperatures owing to the amount of soda in the electrolysed potash.

“I assure you I felt a little limp at the moment—more limp, indeed, than my crushed hat—and, conversation flagging, he suggested that he should show me the place where he intended that I should work. It was in his own little laboratory, a couple of benches away from him, and where I had as companions Victor Meyer and an American—Gideon Moore—a man of extraordinary

ability, who had the misfortune to be stone-deaf, but who taught himself German and spoke it fluently without having heard a sound of the language."

Thorpe's memorial lectures on Kopp and Victor Meyer enable us to gather something of the impressions made by the life and work at Heidelberg. His fellow students included many whose names are writ large in chemical literature, *e.g.*, Erlenmeyer, Ladenburg, Horstmann, Ludwig, Cohen (the mineralogist), Rose, and Emmerling. Thorpe was undoubtedly greatly attracted to Kopp, whose influence and teaching are to be seen in his own researches on specific volumes and other physical constants, remarkable for their exactitude.

At Heidelberg he graduated as Ph.D., and during this period he published papers dealing with (1) nontronite, to which he assigned the formula  $\text{Fe}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 5\text{H}_2\text{O}$ , (2) the analysis of the ash of a diseased orange tree, and (3) observations on the physical properties of chromium oxychloride, directing attention to the identity in the molecular volumes of sulphuryl chloride ( $\text{SO}_2\text{Cl}_2$ ) and chromium oxychloride ( $\text{CrO}_2\text{Cl}_2$ ). From the latter he obtained, by the action of heat, the solid oxychloride of chromium—chromium chlorochromate,  $\text{Cr}_3\text{O}_6\text{Cl}_2$ .

From Heidelberg Thorpe went to Bonn, and whilst there, worked with Kekulé on ethylbenzoic acid, which they isolated from the product of the action of carbon dioxide on sodium and an ethereal solution of ethylbromobenzene.

Returning to Manchester he joined, for what proved a short period, the teaching staff of the chemical department at Owens College, and in 1870 he was appointed Professor of Chemistry at the Andersonian College, Glasgow. Here the association with Young, the founder of the Scottish oil industry, led to the study of paraffin, and in conjunction they conducted a research on the action of heat and pressure on paraffin, which formed the subject of two papers. The authors noted but little gas to be produced, and from 4.5 kilograms of paraffin they obtained 4 litres of liquid hydrocarbons, which were separated into 2.7 litres boiling at 200—300°, 1 litre boiling at 100—200°, and 0.3 litre boiling below 100°. From this last fraction both amylene and hexylene were isolated.

Whilst at the Andersonian College Thorpe attempted, in the light of his experience with vanadium oxychloride, to prepare a lower oxychloride of phosphorus by submitting phosphorus oxychloride to the action of reducing agents, but found the phosphorus compound to behave quite differently, yielding phosphorus trichloride only, and giving no indication of the formation of oxychlorides similar to those of vanadium. The production of phos-

phoryl thioclauride by the interaction of phosphorus pentasulphide and carbon tetrachloride was noted. The determination of the solubility of silver chloride in concentrated nitric acid led to the conclusion that this solubility is of the order of 2 parts of silver chloride in 100,000 parts of concentrated nitric acid. During the tenure of the professorship at Glasgow Thorpe published the textbooks already referred to: (1) *Inorganic Chemistry*, in two volumes (Collins), (2) *Quantitative Analysis* (Longmans), and (3) *Qualitative Analysis*; in the production of this last M. M. Pattison Muir collaborated.

The translation to Leeds took place in 1874, when Thorpe was appointed Professor of Chemistry in the Yorkshire College of Science, with A. W. Rücker in the Professorship of Experimental Physics (with which was associated Mathematics) and A. H. Green in the Professorship of Geology and Mining. In the biography of Sir Henry E. Roscoe, Thorpe gives a sketch of the history of the foundation of the Yorkshire College, from which may be gathered some idea of the conditions under which a beginning was made. He writes:

"The premises in which the College was first housed consisted of a disused Bankruptcy Court situated in Cookridge Street, one of the main thoroughfares leading out of the town. After a somewhat chequered career, the building had been partially used as a school of cookery, with the unfortunate result that it had been largely consumed by a fire just prior to being taken over by the College authorities. Although not so spacious as Richard Cobden's old house in Quay Street, Manchester, in which Owens College first started, the Leeds building, in some respects, was not ill-adapted to the purposes of the limited professoriate with which the Yorkshire College of Science began its operations. At all events, it accommodated without the slightest difficulty all the students who sought admission to it on its opening day.

"The College began its work of teaching on October 26th, 1874—somewhat later than the normal opening of a session—owing to delays in completing the necessary structural arrangements. But as there was no yearning anxiety on the part of anybody to learn, no special inconvenience or disappointment resulted. There was no preliminary flourish of trumpets—hardly so much as an opening speech. The initial ceremony was as simple as the appointments of the College were modest. Each of the three professors in turn gave an introductory lecture to an audience consisting of members of the Council and such of the friends of the embryo institution as cared to attend. Some encouraging remarks were made by the Chairman, and so the College was launched. But for a time the

students were few and their advent as far between as the visits of angels."

Unless one has had the like experience, it is not easy to realise what the first years of such pioneering work meant and entailed. However, the work evidently progressed, as in 1877 the foundation stone of the new College buildings was laid, and before this the professoriate had been extended by the appointment of Professor L. C. Miall to the Chair of Biology, and later the establishment of Chairs of Classical Literature and History, and Modern Literature and History, to which Professor J. Marshall, M.A., of Balliol College, Oxford, and Professor F. S. Pulling, B.A. (Oxon), were, respectively, appointed. "This enlargement," Thorpe writes, "of the educational work of the College necessitated a slight but significant change in its designation: henceforward it became known as the Yorkshire College until it was raised to the rank of a university, when it took the name of the town in which it was situated."

The eleven years spent at Leeds were marked by a steady output of scientific work, and this despite the many and varied demands upon Thorpe's time and energy necessitated in establishing the new College. Amongst the researches of this period, researches marked by the accuracy characteristic of all Thorpe's work, are those concerned with the specific volumes of liquids. He was led to conclude from the specific volumes of phosphorus oxychloride and thiophosphorus chloride that in these compounds phosphorus functions as a tervalent element, thus giving support to the formula

$\begin{array}{c} \text{Cl} \\ \diagup \\ \text{Cl} \end{array} > \text{P} - \text{O} - \text{Cl}$  in preference to the formula  $\begin{array}{c} \text{Cl} \\ \diagup \\ \text{Cl} \end{array} > \text{P} = \text{O}$ , necessitating

a quinquivalent phosphorus. A few years later Thorpe was destined to provide evidence in support of the higher valency for phosphorus, by the discovery of the gaseous pentafluoride, as a product of the interaction of arsenic trifluoride and phosphorus pentachloride. The physical properties of this compound afforded a ready means of fixing its molecular weight, which with its analysis showed the molecular formula to be  $\text{PF}_5$ .

In a lecture to this Society, Thorpe, in 1880, gave an account of his work "On the relation between the molecular weights of substances and their specific gravities when in the liquid state." In recognition of the value of these researches he was awarded the first Longstaff Medal in 1881. Professor Roscoe, the President, in making this presentation, expressed himself as follows:

"Professor Thorpe: I consider it a special privilege that it falls to my lot to present to you, as one of my oldest and most distinguished pupils, the first Longstaff Medal awarded by the

Chemical Society for the best series of original investigations in chemistry published in England during the past three years, amongst which I may mention, as the most important, your discovery of phosphorus pentafluoride; that of the occurrence of heptane in *Pinus Sabiniana*, giving accurate determinations of its physical constants; and, last, the valuable contributions to Physical Chemistry in your researches on the relations between the molecular weights of substances and their specific gravities when in the liquid state. I trust that this recognition by the Chemical Society of your varied and successful labours will stimulate to further efforts, and that before long the Society may be benefited by other communications from your laboratory."

Amongst the communications from the laboratory of the Yorkshire College are to be found: "A Simple and Expeditious Method of Preparing Pyrogallol for Dry Plate Development"; "The Action of Zinc, Magnesium, and Iron as Reducing Agents with Acidulated Solutions of Ferric Sulphate"; "Note on the Action of the Oxychloride of Sulphur on Silver Nitrate"; "Contributions to the History of the Mineral Waters of Yorkshire"; and "On Dust Explosions in Collieries." Further, the re-determination of the atomic weight of titanium was made by Thorpe on the eve of his departure from Leeds. The memorable series of lectures delivered by Thorpe and his colleagues, under the auspices of the Gilchrist Trust, was published in 1878 and edited by him with the title "Coal, its History and Uses."

Considerable activity in research marked the nine years (1885—1894) of the Professorship at the Royal College of Science, as shown by the papers published, conjointly with others, during that period. The determination of the atomic weight of silicon, with J. W. Young, and of gold, with A. P. Laurie, gave the values 28.3 for the former and 196.7 for the latter of these elements. The investigation with Hambly of the vapour density of hydrofluoric acid, proved the density gradually to diminish between the temperatures of 26° and 88°, and, whilst establishing the correctness of the formula HF, demonstrated that it exhibits association similar to that shown by acetic acid and nitrogen peroxide. With Hambly, Thorpe also prepared gaseous phosphoryl trifluoride, which is produced by heating cryolite and phosphorus pentoxide, and showed it to have the molecular formula  $\text{POF}_3$ . With J. W. Rodger, the corresponding sulphur compound,  $\text{PSF}_3$ , was prepared by the action of phosphorus pentasulphide on lead fluoride. The investigation, made with A. E. H. Tutton, of the changes involved in the burning of phosphorus in a limited supply of air led to the recognition of phosphorus tetroxide, and the isolation of phosphorous oxide, the

true nature of which, as an easily fusible (melting at  $22.5^{\circ}$ ) and readily volatile compound, was established. The authors succeeded in obtaining this substance in crystalline form and showed from the vapour density the molecular weight corresponded to the formula  $P_4O_6$ . A thorough and complete examination of the physical and chemical properties of phosphorous oxide was made, and with the aid of Sir Lauder Brunton its physiological properties were studied, from which it would appear that this compound is the responsible agent in the production of match-makers' disease.

Amongst other publications of this period to be mentioned are : "The Decomposition of Carbon Disulphide by Shock" (a lecture experiment); a lecture experiment to illustrate the phenomena of coal-dust explosions; diethylphosphorous acid (with North Barker); fluosulphonic acid (with W. Kirman); and with L. M. Jones the thermal expansion of specific volumes of certain paraffins and paraffin derivatives. In 1893, the determination of the thermal expansion of liquids formed the subject of a paper read before the Chemical Society. In 1894, with J. W. Rodger, he published a paper on "The Supposed Relation between the Solubility of a Gas and the Viscosity of its Solvent," followed some years later by an account of a research on the viscosity of miscible liquids.

In March, 1894, Thorpe forsook the academic sphere to take up the post of Government Chemist, returning fifteen years later when for three years he took over the duties of Professor of General Chemistry in the Imperial College of Science and Technology. It was after his return to South Kensington that he, with A. T. Francis, made a determination of the atomic weight of strontium.

The writer is indebted to Mr. E. Grant Hooper for the following account of the Government laboratories and of Thorpe's administration and other activities whilst Director.

"This post, to which Thorpe was appointed in 1894, was instituted with the stated object of combining the chemical departments of the Inland Revenue and the Customs, then two separate Services. Both laboratories were originally founded for purely Revenue purposes, but whilst the Customs Laboratory staff continued to be occupied solely with such work, the Inland Revenue Laboratory had been invested with special functions such as Referees under the Adulteration of Food and Drugs Acts and, in addition to Revenue work, had for many years acted as the chemists and chemical advisers of nearly all the other Government Departments. Very large numbers of samples of the widest diversity had been annually examined for the Post Office, the India Office, the Admiralty, the Office of Works, and other civil establishments, and the 'Somerset House Laboratory,' as well as advising in other

capacities, had settled the specifications and examined the stores purchased for official use with the exception of explosives, which were dealt with at Woolwich. The 'Inland Revenue Laboratory,' as its official title was, had thus a very wide experience and its staff in 1894 consisted of a chief and deputy, two superintending analysts, five analysts (1st class), seven analysts (2nd class), and forty-five assistants.

"The Treasury decided that the Inland Revenue and Customs Laboratories should be united under the headship of the 'Government Chemist,' who should be paid from the Treasury Vote, although the staff in each case remained members of their original Departments. This continued for several years, but in 1911 a separate establishment, known as the Government Chemists' Department, was created, to which the staff was transferred except for a certain number of young men belonging to the now united Departments of 'Customs and Excise' and who were and are constantly employed on the more simple revenue determinations. The chemical staff at Somerset House had long outgrown its accommodation, and the development of fiscal business, demanding increased room for clerical work, necessitated the removal of the laboratory. The Treasury therefore determined to provide space elsewhere, and almost immediately after his appointment Thorpe and his staff were called upon to design a new laboratory which it was ultimately decided to build just outside Clement's Inn and closely adjacent to the Law Courts and the newer Bankruptcy Buildings. The new Laboratory, a commodious building admirably adapted for the very extensive chemical work, was brought into use in October, 1897. To this building the Inland Revenue staff was transferred, whilst the laboratory at the Custom House was continued for the examination of the more simple and routine Customs or import samples. It is probably little realised how large a proportion of the huge revenue derived from alcohol (now approximately £153,000,000) and from tobacco (now, say, £53,000,000) is really controlled by scientific work. The charging is, of course, done locally by Customs and Excise officers, but the maintenance of the regulations against the use of forbidden materials and adulteration and the checking of exact strengths or proportions wholly depend upon laboratory examination, whilst the assessment of 'drawback,' i.e., the duty returned on exportation or the allowances for waste material destroyed or denatured, is similarly a matter of purely chemical and microscopical determination. Fresh developments occur from time to time and a new method of determining the amount of dutiable ethyl alcohol in fusel oil led to Thorpe's first communication to the Chemical Society on official subjects, a

paper entitled 'The So-called Hydrates of *iso*Propyl Alcohol' (J., 1897, 71, 920), whilst reference may be made to the following papers connected with the everyday work of the laboratory, *viz.*, 'Occurrence of Paraffin in the Leaf of Tobacco' (J., 1901, 79, 982); 'Carbon Monoxide as a Product of Combustion by the Bunsen Burner' (J., 1903, 83, 874); 'Estimation of Ethyl Alcohol in Essences and Medicinal Preparations' (J., 1903, 83, 314); and 'Estimation of Methyl Alcohol in the Presence of Ethyl Alcohol' (J., 1904, 85, 1).

"Much other work either affecting the public or yielding results capable of other than merely official use was accomplished. For many years there had been a demand for duty-free alcohol which should be less objectionable and if possible cheaper than the duty-free alcohol known as methylated spirit. A committee was appointed, of which Thorpe was a member, which brought into existence what was known as 'industrial duty-free alcohol' and further provided for the special denaturing of spirit in cases where the presence of methyl alcohol or of the impurities in the crude wood spirit used for methylation was objectionable. Industrial alcohol had only half the quantity of crude wood spirit used in ordinary methylated spirit and was free from petroleum spirit, and thus was both cheaper and purer, whilst the wider use of specially denatured alcohol afforded substantial relief to many industries and to the fine chemical trade. Improved alcohol tables were also produced. The official strength of alcohols was 'that indicated by Sikes' hydrometer,' and there was no legal authority to ascertain strength in any other manner. By 7 Edward VII, c. 13, s. 4, authority was given to the Commissioners of Customs and Excise to issue regulations for ascertaining the strength of spirits in terms of the 'proof spirit' defined by 56 George III, c. 140. Tables were prepared showing the specific gravity in air at 60°/60° F. of all strengths of alcohol and the equivalent percentage of absolute alcohol by weight and by volume at 60° F. These tables, printed by the Stationery Office and available to the public, were only published after Thorpe's retirement from the Government Laboratory. Other work of a similar character was connected with sugar. Tables of the specific gravity of solutions of cane-sugar had been published by Bell, Thorpe's predecessor as chief of the Inland Revenue Laboratory, in Part I of his book 'Analysis and Adulteration of Foods,' but on the imposition of the sugar duty tables of the specific gravity of solutions of glucose were necessary to permit of the ready charging of the duty on commercial glucose—such were therefore prepared and brought into use.

"The statutory position of the Inland Revenue chemists as referees

in the case of disputed cases under the Food and Drugs Adulteration Acts has been mentioned. For many years difficulties and disputes had arisen in connexion with milk consequent upon the variation in total solids and proportion of butter fat natural to the commodity as drawn from different breeds of cow and under diverse conditions. It had always been evident that to fix a standard, although it might avoid disputes, was not all gain. On the one hand, a workable standard must be lower than the best quality milk, and it was likely that good milk would be systematically reduced to the level of a standard which might be fixed, whilst, further, the existence of a standard was all in favour of the larger organisations and against the smaller men engaged in the trade, who would probably be without chemists or other skilled assistance. In August, 1901, the Board of Agriculture laid down standards for milk solids below which milk was to be deemed adulterated unless the contrary were proved. As Chief Agriculture Analyst under the Board of Agriculture, Thorpe as chief of the Government Laboratory occupied a similar position as referee in disputed cases arising under the Fertilisers and Feeding Stuffs Acts. Just as in the case of milk under the Adulteration of Food and Drugs Acts, standards were laid down for various products and methods of analysis prescribed as the result of collaboration with a committee of representative official analysts.

"Other work connected with the Board of Agriculture may be indicated by the following Government Laboratory publications: 'Effect of feeding Cotton and Sesame Cake on Butter' (A., 1900, i, 237); 'The Fat of the Egg of the Common Fowl' (A., 1902, i, 295); 'Taxine,' the Poisonous Matter of Yew; 'Interdependence of the Physical and Chemical Criteria in the Analysis of Butter Fat' (J., 1904, 85, 248); 'A Simple Thermostat for Use in Connexion with the Refractometric Examination of Oils and Fats' (J., 1904, 85, 257); 'Analyses of Samples of Milk referred to the Government Laboratory in Connexion with the Sale of Food and Drugs Acts' (J., 1905, 87, 206).

"Two subjects of general interest to the public and on which much work was done in the Government Laboratory were connected with lead in pottery glazes and arsenic in food substances and drugs. The Factory Department of the Home Office were, of course, concerned with cases of lead poisoning in industry and especially in connexion with the pottery trade. Regulations as to employment, medical examination of workers, etc., had long been in existence, but a systematic examination of pottery glazes showed considerable variation in the proportions of lead used and in the degree of solubility of the lead, the latter largely depending upon whether

the lead was used as a readily soluble compound such as white lead or whether a fritt was first prepared and the glaze was compounded with the use of such a ground lead silicate. At first the trade as a whole considered the use of lead imperative, and even when it was shown that it was possible to use a lead silicate of a comparatively insoluble character difficulties were alleged, notwithstanding the fact that it was shown that, in addition to endangering the health of the pottery workers, there was pottery on the market which was a danger to the public users because acid fruits, mint-sauce, etc., extracted quite notable proportions of lead from the glaze. Ultimately the use of leadless glazes was proved to be quite practicable, and where lead was still employed the use of comparatively insoluble lead compounds was stimulated by the Home Office granting a relaxation of the conditions of employment in the pottery industry where glazes with a minimum lead-solubility were exclusively employed. Papers on this subject are as follows: 'Lead Silicates in Relation to Pottery Manufacture' (J., 1901, 79, 791; 1910, 97, 2282), and a lecture at the Royal Institution.

"In 1901, the world was startled by several cases of arsenical poisoning in Manchester and its neighbourhood which were proved to be due to the consumption of contaminated beer. It was ultimately proved that these cases were caused by the use of an impure, i.e., an arsenical, sulphuric acid for the conversion of starchy material into glucose, which in turn had been employed as an adjunct to malt in the brewing of beer. Extensive investigation showed that arsenic in small but appreciable proportions was widely present in beer; malt itself was found to be contaminated in many instances, such contamination arising from the presence of small quantities of arsenic in the coal and coke used for drying the malt on the malt-kilns. The Commissioners of Customs and Excise, having control over the materials used for brewing, were naturally involved and at once issued orders against the use of any material containing arsenic and against the dispatch of beer into consumption if it contained that substance. The Government Laboratory became flooded with samples from all over the United Kingdom, and a Royal Commission was appointed to investigate the subject. Lord Kelvin was Chairman and Thorpe was a member of the Commission. For the rapid determination of the presence of poisonous proportions of arsenic in beer the Reinsch test had been first used. Thorpe demanded of his staff a gravimetric method, although it was pointed out that the Marsh test afforded a ready means of determination and that the quantities of arsenic so far reported were so small that their separation by a gravimetric method from a liquid like beer, containing relatively large pro-

portions of organic matter, was likely to be difficult. Such a process was, however, worked out and evidence was given before the Royal Commission showing the actual separation of fractions of a milligram of arsenic from quantities such as a pint of beer, and the results of the examination of samples from various parts of the country were furnished. Meantime Local Government Chemists had been mainly using the Marsh test, although not without some trouble consequent on the difficulty at that time of obtaining for the hydrogen-production zinc which was itself sufficiently free both from arsenic, on the one hand, and, on the other, from impurities interfering with the regular evolution of the arseniuretted hydrogen where arsenic was present in the substance under examination. In view of these difficulties and largely under the influence of Lord Kelvin, an electrolytic Marsh test apparatus was devised at the Government Laboratory and put into use. The discovery of arsenic in beer led to an investigation of other materials, not merely brewing substances, malt and sugars, coal and coke used for drying malt, but other substances employed for various purposes, and especially drugs. The result was the revelation of the widespread distribution of arsenic in small proportion and the general recognition of the necessity of laying down standards of purity so that, if absolute freedom from arsenic were not attainable at a non-prohibitive cost, yet both the public and the manufacturers and vendors could be protected by stated maxima. In addition to the evidence published by the Royal Commission, reference may be made to the following papers on this subject: 'Estimation of Arsenic in Fuel' and 'Electrolytic Estimation of Minute Quantities of Arsenic, more especially in Brewing Materials' (J., 1903, 83, 969, 974); 'Note on the Application of the Electrical Method to the Estimation of Arsenic in Wall-papers, Fabrics, etc.' (J., 1906, 89, 408).

"Another subject affecting public health and especially the health of workpeople employed in the lucifer match industry was that concerned with the presence of white phosphorus in matches. When the use of this substance was forbidden, the detection of small quantities of white phosphorus in the presence of red phosphorus or of other phosphorus compounds became a matter of importance. Hence the paper, 'Note on the Detection of White Phosphorus in the Igniting Composition of Lucifer Matches' (J., 1909, 95, 440).

"In 1907, the Austrian Government having lent to the British Royal Society certain pitchblende residues, Thorpe undertook the purification of the radium chloride and the re-determination of the atomic weight of radium. A very large number of fractional

recrystallisations of radium chloride were made in the Government Laboratory and the atomic weight 226.7 was deduced in close agreement with Madame Curie's number, 226.2 (*Proc. Roy. Soc.*, 1908, 80, A, 298)."

Thorpe took part in four eclipse expeditions, viz., that of December 22nd, 1870, in Sicily; of July, 1878, at La Junta, Colorado; of August, 28—29th, 1886, at Hog Island, Grenada, West Indies, and of August 16th, 1893, at Fundium, French Senegal. On the last two occasions observations were made on the photometric intensity of light, which formed the subject-matter of two papers published in conjunction with Capt. Abney (*Phil. Trans.*, 1889, 180, A, 368; 1896, 187, A, 423). After the eclipse expedition in 1878 he and Sir Arthur Schuster made a series of magnetic observations in America along the Fortieth Parallel, which were communicated to the Royal Society in a paper entitled, "A Magnetic Survey of the Fortieth Parallel in North America between the Atlantic Ocean and the Great Salt Lake, Utah" (*Proc. Roy. Soc.*, 1879, 29, 1; 1880, 30, 132). This was followed in 1880 by a "Note on the Determination of the Magnetic Inclination in the Azores" (*ibid.*, 1881, 31, 237).

The results of an extensive magnetic survey of the British Isles made in collaboration with his colleague, Sir Arthur Rücker, during the years 1884—1888 formed the subject of the Bakerian Lecture delivered by Thorpe in 1889 (*Phil. Trans.*, 1890, 181, A, 55); and an extension of this work, containing the records of observations at 205 stations throughout the British Isles, constitutes the volume 1896, 188, A of the *Philosophical Transactions*.

Thorpe was elected to the Royal Society in 1876, served on the Council during the years 1890—1891, 1893—1895, and 1899—1903, acted as Foreign Secretary during 1899—1903, and represented the Society on the occasion of the 200th celebration of the foundation of the Royal Academy of Sciences of Berlin. He delivered the Bakerian Lecture on two occasions, in 1889 and 1904, the results of his determination of the atomic weight of radium being the subject of the second lecture. In 1889 he was awarded a Royal Medal. The President of the Royal Society (Sir Gabriel Stokes), in making this award, spoke as follows: "Professor Thomas Edward Thorpe's experimental work has secured for him a place in the first rank of living experimentalists. His researches, which are not confined to one department of chemical science, are all distinguished both by accuracy and originality of treatment. As examples of the high character of his investigations, those of the determinations of the atomic weights of titanium and gold may be specially cited as permanently setting the value of two most important chemical

constants; whilst his researches on fluorine compounds, including the discovery of thiophosphorylfluoride, a body capable of existing undecomposed in the state of gas, and his latest work on the vapour density of hydrofluoric acid, do not fall short of the highest examples of classical chemical investigation."

It was at the Edinburgh Meeting of the British Association in 1871 that Thorpe acted as Secretary of Section B (Chemistry) and fifty years later he was President of the Association at its meeting in the same city. At the Leeds Meeting in 1890, he presided over the Chemistry Section. The Presidential Address at the Edinburgh Meeting which, owing to illness, he was unable to deliver in person, was devoted to a plea for an international ban on chemical warfare. He served on several Royal Commissions and numerous Departmental Committees, was an active member of the International Committee of Atomic Weights, contributing experimental data for the determination of the atomic weights of no fewer than six elements. In 1895 he was elected President of the Society of Chemical Industry.

The record of Thorpe's scientific investigations and achievements shows how abundantly he gave of himself without stint or reserve to the advancement of knowledge, and this with a success indicated in the many recognitions and honours received by him from universities and learned societies both at home and abroad. In 1900 he was made a C.B., and on retiring from the Directorship of the Government Laboratory was knighted. In 1912 he resigned the Chair of General Chemistry at the Imperial College of Science and Technology and went to reside at Salcombe in South Devon, where he had built a house, and there devoted himself to literary work, yachting, and gardening. Sailing remained a lasting source of pleasure to him, and it is characteristic of the man that he should use his pleasure cruises as opportunities for research, as in the case of the magnetic surveys, already mentioned. Further, his yachting experiences were made to provide the material for those literary excursions: "A Yachtsman's Guide to the Dutch Waterways" (Standford, 1905), and "The Seine from Havre to Paris" (Macmillan, 1913). The revision and enlargement of the "Dictionary of Applied Chemistry" occupied him to within a few days of the illness which, as already stated, terminated fatally on February 23rd, 1925.

As to Thorpe's influence and personality, no better testimony is needed than that expressed by Dr. Tutton in the obituary notice published in the *Proceedings of the Royal Society* in December, 1925: "An able and incisive speaker, compelling attention (in spite of his stature) both by his resonant voice and his always interesting matter, a brilliant lecturer and experimenter, a faithful teacher

who never failed to make himself clearly understood, and an original investigator of keen penetration, infinite reserve, consummate manipulative skill, scrupulous accuracy and its ever accompanying quality of neatness, Sir Edward Thorpe not only inspired those who had the good fortune to study under him, but impressed the honourable mark of thoroughness and trustworthiness on the department of British Science which he so well represented. The spirit of research ever emanated from him and vivified all his teaching, and it may be hoped, and indeed believed, that its leaven has quickened the spirit of a band of devoted students, striving to emulate his fine example and to work for the honour of British Science and the acquirement of true knowledge for its own sake, throughout the whole Empire."

In conclusion the writer wishes gratefully to acknowledge the kindness of Lady Thorpe and her niece (Miss Watts) in placing at his disposal documents relating to the life and work of Sir Edward Thorpe.

---

CXXXIV.—*Germanium. Part II. Germanium Tetrachloride and its Ammonia Compounds.*

By WILLIAM PUGH and JOHN SMEATH THOMAS.

GERMANIUM tetrachloride was first described by Winkler (*J. pr. Chem.*, 1886, **142**, 177), who obtained it by the action of chlorine on heated germanium. Recently, Dennis and Hance (*J. Amer. Chem. Soc.*, 1922, **44**, 304) have prepared the compound in much larger quantities by a modification of Winkler's method. The disadvantage of this mode of preparation is that it involves the prior preparation of metallic germanium, and although this can be accomplished fairly readily by the reduction of the dioxide with potassium cyanide, as described by the present authors (*J.*, 1924, **125**, 816), it seemed desirable to investigate the possibility of preparing the substance from the dioxide by a simpler and more direct process.

An attempt to prepare germanium tetrachloride by the well-known method of passing chlorine over a strongly heated mixture of the dioxide and carbon did not yield very satisfactory results. However, by the action of a mixture of carbon monoxide and chlorine, or, better still, of carbonyl chloride on strongly heated germanium dioxide, germanium tetrachloride is very readily obtained.

Ten grams of germanium dioxide were placed in a porcelain boat in a silica tube which was heated to dull redness. Carefully dried carbonyl chloride, or a mixture of carbon monoxide and chlorine in approximately equal proportions, was then passed through the tube and a rapid reaction immediately took place. The products of the reaction were passed to the bottom of a long tube terminating in a bulb, of about 15 c.c. capacity, which was immersed in a freezing mixture. From this tube moisture was excluded by means of a phosphoric oxide guard tube attached to the exit. The reaction was complete in 2 hours, only a very small quantity of a yellowish-brown residue remaining in the boat. About 10 c.c. of a greenish-yellow liquid had condensed in the receiver. The colour, due mainly to dissolved chlorine, was less pronounced when carbonyl chloride was used. The dissolved gases were removed from the crude liquid by passing a stream of dry air through it as described by Dennis and Hance (*loc. cit.*), the containing vessel being surrounded by a freezing mixture. Twenty grams of a clear, colourless, and very mobile liquid were obtained (Found: Ge, 33.6; Cl, 66.35. Calc. for  $\text{GeCl}_4$ : Ge, 33.7; Cl, 66.3%).

An experiment was next carried out in which germanium dioxide

was suspended in hot concentrated sulphuric acid through which a stream of hydrogen chloride was bubbled. It was hoped that the hydrogen chloride would react readily under these conditions with the dioxide and that the sulphuric acid would prevent hydrolysis of the resulting tetrachloride. The method did not give satisfactory results. No visible reaction occurred until the sulphuric acid had begun to fume ( $270^{\circ}$ ), but after the mixture had been kept at this temperature for several hours much of the germanium dioxide had disappeared and about 6 c.c. of distillate had collected in the well-cooled receiver. This distillate consisted of two layers, each of about equal volume. On re-distillation, the lower layer came over completely below  $75^{\circ}$ , whilst the upper layer boiled at  $107\text{--}108^{\circ}$ . The first fraction was germanium tetrachloride contaminated with hydrogen chloride. The exact nature of the heavier layer has not been determined, but the point is being investigated. It appears to be sulphuryl chloride.

In a subsequent experiment, 10 g. of pure germanium dioxide were placed in a small distilling flask with 100 c.c. of concentrated hydrochloric acid. The flask was connected with a small double-surface condenser, the delivery tube of which was drawn out to a long capillary tube which dipped to the bottom of a receiver similar to that described previously. This receiver was immersed in a freezing mixture. About 5 c.c. of concentrated sulphuric acid were placed in the receiver, and the flask was heated in a bath at  $90^{\circ}$ . During the distillation a tendency was observed for hydrolysis of the product to take place as the hydrochloric acid became less concentrated. To obviate this, a slow stream of hydrogen chloride was bubbled through the liquid while the distillation was in progress. The dioxide dissolved fairly rapidly. As soon as solution was complete, the process was stopped; a stream of dry air was passed through the well-cooled distillate for several hours in order to remove dissolved hydrogen chloride. The product was then distilled from the sulphuric acid and was collected with the usual precautions in a small distilling flask. After a further distillation, without the addition of sulphuric acid, 20.2 g. of very pure germanium tetrachloride were obtained, b. p.  $85.5^{\circ}$  (Found: Ge, 33.7; Cl, 66.3%). This proved to be the most convenient method of preparing germanium tetrachloride.\* Equally good results were obtained with germanium dioxide which had been ignited at a bright red heat as with the freshly precipitated substance.

During the distillation of germanium tetrachloride from sulphuric

\* Since this was written Tabern, Orndorff, and Dennis have described a somewhat similar method of preparing germanium tetrachloride (*J. Amer. Chem. Soc.*, 1925, 47, 2032).

acid, an interesting phenomenon was observed. The two liquids do not mix and at the ordinary temperature the tetrachloride forms the lower layer. At  $0^{\circ}$ , the interface between the two liquids is perfectly flat. As the temperature rises, this interface becomes more and more convex until at  $50^{\circ}$  the lower layer resembles an egg with the pointed end upwards. Then, quite suddenly, the position of the two layers becomes reversed, the sulphuric acid being the denser, and the liquid interface is now concave. As the temperature is raised still higher, the curvature of this interface becomes less and less until, just below the boiling point of the tetrachloride, it again becomes quite flat and exhibits a very fine play of iridescent colour. On cooling, the liquids undergo the same changes in the reverse order.

*The Action of Dry Gaseous Ammonia on Germanium Tetrachloride.  
Hexamminogermanic Chloride.*

It is well known that ammonia reacts readily with stannic chloride (Rose, *Pogg. Ann.*, 1832, 24, 109), with lead tetrachloride and with zirconium tetrachloride (Matthews, *J. Amer. Chem. Soc.*, 1899, 20, 815, 839, 843). In each case solid compounds are produced which, however, do not appear to have been fully investigated. Further work in this direction is now being carried out in these laboratories.

Germanium tetrachloride also combines readily with ammonia. In a preliminary experiment, dry ammonia was led on to the surface of germanium tetrachloride, cooled in a freezing mixture. A vigorous reaction took place, dense white fumes were formed, and much heat was evolved. Absorption of ammonia proceeded quietly after a time, and the passage of the gas was continued for several hours. The product was a white powder having a strong smell of ammonia which, however, disappeared after the substance had been exposed to the air for several hours (Found: Ge, 20.7; Cl, 40.75;  $\text{NH}_3$ , 24.3%. Ratio Ge : Cl = 1 : 3.99; Cl :  $\text{NH}_3$  = 1 : 1.24). Analyses of other specimens prepared in the same way yielded similar results. In every case, the ratio Ge : Cl was the same within the limits of experimental error, but the ratio Cl :  $\text{NH}_3$  varied considerably; further, from 14% to 20% of the material always remained unaccounted for.

These analytical results may, of course, be attributed to replacement of ammonia in the original ammine by water molecules derived from the moisture in the air. In order to test this possibility, a further preparation was undertaken in which every precaution was taken to exclude moisture. The apparatus employed is illustrated in Fig. 1.

The reaction vessel, A, was about 9 inches long and  $1\frac{1}{4}$  inches in

diameter. It was closed by means of a tight-fitting rubber stopper, through which passed two fairly wide tubes, *B* and *C*, which served to admit ammonia and germanium tetrachloride, respectively. In order to prevent the choking of these tubes by the product of the reaction, they were provided with thin glass rods, attached by means of rubber tubing, by the movement of which they could be cleared as necessity arose. After the apparatus had been thoroughly dried, about 1 c.c. of germanium tetrachloride was distilled into *D* from the main supply and through it a slow stream of dry air was bubbled; at the same time, *D* was heated to 50° by means of a bath of warm water. In this way, a steady stream of tetrachloride

FIG. 1.

vapour was introduced into *A*, which was kept cold by means of a freezing mixture. At the same time, dry ammonia was also admitted to the reaction vessel, the rate of flow of the gases being so regulated that a slight excess of ammonia was always present. This rate had to be slow, otherwise much of the finely divided product was carried away by the stream of air and lost. The waste gases escaped by the exit tube, *E*, which was fitted with a suitable guard tube to prevent ingress of moisture.

After all the germanium tetrachloride had been driven over, the flow of ammonia was continued for an hour to ensure complete combination and any excess, together with some adsorbed ammonia, was then removed by passing dry air through the apparatus until no smell of ammonia could be detected at the exit tube. The product was then transferred to a well-stoppered bottle and kept

over quicklime in a desiccator. It was a pure white, light, and extremely soft powder which proved to be  $\text{GeCl}_4 \cdot 6\text{NH}_3$  (Found: Ge, 22.95; Cl, 44.9;  $\text{NH}_3$ , 31.9. Ratio Ge : Cl = 1 : 3.97; Cl :  $\text{NH}_3$  = 1 : 1.49.  $\text{GeCl}_4 \cdot 6\text{NH}_3$  requires Ge, 22.8; Cl, 44.9;  $\text{NH}_3$ , 32.3%).

In order to obtain further information regarding the change which the hexammine undergoes when it is exposed to moist air, 2 grams of the freshly prepared substance were exposed to the action of moist carbon dioxide-free air and the change of weight was observed at frequent intervals. During the first 2 days, the weight increased rapidly; the increase then became more gradual, until after a month the weight was constant; the increase then amounted to 11.9% [Found: Ge, 20.4; Cl, 40.3;  $\text{NH}_3$ , 19.8;  $\text{H}_2\text{O}$  (diff.), 19.4%. Ratio Ge : Cl = 1 : 4.0; Cl :  $\text{NH}_3$  = 1 : 1.03]. This change in composition taken in conjunction with the observed increase of weight corresponds to the replacement of two molecules of ammonia by four molecules of water ( $\text{GeCl}_4 \cdot 4\text{NH}_3 \cdot 4\text{H}_2\text{O}$  requires Ge, 20.3; Cl, 40.1;  $\text{NH}_3$ , 19.8%, and an increase in weight of 12.03%).

According to Mendeléev (*Ber.*, 1870, 3, 422), water, in similar circumstances, replaces ammonia in pentamminocupric sulphate, molecule for molecule; from the analytical results, however, it is clear that such simple replacement does not occur in this case. Examples of the replacement of a molecule of ammonia by two molecules of water do not appear to have been observed and it may be pointed out that in this case such a replacement would involve a change in the co-ordination number of germanium, unless, indeed, double molecules of water are concerned, as Werner suggested is the case in the alums.

This replacement of ammonia by water molecules may, however, be explained in another way. Instead of replacement of ammonia according to the equation

the hexammine may undergo hydrolysis thus :

In either case, the solid product would have the same composition, and analytical methods cannot decide, therefore, which is the correct explanation. The behaviour of the substance on treatment with water points, however, to the second explanation. The hexammine itself dissolves completely in water to a clear and colourless solution which only becomes turbid after standing for several hours. A compound such as  $\text{GeCl}_4 \cdot 4\text{NH}_3 \cdot 4\text{H}_2\text{O}$  might be expected to behave in a similar way. The actual substance does

not dissolve completely in water, but leaves a residue which is readily soluble in sodium hydroxide and does not contain chlorine, a behaviour which might be expected from a mixture of ammonium chloride and hydrated germanium dioxide.

*The Action of Ammonia on Germanium Tetrachloride Dissolved in Ether.*

Germanium tetrachloride (1 c.c.) was dissolved in 100 c.c. of dry ether contained in a flask cooled in a freezing mixture, and dry ammonia was bubbled through the solution. A white precipitate at once formed and the heat of the reaction caused the ether rapidly to evaporate. The current of ammonia was continued until all the ether had thus been removed, and the white powder remaining was transferred to a bottle and stored in a desiccator over quicklime. It smelled strongly of ammonia. It was identical with the product obtained by the interaction of the gaseous substances (Found: Ge, 23.0; Cl, 44.8;  $\text{NH}_3$ , 31.85%). All the values are slightly low; this is probably accounted for by access of moisture during transference from one vessel to another.

The ammonia pressure of the hexammine is very small; a specimen was kept over concentrated sulphuric acid for a week without undergoing any appreciable change in weight. The compound is readily soluble in water, but is slowly hydrolysed in solution and the liquid becomes turbid. The solution smells strongly of ammonia. The hexammine is insoluble in ether, alcohol, chloroform and all the common organic solvents. When it is heated in dry air, the substance sublimes completely but with slight loss of ammonia. An analysis was made of a specimen which had been sublimed in a current of dry air in a specially constructed apparatus from which air was carefully excluded (Found: Ge, 23.2; Cl, 46.4;  $\text{NH}_3$ , 30.5%). Possibly a lower ammonia compound is formed at very high temperatures.

*The Interaction of Germanium Tetrachloride with some Amines.*

A number of amines being available in connexion with another investigation, the interaction of these substances with germanium tetrachloride was studied. Additive compounds with mono-, di-, and tri-ethylamine, with propylamine, and with butylamine were prepared by bringing the vapours of the two substances into contact in the same way as in the preparation of the ammonia compounds. These additive compounds were also obtained by passing amine vapour into solutions of germanium tetrachloride in ether. In every case, the product was a white powder closely resembling the hexammine both in appearance and in properties.

The amine derivatives are quite stable in dry air and have little or no smell. They are decomposed by moist air and under these conditions they smell strongly of the amine. They are readily soluble in water, but the solutions undergo hydrolysis and become turbid on standing. They are insoluble in the common organic solvents. They contain six molecules of amine to each molecule of the tetrachloride [Found for the diethylamine compound: Ge, 11.0; Cl, 21.7;  $(C_2H_5)_2NH$ , 67.2.  $GeCl_4 \cdot 6(C_2H_5)_2NH$  requires Ge, 11.1; Cl, 21.8;  $(C_2H_5)_2NH$ , 67.1%].

*The Existence of Higher Ammonia Derivatives of Germanium Tetrachloride.*

During the investigation of germanium tetrachloride hexamine, absorption of ammonia was observed to occur when this gas was

FIG. 2.

compressed in contact with the hexamine. In order to determine the nature of this change, a known weight of the solid was treated with ammonia under a pressure of about 3 atmospheres until no more of the gas was absorbed. Small, measured quantities of ammonia were then removed and after each such removal the equilibrium pressure was measured. Owing to the high pressures developed at higher temperatures, it was found most convenient to work at  $0^\circ$ . The apparatus employed is sketched in Fig. 2.

The hexamine (1.3756 g.), contained in a small stoppered bottle, was placed in the tube A, which was then sealed in such a way as to prevent ingress of moisture. The tap  $T_1$  being closed, the stopper of the bottle was removed by gentle shaking. After sealing A to

the remainder of the apparatus, the whole was thoroughly dried by alternately exhausting and then filling it with air which had passed over phosphoric oxide. The apparatus was then washed out several times with dry gaseous ammonia, obtained by the evaporation of liquid ammonia in the Dewar vessel, *E*, from which superfluous gas escaped by means of the mercury trap, *F*.

All the air being in this way removed, *A* was immersed in a thermostat kept at 0°, and the vessel *B*, having a capacity of 200 c.c., was filled with ammonia, which was then compressed into *A* by closing *T*<sub>2</sub> and *T*<sub>4</sub>, opening *T*<sub>1</sub> and *T*<sub>3</sub>, and raising the mercury reservoir, *C*. Under a pressure of 3 atmospheres absorption of ammonia took place very rapidly at first—600 c.c. were taken up in the first  $\frac{1}{2}$  hour. The process then became gradually slower, until eventually about 1100 c.c. of ammonia had been absorbed. By this time the substance in *A* had become liquid.

Ammonia was then removed from the reaction vessel in small quantities at a time, each amount being measured by means of the gas burette, *D*. All volumes were reduced to *N.T.P.* After each removal, the apparatus was allowed to stand until the pressure became constant. The pressure was measured by means of the manometer, *M*, which allowed of any pressure from 0 to 2400 mm. being determined. When not in use, *T*<sub>2</sub> and *T*<sub>3</sub> were sealed with mercury. All pressure measurements were made from the same point on the manometer, so that the volume of the apparatus was always the same. The amounts of ammonia and the corresponding equilibrium pressures are in Table I.

TABLE I.

60.3	1044	379.0	1040	812.6	1041	1063.0	295
77.1	1045	422.0	1041	854.4	1040	1087.2	95
95.3	1044	459.3	1041	896.1	1041	1105.3	0
114.8	1042	496.0	1040	936.9	1042		

From this table it is clear that only one higher ammonia compound can exist within the range of pressures examined and that the dissociation pressure of this compound at 0° is 1040 mm., that is to say, the compound cannot exist at the ordinary temperature and pressure. It is curious that this compound should be a liquid.

When all the ammonia had been removed, the volume of *A* was

determined by filling the vessel with dry air and then pumping off and measuring the volume of air used. The volume was 32 c.c. The vessel was then opened and a specimen of the solid, which had now acquired a porous structure, was analysed (Found: Ge, 22.9; Cl, 44.8;  $\text{NH}_3$ , 32.0. Calc. for  $\text{GeCl}_4 \cdot 6\text{NH}_3$ : Ge, 22.8; Cl, 44.9;  $\text{NH}_3$ , 32.3%). This proves the end-product to be the hexammine and confirms the statement made in an earlier paragraph that the ammonia pressure of this compound is extremely small.

From the quantities of ammonia removed, together with the weight of the hexammine originally taken, the formula of the higher ammine can be calculated. By a graphical method, it was estimated that the dissociation pressure of the compound was reached after the removal of 57.5 c.c. of ammonia and that the compound was completely dissociated after the removal of 1004 c.c. of the gas (both measured at *N.T.P.*). Thus, 1.3756 g. of the hexammine had combined with 946.5 c.c. of ammonia. Now the addition of each additional molecule of ammonia to the hexammine requires 96.92 c.c. of the gas, and hence, within the limits of experimental error, 10 additional molecules of ammonia have been taken up and the higher compound thus has the formula  $\text{GeCl}_4 \cdot 16\text{NH}_3$ .

The variation of the dissociation pressure of the higher compound was also investigated between the temperatures  $0^\circ$  and  $16^\circ$ . The pressures observed, which are in Table II, were found, when plotted against the temperature, to lie on a straight line. By extrapolating this curve, the dissociation pressure was found to be 760 mm. at  $-4^\circ$ .

TABLE II.

Temp. ....	$0^\circ$	$0.4^\circ$	$1.8^\circ$	$4.0^\circ$	$6.0^\circ$
Press. (mm.) ....	1040	1055	1164	1309	1462
Temp. ....	$7.9^\circ$	$9.9^\circ$	$11.9^\circ$	$13.4^\circ$	$16.1^\circ$
Press. (mm.) ....	1590	1733	1889	2001	2190

An examination of Table I shows that, in addition to the formation of the higher ammonia compound, adsorption of the gas also takes place, for neither the volume of ammonia removed in reducing the pressure from 1998 mm. to the equilibrium pressure nor the volume pumped off after the complete dissociation of the higher compound is in agreement with that calculated by means of the gas laws. The discrepancy was far greater at low pressures, for, whilst the removal of 57.5 c.c. of ammonia (measured at *N.T.P.*) reduced the pressure from 1998 mm. to 1040 mm., the ammonia remaining after the higher compound had completely dissociated occupied 101.3 c.c. under the same conditions. Thus it appears that adsorption of ammonia occurs to a greater extent at low pressures.

This abnormality is, however, easily explained by the fact that

$\text{GeCl}_4 \cdot 16\text{NH}_3$ , being liquid, exposes a comparatively small surface, whereas the hexammine produced by its dissociation is rendered extremely porous by the escape of ammonia during the process of dissociation.

The constitution of the hexammine is readily explained by means of Werner's co-ordination theory if the co-ordination number of germanium is taken to be 6 and the whole of the chlorine is ionisable. It is, however, somewhat difficult to reconcile this with the electron theory of valency. According to Langmuir's theory, the germanium atom (atomic number 32) has 2, 8, 8, 14 electrons in the various shells and requires 4 electrons to bring the number of electrons in the outer shell up to that of the inert gas immediately following. In the hexammine, the central atom  $[\text{Ge}(\text{NH}_3)_6]^{++++}$  must therefore have an outer shell of 22 electrons. But such a compound should be unstable and should readily lose ammonia, as do the solid hexammines of zinc, nickel, and copper. So far from this being the case, germanium tetrachloride hexammine is remarkably stable and shows no tendency to lose ammonia when kept free from moisture, although, on the addition of water, ammonia is immediately liberated. Possibly a tetrammine complex is formed in solution, but the rapidity with which hydrolysis takes place makes the investigation of this point difficult.

As yet no adequate explanation of the constitution of this substance, and still less of that of the higher compound, can be offered, but the nature of these compounds and also the ammonia derivatives of the tetrachlorides of tin and lead are being further investigated.

#### *Summary.*

1. Various methods for the preparation of germanium tetrachloride have been investigated. By the action of hydrogen chloride on germanium dioxide in concentrated hydrochloric acid, under suitable conditions, the compound may readily be obtained pure.

2. The action of gaseous ammonia on germanium tetrachloride vapour and also on a solution of the compound in ether has been investigated. In each case the compound  $\text{GeCl}_4 \cdot 6\text{NH}_3$  is produced. Amines react in a similar manner.

3. Hexamminogermanic chloride is a white, very light powder which is very stable in dry air but is hydrolysed by moist air, a residue of hydrated germanium dioxide and ammonium chloride remaining. The hexammine dissolves readily in water, but becomes turbid after a time owing to separation of hydrated germanium dioxide produced by hydrolysis of the compound.

4. The hexammine when treated with ammonia under pressure absorbs the gas readily at low temperatures. A higher compound,

$\text{GeCl}_4 \cdot 16\text{NH}_3$ , is produced which is a liquid at  $0^\circ$  and has a dissociation pressure of 1040 mm. at  $0^\circ$ , 2085 mm. at  $15^\circ$ , and 760 mm. at  $-4^\circ$ .

5. No evidence of any other ammonia compound was obtained.  $\text{GeCl}_4 \cdot 16\text{NH}_3$  dissociates directly to the hexammine, which is extremely stable, having no measurable ammonia pressure at  $0^\circ$ . At this temperature, it can be kept over concentrated sulphuric acid for days without losing weight.

6. The application to these compounds of the co-ordination theory and of the electron theory of valency is briefly discussed.

### CXXXV.—The Binary System Barium Iodide-Water.

By JOHN PACKER and ALBERT CHERBURY DAVID RIVETT.

HAVING had occasion recently to seek information regarding the solubility of barium iodide in water at three or four temperatures, we found the available figures scanty and uncertain and were obliged to make new measurements. It seemed worth while to supplement these and to place on record the full binary system from the eutectic temperature ( $-33.5^\circ$ ) to  $120^\circ$ .

Commercial (B.D.H.) barium iodide, approximating in composition to  $\text{BaI}_2 \cdot 2\text{H}_2\text{O}$ , was purified by crystallisation, and used, as the hydrate  $2\text{BaI}_2 \cdot 15\text{H}_2\text{O}$ . The procedure adopted in examining the

system followed the usual lines. Concentrations were determined by estimating iodide volumetrically against silver nitrate, with ferric thiocyanate as indicator: they are expressed in the table as weights of anhydrous salt in 100 g. of solution. In some cases, the values were checked by estimations of barium as sulphate. Transition points were measured thermometrically and confirmed by intersections of extrapolated curves.

The mono- and di-hydrates are well known, whilst hydrates with six and seven molecules of water have been stated to exist. It is difficult to obtain a deliquescent hydrate, like the highest in this series, in a sufficiently pure state for analysis. Probably the surest procedure is to investigate it by the method depending on analysis of wet solids in a suitable ternary system, and this we have done in the system barium iodide-iodine-water, which we hope shortly to describe. The highest hydrate appears to be  $2\text{BaI}_2 \cdot 15\text{H}_2\text{O}$ , and we have not found either hexa- or hepta-hydrate.

The table and figure indicate all details of the system.

CXXXVI.—*The Constitution of Magnesium Acetate Solutions.*

By ALBERT CHERBURY DAVID RIVETT.

THE constitution of basic beryllium acetate (Urbain and Lacombe, *Compt. rend.*, 1901, **133**, 874; Bragg, *Nature*, 1923, **111**, 532; Sidgwick, *ibid.*, 808; Bragg and Morgan, *Proc. Roy. Soc.*, 1923, *A*, **104**, 437) is explicable in terms of a marked tendency on the part of the beryllium atom to exercise a co-ordination number of 4 in its linkings with oxygen. The readiness with which this occurs may be connected with the fact that the outer electrons in the atoms of beryllium and oxygen are at similar energy levels: there may thus be a decreasing tendency towards such linkings with oxygen as one passes down Group II of the Periodic Classification through magnesium, calcium, strontium, and barium. In magnesium acetate one might expect to find, at any rate, an appreciable tendency for the formation of a compound analogous to the basic beryllium salt.

In preparing hydrated magnesium acetate from magnesium oxide, acetic acid, and water, with a view to seek such a basic acetate in the ternary system oxide-acetate-water, one was struck by the ease with which supersaturated solutions could be formed, by the slow rate of their crystallisation after seeding, and by the very high viscosity possessed by solutions above a certain range of concentration. Measurements of some of the properties of these solutions have therefore been made, and from them it seems that some guidance may be obtained as to the probable condition of magnesium acetate in solutions of varying concentrations.

## EXPERIMENTAL.

The solid salt used was prepared from magnesium oxide (B. D. H.), free from sulphur, and excess of acetic acid (A. R.) diluted about fourfold with water. The crystals formed were separated on a silver gauze basket in a centrifuge of 6-inch radius at 1800 r.p.m., and kept for some weeks in a vacuum desiccator over concentrated caustic soda to remove excess acetic acid. Analysis showed them to be  $\text{Mg}(\text{C}_2\text{H}_3\text{O}_2)_2 \cdot 4\text{H}_2\text{O}$ .

All solutions were analysed by conversion of dissolved salt into anhydrous magnesium sulphate and weighing as such. Compositions of solutions are given throughout the sequel in percentages of anhydrous salt by weight; but, in the discussion, concentrations are usually quoted in g.-mols. per 1000 g. of water ( $M_w$ ) or g.-mols. per litre at 25° ( $M_v$ ).

FIG. 1.  
Binary system magnesium acetate-water.

solutions in the region of 30% by weight are so viscous that the phase-reaction between ice and solution proceeds too slowly for accurate measurements. On the salt-solution curve, hydrolysis sets an upper limit. The solid hydrate begins to melt at about 68°, so that this curve reaches a maximum somewhere near that temperature, as indicated by the dotted extension in Fig. 1. An extrapolation of ice and salt curves downwards points to a eutectic temperature (hydrate-ice-solution) of about -29°: but a figure so obtained is very uncertain.

Table II gives the viscosities of solutions of magnesium acetate (and a few, for comparison, at high concentrations of magnesium chloride and sodium acetate) at 25° relatively to water taken as unity. They have been measured in viscosimeters of the Ostwald pattern with time of water-flow of about 3 minutes. Pyknometers of 5 c.c. were used for determinations of density.

In Table IV are the specific conductivities ( $\text{ohm}^{-1} \text{ cm}^{-1}$ ) at 18° and 25° measured in a cell of the form shown in Fig. 4. The total volume of the cell is 400 c.c., that of the lower tube,  $a$ , being 15 c.c. This is a useful shape when a series of dilutions is to be examined, since, provided that the lower tube be filled, the resistance of a solution is independent of the volume taken. Successive dilutions were effected by additions of water from a weight burette.

Table V shows the way in which the conductivity of a highly concentrated solution ( $M_w = 5.5$ ) varies with temperature.

### Discussion.

Fig. 2 shows the remarkable rapidity with which viscosity at  $25^\circ$  increases with concentration. No simple equation has been found to cover the relation between the two. Rapid rise begins at about  $2.5M_w$ , the value relative to water as unity increasing from approximately 7 at that concentration to 155 at  $M_w = 5.4$  ( $M_v = 3.9$ ), a supersaturated solution. One might suppose this great change to be due to hydration of the salt, the amount of free solvent water becoming steadily less. The evidence is, however, rather contrary to any such supposition. Thus, ease of hydration is doubtless, to some extent, a characteristic of both radicals of the salt, yet neither magnesium chloride nor sodium acetate shows anything approaching the behaviour of magnesium acetate. At  $4.5M_w$ , the former has a relative viscosity of only about 9: the latter, at  $2.5M_w$ , (calculated on a doubled formula), the maximum concentration attainable, has the value 5.5. There is no indication in either case that a rapid rise is likely.

Further, if the production of heavily hydrated molecules were the cause of the high viscosity of magnesium acetate solutions compared with those of magnesium chloride, one would expect the curve of the molecular lowering of freezing point of the former to lie well above that of the latter. Fig. 3 shows how very far

this is from being the case. The figures for magnesium chloride at the dilute end are by the author (*Z. physikal. Chem.*, 1912, **80**, 546), while those for concentrated solutions are taken from the Landolt-Börnstein "Tabellen." In infinitely dilute solution a lowering of  $3 \times 1.85^\circ$  is to be expected for a ternary electrolyte fully dissociated. As concentration increases, the lowering diminishes with decreasing dissociation and then, as is usual, passes

through a minimum and begins to rise. This rise is commonly attributed, in part at least, to removal of solvent by hydration of solute. With magnesium chloride it becomes very great, exceeding  $12^\circ$  at  $2.7M_w$ ; with the acetate it is only  $6.5^\circ$  at  $2.35M_w$ . If the extrapolation in Fig. 1 to a eutectic at  $-29^\circ$  and 34.5% anhydrous salt ( $M_w = 3.7$ ) is correct, the molecular lowering at that temperature is only  $7.8^\circ$ ; but one cannot be sure of this figure. Thus

the relation to magnesium chloride is incompatible with an assumption that the acetate is the more highly hydrated, and it appears that the increase in viscosity in concentrated solutions of the latter is due to some other property of the magnesium and acetate radicals in conjunction.

A plausible suggestion is that as one passes from relatively dilute solutions, where ionic dissociation is considerable, there is an increasing tendency for association of molecules to occur, such association being the result of chelate ring-formation by means of the magnesium atom exercising a co-ordination number of 4 towards oxygen atoms. In a single molecule, such a structure as  $\text{H}_3\text{C}\cdot\text{C}\begin{smallmatrix} \diagup \text{O} \\ \diagdown \text{O} \end{smallmatrix} \cdots \text{Mg} \begin{smallmatrix} \diagdown \text{O} \\ \diagup \text{O} \end{smallmatrix} \cdots \text{C}\cdot\text{CH}_3$ , with four-atom rings, is not likely to

FIG. 3.

FIG. 4.

be stable, particularly in dilute solution where ionisation is considerable; but, with increase of concentration, polymerisation may occur to an indefinite extent with production of such chains as  $\text{---Mg}\begin{smallmatrix} \diagup \text{A} \\ \diagdown \text{A} \end{smallmatrix} \text{---Mg}\begin{smallmatrix} \diagup \text{A} \\ \diagdown \text{A} \end{smallmatrix} \text{---Mg}\begin{smallmatrix} \diagup \text{A} \\ \diagdown \text{A} \end{smallmatrix} \text{---Mg}\begin{smallmatrix} \diagup \text{A} \\ \diagdown \text{A} \end{smallmatrix} \text{---}$  where each unit in the chain

(straight or branched) is  $\text{---Mg}\begin{smallmatrix} \diagup \text{O}=\text{C}(\text{CH}_3)-\text{O} \\ \diagdown \text{O}-\text{C}(\text{CH}_3)=\text{O} \end{smallmatrix} \text{---}$ , a magnesium atom being linked by a co-valence to a doubly-linked oxygen atom of an acetate radical other than that originally attached to itself. It is a simple matter to draw possible spatial structures for di-, tri-, and higher molecular aggregates. Such polymerisation is of a type similar to that which apparently is shown by basic beryllium acetate.

Chains of this kind will no doubt contribute very greatly to the viscosity of a solution and might well account for the values recorded

at high concentrations. If now there is such a progressive alteration in the constitution of solute, from simple ionised salt to more or less highly polymerised molecules, there should be marked differences in the effects of temperature upon differing concentrations. At higher concentrations, increase of temperature, by promoting dissociation, should have a much greater effect upon viscosity, for instance, than it will have at lower concentrations where there is little or no polymerisation. The measurements of Table III, shown in the broken lines of Fig. 2, prove quite definitely that this is the case. Three solutions have been measured at several temperatures and each viscosity has again been expressed relatively to water at the same temperature. For an 18.4% ( $1.805M_w$ ) solution the curve (A, Fig. 2) is almost horizontal; for 46% ( $5.97M_w$ ) it (C) is very steep, and the lower the temperature the steeper is the gradient.

The measurements of specific conductivity (Table IV) show the usual maximum as concentration increases, but whereas this occurs at  $2.5M_w$  with magnesium chloride, it is at under  $1M_w$  with magnesium acetate, the conductivity being only one-fifth of the corresponding value for the former. It is idle, on the basis of conductivity work, to attempt comparisons of dissociation and ionic concentrations in cases like these, where one cannot be certain that the ions are the same in concentrated as in dilute solutions, and where any allowance for viscosity can be nothing more than conjecture. Some interest, however, attaches to the temperature coefficient of the conductivity. Values at both  $18^\circ$  and  $25^\circ$  are included in Table IV, so that for each solution one can obtain the mean percentage increase in conductivity per degree between these two temperatures. The values of  $100(\kappa_{25} - \kappa_{18})/7 \times \kappa_{18}$  are given in the sixth column of the table. Up to about  $1M_w$  the increase is close to 2.5% per degree—quite a normal figure for salts—but the coefficient continues to grow at an increasing rate as concentration rises, reaching 7%, and rising rapidly, at  $5.5M_w$ . Here again magnesium acetate furnishes an unusual case and an assumption of polymerisation leads to a qualitative explanation. Dissociation of polymerides with rising temperature will increase the number of simple molecules, which presumably are much more capable of ionisation, and so give increased conductivity: here also, however, it is unfortunate that one cannot deduct the effect, if any, due to change of viscosity between  $18^\circ$  and  $25^\circ$ .

Keeping to one and the same highly concentrated solution, containing 43.9% of anhydrous acetate ( $M_w = 5.50$ ;  $M_v = 3.87$ ) the figures of Table V show how conductivity varies over a wider range of temperature ( $12.7^\circ$  to  $55.1^\circ$ ). This solution is saturated

at 45°, but may be kept indefinitely at room temperature. Between the temperatures mentioned, the conductivity changes by more than 850% of its initial value—a very high figure for a salt. The rate of increase of conductivity with temperature is greater at higher temperatures, but the relative increase in value per degree is greater at the lower temperatures.

While this high temperature coefficient may simply reflect altered mobility consequent upon altered viscosity, it is more probable that both viscosity and conductivity changes are due to a common cause, polymerisation, which is highly sensitive to temperature change.

Some approximate measurements of surface tension have been made by the capillary tube method at 25°. There would seem to be little difference between the surface tensions of water and magnesium acetate solutions. Multiplying each rise by the density of the solution and dividing by the rise of pure water in the same tube, the following relative figures were obtained:

% anhyd. $\text{Mg}(\text{C}_2\text{H}_3\text{O}_2)_2$	6.01	14.0	23.5	23.6	31.4	39.3
S .....	1.013	1.006	1.002	1.001	0.980	0.968

No great accuracy is claimed for the figures and the third decimal place may be incorrect by several units, but it appears fairly certain that there is an initial rise, as is usual with salts, which is followed by a decrease to less than the value for water: at none of the concentrations examined does the change in surface tension due to the presence of the salt exceed a few parts per cent.

There are other physical properties of these solutions which will be investigated later and a comparison will be made with the acetates of calcium, strontium, and barium, the higher positivity of the atoms of which will presumably involve less tendency towards formation of polymers by non-polar linkages of the type so markedly shown by beryllium, and apparently still characteristic in magnesium.

THE UNIVERSITY OF MELBOURNE.

[Received, January 25th, 1926.]

## CXXXVII.—*The Nitration of Benzil.*

By FREDERICK DANIEL CHATTAWAY and EDWARD AUTY  
COULSON.

ALTHOUGH benzil is scarcely attacked by ordinary strong nitric acid, it is readily nitrated by fuming nitric acid. The reaction was first carried out by Zinin (*Annalen*, 1864, Suppl. 3, 153), who recognised that a new compound distinct from benzil and *p*-nitrobenzil was formed, but did not pursue the investigation further.

It was next studied by Zagumenny (*J. Russ. Phys. Chem. Soc.*, 1872, 4, 278), who, by crystallising the crude viscid product from alcohol, obtained a moss-like mass of irregular needles melting at 107°, in which after some weeks two different kinds of crystals made their appearance and could be picked out. He thus obtained two substances crystallising respectively in yellow octahedra, m. p. 131°, and in faintly yellow, rectangular plates, m. p. 147°. Analyses showed that all these substances had the composition of dinitrobenzil, but Zagumenny expressed no opinion as to their nature. His observations were apparently overlooked, for much later Klinger and Martinoff (*Annalen*, 1912, 389, 232) claim to have obtained an almost theoretical yield of pure *mm'*-dinitrobenzil, m. p. 108·5—109°, by nitrating benzil with a large excess of cold fuming nitric acid, and more recently Barnett and Kay (*Chem. News*, 1922, 125, 57), after remarking that the preparation of dinitrobenzil is much simpler than would be gathered from the literature, state that a nearly theoretical yield of practically pure *mm'*-dinitrobenzil, m. p. 109°, can be obtained by dissolving or suspending benzil in concentrated sulphuric acid and adding slowly an equal weight of potassium nitrate.

The products described by Zagumenny (m. p. 107°), by Klinger and Martinoff (m. p. 108·5—109°), and by Barnett and Kay (m. p. 109°) appear from their melting points to have been the same, and a re-examination of the crude substances obtained by each of the three methods proves that they are substantially identical.

A closer examination of the nitration product, however, shows that it is not a single substance but a mixture of at least three isomeric dinitrobenzils. These have been separated, mainly by fractional recrystallisation, but partly by mechanical assortment of the crystals.

The crude nitration product, which melts not very sharply at about 107°, has been thus shown to consist of approximately 70% of *mm'*-dinitrobenzil, m. p. 132°, 20% of *om'*-dinitrobenzil, m. p. 149°, and about 10% of *oo'*-dinitrobenzil, m. p. 208°.

The constitutions of the first two isomerides have been established by their oxidation to the corresponding nitrobenzoic acids, whilst the third has been shown to be identical with the *oo'*-dinitrobenzil obtained by Kliegl and Haas (*Ber.*, 1911, 44, 1213) by the oxidation of *oo'*-dinitrotolane.

#### EXPERIMENTAL.

*Nitration of Benzil.*—Preliminary experiments in which benzil was heated with fuming nitric acid as described by Zagumenny showed that the product very closely resembled those obtained

when the nitration was effected by a large excess of cold fuming nitric acid as described by Klinger and Martinoff or by a mixture of cold strong sulphuric acid and potassium nitrate as described by Barnett and Kay. The crude products were identical in appearance, and the moss-like, fluffy crystals obtained by cooling saturated solutions in boiling alcohol had a similar appearance and were of approximately the same melting point, although this varied somewhat and was never sharp. All three products were similar mixtures of isomerides. The behaviours of the moss-like masses of yellow crystals, which separated when solutions of the crude products in boiling alcohol were cooled, on recrystallisation from acetone were similar, and the proportions of the various constituents of the mixture, separated as described later, were as far as could be judged about the same.

*Preparation of the Crude Mixture of Isomeric Dinitrobenzils.*—Benzil (120 g.) and 240 g. of nitric acid ( $d$  1.52) were slowly heated in a litre Jena flask with a ground-in air condenser and allowed to boil gently for about 5 hours. The mixture was then poured on to crushed ice, when a viscid, yellow mass separated. The aqueous supernatant liquid was decanted off and the yellow product, which collected together and could be easily separated, was repeatedly extracted with boiling water. In this way the nitrobenzoic acids formed as by-products were removed. The warm, yellow, plastic mass was then drained as completely as possible and allowed to cool, when it slowly solidified. The yield of crude product was about 150 g. (about 80% of the theoretical). The dry product was finely powdered and dissolved in boiling acetone. On cooling, a moss-like, crystalline mass separated in which larger, definitely-shaped crystals slowly made their appearance. On allowing the crystalline mass to remain for some days in the mother-liquor at the ordinary temperature, the quantity of compact crystals appeared to increase, and under the microscope they were seen to be of different kinds.

The whole crude product was therefore systematically fractionally crystallised from acetone and was thus separated into three fractions of very different appearance and solubility.

The three fractions were finally repeatedly crystallised until their behaviour and appearance remained unchanged after several crystallisations from different solvents. The least soluble fraction was *oo'*-dinitrobenzil, the fraction of intermediate solubility was *om'*-dinitrobenzil, whilst the most soluble constituent was *mm'*-dinitrobenzil.

*mm'*-Dinitrobenzil,  $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CO}\cdot\text{CO}\cdot\text{C}_6\text{H}_4\cdot\text{NO}_2$ , is moderately easily soluble in boiling alcohol and very easily soluble in boiling

acetic acid, benzene, chloroform, or acetone. It separates from each of these solvents in tufts of pale yellow, irregular, slender, prismatic crystals, m. p. 132°. These crystals in the mother-liquor have a moss-like appearance (Found: C, 56.2; H, 2.8; N, 9.5. Calc. for  $C_{14}H_8O_6N_2$ , C, 56.0; H, 2.7; N, 9.3%). When dissolved in boiling acetic acid and oxidised by adding chromic acid from time to time, it is converted into *m*-nitrobenzoic acid only (yield 52–55% of the theoretical).

*om'*-Dinitrobenzil is much less soluble in all solvents than the *mm'*-isomeride, but is somewhat more soluble than the *oo'*-isomeride. It is sparingly soluble in boiling acetic acid, chloroform, benzene, or acetone, and separates from the last in pale yellow, short, compact, six-sided prisms, m. p. 149°, showing a tendency to aggregate in warty-looking crusts. The crystals are phototropic and on exposure to light assume a green colour (Found: C, 56.0; H, 2.7; N, 9.4%). On oxidation by chromic acid, a mixture of *m*- and *o*-nitrobenzoic acids was obtained.

In the early stages of the fractional crystallisation of the crude product of intermediate solubility, clear, transparent crystals of a much deeper shade of yellow than the others make their appearance. These apparently are the crystals described as yellow octahedra by Zagumenny. In spite of their characteristic shape and colour, however, they prove to be, not a fourth isomeride, but mixed crystals containing the *oo'*- and the *mm'*-isomerides. On heating, they soften at about 129°, but do not melt completely till a temperature in the neighbourhood of 190° is reached, and if recrystallised from acetone can be separated into *mm'*-dinitrobenzil and *oo'*-dinitrobenzil.

*oo'*-Dinitrobenzil is very sparingly soluble in boiling alcohol and only sparingly soluble in boiling acetone, acetic acid, chloroform, or benzene. From solutions in these solvents, it separates in small, compact, pale yellow, six-sided prisms with basal ends, m. p. 208° (Found: C, 55.9; H, 2.8; N, 9.2%). It is phototropic and becomes green when exposed to light. It is scarcely attacked by chromic acid and can be recovered practically unchanged after prolonged boiling with chromic acid in acetic acid solution. Its constitution was established by comparing it with *oo'*-dinitrobenzil prepared by the oxidation of *oo'*-dinitrotolane (Kliegl and Haas, *loc. cit.*). The two specimens were identical in colour, appearance, and properties. They melted at the same temperature, 208°, alone and when mixed together, and were similarly phototropic and resistant to oxidation.

CXXXVIII.—*Synthesis of 7-Methoxy-3-(6'-bromohomopiperonyl)-2-methyl-1 : 4-benzopyrone.*

By WILSON BAKER.

BAKER and ROBINSON (J., 1925, 127, 1426) recently described the dibromide of 7-methoxy-3-homopiperonyl-2-methyl-1 : 4-benzopyrone (I), and showed that it was transformed by boiling with alcohol into a monobromo-substitution product of the original pyrone, which was formulated as the 6-bromohomopiperonyl derivative (II).

As some theoretical conclusions were drawn from this reaction, it has been considered advisable to establish definitely the constitution of the monobromo-derivative. The compound (II) has therefore been synthesised. It is identical in all respects with the product obtained from the dibromide, the original formula being thus confirmed.

The synthesis was first attempted from 6-bromopiperonal by a series of reactions analogous to those used for the preparation of 7-methoxy-3-homopiperonyl-2-methyl-1 : 4-benzopyrone (Baker and Robinson, *loc. cit.*), but this was found impracticable. 6-Bromopiperonal could not be induced to condense with an alkaline, aqueous solution of sodium cyanoacetate, but it condensed readily with ethyl cyanoacetate in presence of piperidine, and the resulting ester was hydrolysed to 6-bromopiperonylidencyanoacetic acid (III). This

acid on reduction with sodium amalgam in aqueous solution gave, however,  $\alpha$ -cyano- $\beta$ -piperonylpropionic acid, the bromine atom being eliminated.

The nitrile (IV) was therefore prepared by bromination of  $\beta$ -piperonylpropionitrile, the position of the bromine atom being established by the fact that on hydrolysis it gave the corresponding acid, m. p. 139—140°, described by Weinstein (*Annalen*, 1885, 227, 43). The position of the bromine atom in Weinstein's acid was not known at the time, but it was prepared by the oxidation of the

acid  $\text{CH}_2\text{O}_2\cdot\text{C}_6\text{H}_2\text{Br}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}\cdot\text{CH}\cdot\text{CO}_2\text{H}$ , and its formation was accompanied by the production of a bromopiperonal, m. p.  $129^\circ$ , and a bromopiperonylic acid, m. p.  $204^\circ$ , both of which have since been shown to be 6-bromo-derivatives. It follows that the bromopiperonylpropionic acid was also the 6-derivative. By condensation with resorcinol under the conditions of the Hoesch synthesis  $\beta$ -6-bromopiperonylpropionitrile gave 6'-bromohomopiperonylresacetophenone (V), which by acetylation with acetic anhydride in presence of sodium acetate, followed by hydrolysis and methylation, gave the chromone (II).

### EXPERIMENTAL.

**6-Bromopiperonylideneacyanoacetic Acid (III).**—6-Bromopiperonal (10 g.), ethyl cyanoacetate (10 c.c.), alcohol (50 c.c.), and piperidine (10 drops) were heated for 10 minutes. The yellow crystals, m. p.  $131^\circ$ , obtained were identical with the product prepared by Bechert (*J. pr. Chem.*, 1894, 50, 19) by brominating piperonylideneacyanoacetic ester, which has since been shown by Piccinini (*Atti R. Accad. Sci. Torino*, 1905, 40, 463) to be the 6-bromo-derivative. By hydrolysis with a slight excess of alcoholic sodium hydroxide for 5 minutes, dilution, extraction with ether, and acidification, the acid was precipitated. It crystallised from much alcohol in bright yellow, lustrous needles, which melted on rapid heating at about  $300^\circ$  (decomp.) (Found: C, 44.7; H, 2.3; N, 4.9; Br, 27.1.  $\text{C}_{11}\text{H}_6\text{O}_4\text{NBr}$  requires C, 44.6; H, 2.0; N, 4.7; Br, 27.0%). It gives a yellow solution in concentrated sulphuric acid.

**$\beta$ -6-Bromopiperonylpropionitrile (IV).**—A mixture of  $\beta$ -piperonylpropionitrile (25 g.), glacial acetic acid (500 c.c.), and bromine (25 g.) was kept for  $\frac{1}{2}$  hour, heated for 5 minutes, and poured into water. The product crystallised from alcohol in colourless needles, m. p.  $81^\circ$  (Found: C, 47.4; H, 3.4; N, 5.7; Br, 31.8.  $\text{C}_{10}\text{H}_8\text{O}_2\text{NBr}$  requires C, 47.3; H, 3.2; N, 5.5; Br, 31.5%). The reaction mixture must not stand for longer, as owing to the action of hydrogen bromide and acetic acid  $\beta$ -6-bromopiperonylpropionamide separates. This crystallises from alcohol in colourless, lustrous needles, m. p.  $151^\circ$  (Found: C, 44.3; H, 3.9; N, 5.4; Br, 29.6.  $\text{C}_{10}\text{H}_{10}\text{O}_3\text{NBr}$  requires C, 44.1; H, 3.7; N, 5.2; Br, 29.4%).  $\beta$ -6-Bromopiperonylpropionic acid crystallises from chloroform in colourless prisms, m. p.  $139$ – $140^\circ$  (Found: Br, 29.4. Calc., Br, 29.3%) (compare Weinstein, *loc. cit.*). In concentrated sulphuric acid, these substances, compound (V), and 6-bromopiperonal give cherry-red solutions, which

soon darken, turn brown, and finally brownish-green. In the last case, the final colour is more brown.

*6'-Bromohomopiperonylresacetophenone* (V).— $\beta$ -6-Bromopiperonyl-propionitrile (10 g.), resorcinol (20 g.), anhydrous ether (200 c.c.), and powdered zinc chloride (10 g.) were saturated with anhydrous hydrogen chloride, and again after 24 hours. After standing, the solid ketimine was washed with ether and hydrolysed by heating with water for 2 hours. The ketone was dissolved in aqueous sodium hydroxide, the solution extracted with ether, and the product precipitated by carbon dioxide (yield 4 g.). It crystallises from slightly diluted acetic acid in pale brown prisms, m. p.  $163^{\circ}$  (Found: C, 52.3; H, 3.5; Br, 21.6.  $C_{16}H_{13}O_5Br$  requires C, 52.6; H, 3.6; Br, 21.9%).

*7-Methoxy-3-(6'-bromohomopiperonyl)-2-methyl-1:4-benzopyrone* (II).—The above ketone (2 g.), anhydrous sodium acetate (2 g.), and acetic anhydride (20 c.c.) were heated at  $180^{\circ}$  for 36 hours. Treatment with water gave a dark, uncrystallisable oil, which was hydrolysed with dilute alcoholic sodium hydroxide. The phenolic compound was methylated at  $60^{\circ}$  with methyl sulphate and aqueous potassium hydroxide; a solid (1.4 g.) then separated which by crystallisation from alcohol (200 c.c.) (charcoal) formed bunches of pale brown prisms, m. p.  $206-207^{\circ}$ . The melting point was not depressed on admixture with a specimen of the bromo-derivative prepared from the dibromide (I). Further, its reaction with sulphuric acid was identical with that given by the compound prepared from (I). The cherry-red solution rapidly became somewhat purple and darker, then light grey, and finally bright olive-green, the changes occupying about 3 minutes at the ordinary temperature.

The author wishes to thank Professor R. Robinson for the interest he has taken in the research, and Mr. A. Pollard for assistance with a portion of the experimental work.

### CXXXIX.—*Preparation and Resolution of dl-cis-2:5-Dimethylpiperazine.*

By FREDERIC BARRY KIPPING and WILLIAM JACKSON POPE.

ON reducing 2:5-dimethylpyrazine,  $N \begin{smallmatrix} \text{CMe} \cdot \text{CH} \\ \text{CH} \cdot \text{CMe} \end{smallmatrix} N$ , with sodium and alcohol, Stoehr (*J. pr. Chem.*, 1893, 47, 494; 1897, 55, 49) obtained two products which he described as the  $\alpha$ - and  $\beta$ -2:5-

dimethylpyperazines; the  $\alpha$ -compound constituted the main product and only small quantities of the  $\beta$ -isomeride were formed. Pope and Read identified Stoehr's  $\alpha$ -2 : 5-dimethylpyperazine as the *trans*-isomeride (J., 1912, **101**, 2325), but did not separate the  $\beta$ -compound from the reduction product of the pyrazine; they secured, however, a quantity of residues left during the manufacture of lycetol, the tartrate of the  $\alpha$ -base, and separated therefrom a substance which corresponded closely in properties with Stoehr's  $\beta$ -base. The study of the latter product (J., 1914, **105**, 219) conclusively proved it to be the *cis*-2 : 6-dimethylpyperazine, which Pope and Read hence supposed to be Stoehr's  $\beta$ -2 : 5-dimethylpyperazine. This supposition is now shown to be erroneous.

The confusion arose from the close similarity in physical properties between the *dl-cis*-2 : 5-dimethylpyperazine, m. p. 114—115°, and the *cis*-2 : 6-dimethylpyperazine, m. p. 110—111°; the 1 : 4-dibenzoyl derivatives melt at 145—146° and 147—148°, respectively, but mixtures of the two melt at about 120—130°.

The present paper describes the repetition of Stoehr's preparation of his  $\beta$ -2 : 5-dimethylpyperazine and the resolution of this compound into its *d*- and *l*-components. The resolution was effected by Pope and Read's method of condensation with *d*-hydroxymethylenecampbor, and Stoehr's  $\beta$ -compound is thus proved to be the *dl-cis*-2 : 5-dimethylpyperazine.

#### EXPERIMENTAL.

*iso*Nitrosoacetone (270 g.) was prepared from ethyl acetoacetate (700 g.) by the method of Ceresole (*Ber.*, 1882, **15**, 1326) and then reduced by the method of Gabriel and Pinkus (*Ber.*, 1893, **26**, 2206) to 2 : 5-dimethylpyrazine, each 50 g. yielding about 12 g. of the base. The 2 : 5-dimethylpyrazine (10 g.) was then reduced as described by Stoehr and the mixture of  $\alpha$ - and  $\beta$ -dimethylpyperazine hydrochlorides (about 8 g.) isolated; the operation was repeated until about 160 g. of the salt had been obtained. The dried and powdered hydrochloride was repeatedly extracted with boiling absolute alcohol, in which the  $\alpha$ - or *trans*-compound is very sparingly soluble; the alcoholic extract on evaporation yielded about 8 g. of crude *dl-cis*-dimethylpyperazine. The reduction product of the pyrazine thus contains about 95% of the *trans*-compound and only about 5% of the *cis*-isomeride.

*dl*-1 : 4-Dibenzoyl-*cis*-2 : 5-dimethylpyperazine.—This compound, prepared by the Schotten-Baumann reaction from the hydrochloride, crystallises from alcohol in colourless prisms, m. p. 145—146°; Stoehr gives 147—148° for his  $\beta$ -compound. Analysis failed to reveal the presence of a molecule of water of crystallis-

ation indicated by Stoehr (Found: C, 74.4; H, 6.8; N, 8.7. Calc. for  $C_{20}H_{22}O_2N_2$ , C, 74.5; H, 6.8; N, 8.7%); the identity in composition between the  $\alpha$ - and  $\beta$ -compounds may be associated with the close similarity in crystalline form previously noted (J., 1914, 105, 223). As remarked above, the compound depresses the melting point, namely, 145–146°, of Pope and Read's 1:4-dibenzoyl-*cis*-2:6-dimethylpiperazine.

*The p-Toluenesulphonyl Derivatives.*—In view of the similarity in melting point between the *cis*-2:5- and *cis*-2:6-isomerides just noted, it was thought desirable to prepare other acidic derivatives. The 1:4-di-*p*-toluenesulphonyldimethylpiperazines were made by warming the hydrochlorides of the base with *p*-toluenesulphonyl chloride and caustic soda solution.

1:4-Di-*p*-toluenesulphonyl-*cis*-2:5-dimethylpiperazine crystallises from alcohol in minute, colourless prisms, m. p. 146–147°, the melting point being the same as that of the corresponding benzoyl derivative (Found: C, 56.9; H, 6.15.  $C_{20}H_{16}O_4N_2S_2$  requires C, 56.8; H, 6.2%).

1:4-Di-*p*-toluenesulphonyl-*trans*-2:5-dimethylpiperazine is almost insoluble in the usual solvents and after washing with alcohol melted at 225°; it is remarkable that this melting point is also identical with that of the benzoyl derivative (Found: C, 56.9; H, 6.2%).

1:4-Di-*p*-toluenesulphonyl-*cis*-2:6-dimethylpiperazine is very soluble in alcohol and acetone, but less soluble in light petroleum; it crystallises from the latter, to which a little alcohol has been added, in needles, m. p. 89–90° (Found: C, 56.8; H, 6.2%). The marked difference in physical properties between these three isomerides is further confirmation of the separate identity of the three parent bases.

*Resolution of cis-2:5-Dimethylpiperazine.*—The hydrochloride of the racemic base was boiled in alcoholic solution with caustic potash (2 mols.) and *d*-hydroxymethylenecamphor (2 mols.) for  $\frac{1}{2}$  hour; the gummy deposit obtained on pouring into water crystallised on treatment with light petroleum and then melted at 167–170°. On fractional crystallisation from light petroleum containing a little alcohol *d*-*cis*-2:5-dimethylpiperazine-*d*-bismethylenecamphor,  $C_8H_{14} \begin{array}{c} \diagup C:CH \cdot N-CH_2-CHMe \diagdown \\ CO \quad CHMe-CH_2-N-CH=C \end{array} OC \begin{array}{c} \diagup \\ \diagdown \end{array} C_8H_{14}$ , was obtained in colourless needles, m. p. 210°. 0.1016 G. made up to 20 c.c. with alcohol gave  $\alpha_{5461} + 7.6^\circ$  in a 2-dcm. tube; whence  $[\alpha]_{5461}^{20} = +747^\circ$ . The more soluble fraction after several crystallisations melted at 176–177°; this product represents 1-*cis*-2:5-dimethylpiperazine-*d*-bismethylenecamphor which still contained some stereo-

isomeride and gave  $[\alpha]_{5461}^{20} + 635^{\circ}$  in alcoholic solution (Found: C, 76.8; H, 9.6.  $C_{28}H_{42}O_2N_2$  requires C, 76.7; H, 9.6%).

The *d*- and *l*-dimethylpiperazines were separated from the above derivatives by treatment with bromine by the method of Read and Pope and isolated as the hydrobromides; neither salt showed measurable rotatory power in alcoholic solution. In many analogous cases, however, the specific rotation of a base is a small fraction of that of the benzoyl derivative; the *d*- and *l*-hydrobromides were therefore benzoylated in the hope that optical activity might be detected.

*d*- and *l*-1:4-Dibenzoyl-*cis-2:5-dimethylpiperazine*.—The *d*-isomeride was obtained pure by crystallisation from acetone and forms colourless prisms, m. p. 164–165° (Found: C, 75.1; H, 6.7.  $C_{20}H_{22}O_2N_2$  requires C, 74.5; H, 6.8%). 0.0985 G. made up to 20 c.c. with alcohol gave  $\alpha_{5461} + 2.44^{\circ}$  in a 2-dcm. tube; whence  $[\alpha]_{5461} = + 247^{\circ}$ .

The *l*-isomeride was not separable in a pure state from the material available, and the best specimen obtained melted at 140–142° and gave  $[\alpha]_{5461} - 146^{\circ}$  in alcoholic solution.

In order to make sure that these compounds had not been confused with the benzoyl ester of hydroxymethylenecamphor, which has nearly the same carbon and hydrogen content, the latter substance was prepared; it melts at 119–120° (Bishop, Claisen, and Sinclair, *Annalen*, 1894, 281, 374). 0.0820 G. made up to 20 c.c. with alcohol gave  $\alpha_{5461} + 1.44^{\circ}$  in a 2-dcm. tube, whence  $[\alpha]_{5461}^{20} = + 175^{\circ}$ . Further to ensure that no confusion has occurred, the *trans-2:5-dimethylpiperazine-d*-methylenecamphor of Pope and Read (J., 1912, 101, 2334) was again recovered from the various fractions and converted into its benzoyl derivative. In no case was an optically active benzoyl derivative obtained.

### Summary.

Stoehr's  $\beta$ -2:5-dimethylpiperazine has been identified as the *cis*-isomeride by resolving it into optically active components. It is not identical with the *cis-2:6-dimethylpiperazine* of Pope and Read, although the similarity in physical properties between the two bases and their corresponding derivatives is such as to suggest identity.

CAMBRIDGE.

[Received, February 22nd, 1926.]

CXL.—*Interactions of Tellurium Tetrachloride and Aryl Alkyl Ethers. Part II.*

By GILBERT T. MORGAN and RICHARD EATOUGH KELLETT.

THE interaction of tellurium tetrachloride and anisole is first mentioned in a communication by Michaelis (*Ber.*, 1897, 30, 2821) on organic compounds containing inorganic radicals, where he refers to the ready introduction of the bivalent radicals  $\text{SeCl}_2$  and  $\text{TeCl}_2$  into various classes of organic substances. Aromatic derivatives of the former radical had been previously described by one of his pupils, Kunckell (*Ber.*, 1895, 28, 609), and Michaelis was then announcing the discovery of an analogous series of tellurium derivatives, the work of Rust, another collaborator in the Rostock laboratories (*Ber.*, 1897, 30, 2828).

By warming together tellurium tetrachloride (1 mol.) and anisole (2 mols.), Rust obtained a yellow compound to which, from his analyses given in duplicate, he gave the name "dichlorotelluro-anisol" with formula  $\text{TeCl}_2(\text{C}_6\text{H}_4\cdot\text{O}\cdot\text{CH}_3)_2$ . This substance was purified from crude material by transforming the latter into dihydroxide,  $(\text{CH}_3\cdot\text{O}\cdot\text{C}_6\text{H}_4)_2\text{Te}(\text{OH})_2$ , and regenerating the dichloride with hydrogen chloride.

From this dihydroxide Rust also prepared the dibromide,  $\text{TeBr}_2(\text{C}_6\text{H}_4\cdot\text{O}\cdot\text{CH}_3)_2$ , di-iodide,  $\text{TeI}_2(\text{C}_6\text{H}_4\cdot\text{O}\cdot\text{CH}_3)_2$ , dinitrate,  $(\text{CH}_3\cdot\text{O}\cdot\text{C}_6\text{H}_4)_2\text{Te}(\text{NO}_3)_2$ , and chloroplatinate,  $(\text{CH}_3\cdot\text{O}\cdot\text{C}_6\text{H}_4)_2\text{TeCl}_2\cdot\text{PtCl}_4$ .

The subject was next taken up by Rohrbach (*Annalen*, 1901, 315, 9), who referred to the dissimilarities observable in the behaviour of selenium tetrachloride and tellurium tetrachloride as regards their condensations with aryl alkyl ethers. In the former case two substances were obtained, bisanisyl selenide and bisanisyl selenidichloride, whereas in Rust's experiments bisanisyl telluridichloride was the sole product.

In order, therefore, to obtain bisanisyl telluride, Rohrbach removed chlorine from Rust's alleged dichloride with zinc dust in benzene and obtained a highly coloured compound which he stated was "*p*-telluroanisole,"  $\text{Te}(\text{C}_6\text{H}_4\cdot\text{O}\cdot\text{CH}_3)_2$ . He also converted this alleged monotelluride, by suitable treatment with chlorine, bromine, and dilute nitric acid, respectively, into Rust's dichloride, dibromide and dinitrate.

Fourteen years later, Rohrbach's supposed bis-*p*-anisyl telluride,  $\text{Te}(\text{C}_6\text{H}_4\cdot\text{O}\cdot\text{CH}_3)_2$ , was examined by Lederer (*Ber.*, 1915, 48, 1424), who prepared its mercurichloride, mercuribromide, and mercuriodide,  $\text{C}_{14}\text{H}_{14}\text{O}_2\text{TeHgX}_2$  ( $\text{X} = \text{Cl}, \text{Br}, \text{or I}$ ). Lederer also obtained

(*loc cit.*, p. 2053) by the action of methyl iodide on Rohrbach's telluride a product yielding anisoledimethyltelluronium picrate. But the conclusions which he drew from this methylation have, however, been already shown to be groundless and a complete explanation of the reaction has been given in the previous paper on this subject (Morgan and Drew, J., 1925, 127, 2310).

In a subsequent paper, Lederer (*Ber.*, 1916; 49, 1076) obtained the true bis-*p*-anisyl telluride by the interaction of tellurium dibromide and magnesium *p*-anisyl bromide and converted this telluride into dichloride, dibromide, di-iodide, and oxide. The whole para-series differed essentially from the corresponding derivatives of Rohrbach's telluride made either by that investigator, or by Rust or by Lederer himself. Later, Lederer prepared the corresponding members of the meta- and ortho-series, again using the Grignard reaction but with the appropriate magnesium *m*- or *o*-anisyl iodide (*Ber.*, 1919, 52, 1989; 1920, 53, 712), and since these two series also differed from Rohrbach's presumably isomeric series it followed by exclusion that, in the Rust-Rohrbach preparations, tellurium had been introduced into the side chain, thus giving the formula  $\text{Br}_2\text{Te}(\text{CH}_2\cdot\text{O}\cdot\text{C}_6\text{H}_5)_2$ . But this conclusion is fallacious, because the original assumption of isomeric relationship between the Rust-Rohrbach and Lederer series of compounds is incorrect.

The researches described in the present communication furnish a correct explanation of the foregoing differences.

The compound first handled by Rust was not dichlorotelluro-bisanirole,  $\text{Cl}_2\text{Te}(\text{C}_6\text{H}_4\cdot\text{O}\cdot\text{CH}_3)_2$ , but *p*-anisyltelluritrichloride (I), and accordingly its highly coloured reduction product obtained by Rohrbach with complete elimination of chlorine was not a bisanisyl telluride  $(\text{CH}_3\cdot\text{O}\cdot\text{C}_6\text{H}_5-\text{H})_2\text{Te}$ , but bis-*p*-anisyl ditelluride (II).

Hence Lederer's discussion of the constitution of Rohrbach's assumed bisanisyl telluride is irrelevant, inasmuch as he was not even dealing with an isomeride of his three *o*-, *m*-, and *p*-bisanisyl tellurides.

Our experiments show conclusively that *p*-anisyltelluritrichloride (I) is the sole product of the interaction of tellurium tetrachloride (1 mol.) and anisole (3 mols.) in warm chloroform, the yield being quantitative. In the preparations made by Rust and by Lederer the reagents were heated together without solvent on the water-bath, but on repeating their experimental conditions we again

obtained *p*-anisyltelluritrichloride as the sole product. The yellow colour of the substance and its mode of hydrolysis together with complete analytical data confirm our conclusions as to its constitution (I).

On reduction with potassium metabisulphite, the trichloride gave a quantitative yield of bis-*p*-anisyl ditelluride (II), obtained in dark brownish-red crystals with green, metallic lustre. In its intense colour this ditelluride resembles Lederer's bisphenyl ditelluride (*Ber.*, 1915, 48, 1345), which is described as separating in blood-red crystals. Further evidence for the composition of bis-*p*-anisyl ditelluride (II) is afforded by molecular-weight determination and by the large tellurium content of the compound.

It now remained to prepare the true *bis-p-anisyltelluridichloride* (III) and this was accomplished by heating tellurium tetrachloride with excess of anisole at 150–180°; this dichloride was then obtained in practically quantitative yield.

This dichloride (III), unlike the trichloride (I), is colourless and reducible only with difficulty, but when the chlorine is removed entirely with zinc dust, the product, *bis-p-anisyl telluride* (IV), is also colourless. As already pointed out in earlier papers on organic tellurium compounds, these colour differences are themselves a useful guide to the constitution of tellurium derivatives (Morgan and Drew, J., 1925, 127, 531, 2307).

Having thus established the nature of the tellurium anisyl derivatives, we made comparative experiments on the next homologues of anisole and found that the formation of telluritrichlorides took place most readily with *o*-tolyl methyl ether, and the resulting yellow 2-methoxytolyl-5-telluritrichloride was reducible to the intensely coloured bis-2-methoxy-5-tolyl ditelluride. Telluritrichlorides were obtained, but with greater difficulty, from *m*- and *p*-tolyl methyl ethers.

*Addendum. Interaction of Tellurium Tetrachloride and the Homologues of Acetic Anhydride.*

During this collaboration, experiments were also made to ascertain whether the condensation found to take place between tellurium tetrachloride and acetic anhydride (Morgan and Drew, J., 1925, 127, 531) could be effected with anhydrides of the homologues of acetic acid.

The results showed that the tendency to undergo this condensation with tellurium tetrachloride fades away rapidly as the homologous series is ascended.

*Trichlorotelluripropionic acid* obtained from propionic anhydride was reducible to *ditellurodipropionic acid*. With *n*-butyric anhydride, tarry products predominated and only a very little of the telluriferous butyric acid was observed. With *isovaleric* anhydride, a considerable proportion of the tetrachloride was reduced with elimination of tellurium.

## EXPERIMENTAL.

### *Condensation of Tellurium Tetrachloride and Anisole.*

1. *Interaction in Chloroform*.—Tellurium tetrachloride (2 g.), 2.4 g. of anisole, and 30 c.c. of dry chloroform were heated on the water-bath for 2 hours. The mixture became yellowish-red even in the cold, but on warming hydrogen chloride was evolved copiously and the condensation product crystallised to a mass of yellow needles. No tellurium was evolved and the condensation proceeded quantitatively. The crude product melted at 190° and gave Cl, 30.7% (Calc. for di- and tri- chlorides, Cl, 17.2 and 31.2, respectively).

In contact with water, this crude yellow trichloride was hydrolysed to a white hydroxide. When treated with cold aqueous potassium metabisulphite ( $2\frac{1}{2}$  mols.), the hydroxide was reduced to an insoluble dark red product which on crystallisation from dilute alcohol melted at 57° and gave Te, 56.8% (Calc. for dianisyl monotelluride and ditelluride, Te, 37.3 and 54.8 respectively).

The foregoing analyses, even when effected on the crude products of reaction, show that in chloroform, tellurium tetrachloride and anisole (3 mols.) yield an anisyltelluritrichloride which on reduction furnishes dianisyl ditelluride.

2. *Condensation without Solvent* (Method of Rust and Lederer).—The trichloride obtained by the foregoing procedure was apparently identical with Rust's "dichlorotelluroanisole," although our analysis indicated a trichloride. As the solvent used in our experiments may have modified the reaction, we repeated the condensation according to Rust's recipe, which is practically identical with the method adopted by Lederer (*loc. cit.*). The crude products in two preparations melted at 195° and 190° and after one crystallisation from dry chloroform gave Cl, 29.8 and 30.9%, whereas the di- and tri-chlorides require, respectively, Cl, 17.2 and 31.2%.

Reduction of the foregoing products of the dry process with ice-cold aqueous potassium metabisulphite furnished a substance which crystallised from warm alcohol, on addition of water, in dark red,

glistening crystals, m. p. 57°. Reduction with zinc dust in benzene led to a dark red oil, the alcoholic solution of which yielded a dark red substance melting at 49–51°, a melting point corresponding with Rohrbach's 50° and Lederer's "50° not easily observed because of the dark colour."

*p*-Anisyltelluritrichloride,  $\text{CH}_3\cdot\text{O}\cdot\text{C}_6\text{H}_4\cdot\text{TeCl}_3$ .—On warming together tellurium tetrachloride (1 mol.) and anisole ( $1\frac{1}{2}$ –2 mols.) in dry chloroform solution a practically quantitative yield of the trichloride was obtained, calculated on the tetrachloride; the product separated directly in a nearly pure condition. Dry chloroform or ether was used for recrystallisation, the substance separating in yellow needles, m. p. 190° (Found: C, 24.3, 24.7; H, 2.3, 2.1; Cl, 31.1; Te, 37.7.  $\text{C}_7\text{H}_7\text{OCl}_3\text{Te}$  requires C, 24.6; H, 2.05; Cl, 31.2; Te, 37.4%).\*

*p*-Anisyltelluritrichloride was almost insoluble in cold chloroform, benzene, or light petroleum and dissolved only moderately in the warm solvents. With water and moist solvents, it decomposed to a white hydroxide; it dissolved completely in hydrochloric acid or aqueous caustic soda.

Acetic acid added to a solution of 2 g. of *p*-anisyltelluritrichloride in 2*N*-sodium hydroxide precipitated a white amorphous powder having no definite melting point. Dissolution in alkali and precipitation with acetic acid were repeated; the amorphous product, after drying, gave C, 28.4; H, 2.6; whereas a trihydroxide,  $\text{CH}_3\cdot\text{O}\cdot\text{C}_6\text{H}_4\cdot\text{Te}(\text{OH})_3$ , would require C, 29.4; H, 3.5%. As the substance was insoluble in ordinary solvents and uncrystallisable, it was not investigated further. For a product obtained under essentially the same conditions Rust obtained Te, 33.55, 33.60; C, 44.37, 44.46; H, 4.34, 4.33%, corresponding with a di-*p*-anisyltelluridihydroxide,  $(\text{CH}_3\cdot\text{O}\cdot\text{C}_6\text{H}_4)_2\text{Te}(\text{OH})_2$ . Two other carbon and hydrogen determinations confirmed the lower values for these elements, and a portion of the hydroxide when evaporated with concentrated hydrochloric acid regenerated yellow needles of *p*-anisyltelluritrichloride (m. p. 191°. Found: Cl, 30.3; calc., Cl, 31.2%).

This hydrated oxide dissolved in warm dilute nitric acid and, on cooling, a yellowish-pink, amorphous precipitate separated (m. p. 190–210°); the filtrate yielded yellowish-white plates, identified by melting point and analysis as 2:4-dinitrophenol.

*Bis-p-anisyltelluride* (II), obtained in almost quantitative yield

\* Tellurium is most satisfactorily determined in these compounds by the Carius method (9–10 hours at 260°); the solution is evaporated to dryness with hydrochloric acid, the residue dissolved in water, and the tellurium precipitated with hydrazine hydrochloride and sulphurous acid.

on adding gradually potassium metabisulphite to *p*-anisyltelluritrichloride suspended in ice-water, crystallised from dilute alcohol or petroleum (b. p. 40–60°) in reddish-brown crystals. From its more concentrated solution in benzene the ditelluride separated in highly lustrous, green crystals (Found: C, 35.6; H, 3.0; Te, 54.2; *M*, cryoscopic in benzene, 472.5.  $C_7H_7OTe$  requires C, 35.8; H, 3.0; Te, 54.4%.  $C_{14}H_{14}O_2Te_2$  requires *M*, 469).

The ditelluride oxidised slowly in air to a yellowish-grey substance, and its alcoholic solution was at once decolorised by hydrogen peroxide; a white, amorphous product was obtained on concentrating the liquid. On passing chlorine through its chloroform solution, the colour changed and *p*-anisyltelluritrichloride crystallised out (m. p. 192°). Bromine in similar circumstances yielded *p*-anisyltelluritribromide, separating in orange-yellow crystals, m. p. 187.5° (Rust's dibromotelluroanisole melted at 183–185°). This tribromide was hydrolysed by water to the white hydroxide and with metabisulphite it regenerated the di-*p*-anisyl ditelluride. On adding aqueous mercuric chloride to the ditelluride in ethereal solution, a light brown mercurichloride was precipitated.

*Di-p-anisyltelluridichloride* (III).—Tellurium tetrachloride (15 g.) and 30 g. of anisole (5 mols.) were heated for 24 hours at 150–180°, the solution being afterwards allowed to solidify in a vacuum. The yield of crystalline product was 95% of the theoretical. The dichloride crystallised from benzene-petroleum (b. p. 40–60°) in colourless prisms, often retaining a slightly pink tinge; it melts at 181–182° (Found: C, 40.5; H, 3.6; Cl, 17.25; Te, 30.9.  $C_{14}H_{14}O_2Cl_2Te$  requires C, 40.7; H, 3.4; Cl, 17.2; Te, 30.9%). The dichloride was insoluble in water, although slightly hydrolysed by this solvent; it was completely hydrolysed by aqueous sodium hydroxide, but dissolved only sparingly in excess of this alkali. It was not readily reduced, being resistant to the action of metabisulphite and only attacked with difficulty by zinc dust.

*Bis-p-anisyl Telluride* (IV).—Di-*p*-anisyltelluridichloride (10 g.) and 5 g. of zinc dust in 150 c.c. of benzene were heated for 24 hours under reflux. Some tar separated and the filtered solution was concentrated. The white crystals which separated still contained chlorine and were subjected to the action of more zinc dust until all the halogen was eliminated. The halogen-free compound (yield 37%) crystallised from dilute alcohol in colourless, nacreous plates, m. p. 53–54° (Found: C, 49.0; H, 4.2; Te, 37.6.  $C_{14}H_{14}O_2Te$  requires C, 49.2; H, 4.1; Te, 37.3%).

On mixing chloroform solutions of the telluride and bromine, di-*p*-anisyltelluridibromide separated in sulphur-yellow crystals,

m. p. 190°; the bromo-derivative of Rohrbach's ditelluride was described as orange-yellow.

*2-Methoxytolyl-5-telluritrichloride*,  $\text{CH}_3\cdot\text{O}\cdot\text{C}_6\text{H}_3(\text{CH}_3)\cdot\text{TeCl}_3$ .—Four g. of tellurium tetrachloride (1 mol.) and 3.7 g. of *o*-tolyl methyl ether (2 mols.) in 30 c.c. of dry chloroform were heated together on the water-bath; hydrogen chloride was evolved and, after one hour, yellow needles separated (Found: Cl, 29.6.  $\text{C}_8\text{H}_5\text{OCl}_3\text{Te}$  requires Cl, 30.0%). The product was only very sparingly soluble in ordinary organic media with the exception of acetone, but when separating from this solvent after the addition of light petroleum, the crystals obtained were progressively whiter and showed a diminution in the percentage of chlorine.

These decomposition products were extracted with chloroform and the filtered solution was saturated with hydrogen chloride. A deposit of pale yellow needles was formed melting to a red liquid at 232–233° (Found: Cl, 30.0%).

The trichloride was insoluble in cold water, but hydrolysed, on warming, to a white hydroxide which dissolved readily in benzene or chloroform. With potassium metabisulphite, the trichloride was reduced to a highly coloured ditelluride.

A large excess of *o*-tolyl methyl ether and tellurium tetrachloride with a little dry chloroform were gradually heated to 170°; the solid product was filtered from unchanged ether and extracted under reflux with chloroform, but no soluble dichloride was obtained.

*Bis-2-methoxy-m-tolyl Ditelluride*,  $\{\text{CH}_3\cdot\text{O}\cdot\text{C}_6\text{H}_3(\text{CH}_3)\cdot\text{Te}\}_2$ .—To 5 g. of the preceding trichloride in 50 c.c. of ice-cold water were added slowly 9.5 g. of potassium metabisulphite (3 mols.); the reduction proceeded rather more slowly than in the case of the anisyl derivative, the colour changing from yellow to black. After stirring occasionally for an hour, the black residue was extracted with ether. The dark red solution deposited dark needles, which recrystallised from petroleum (b. p. 40–60°) in similar forms with a brownish-green bronzy lustre; m. p. 77–78° (Found: C, 38.6; H, 3.6; Te, 51.5; *M*, cryoscopic in benzene, 493.  $\text{C}_8\text{H}_5\text{OTe}$  requires C, 38.6; H, 3.6; Te, 51.3%.  $\text{C}_{16}\text{H}_{18}\text{O}_2\text{Te}_2$  requires *M*, 497).

This ditelluride was very soluble in benzene, chloroform, acetone or ether, but only sparingly soluble in cold alcohol or petroleum (b. p. 40–60°), dissolving more readily on warming. From its alcoholic solution, water precipitated a bright red emulsion which solidified to a dark green, crystalline mass. Hydrogen peroxide instantly decolorised the alcoholic solution. Chlorine passed into the chloroform solution regenerated 2-methoxytolyl-5-telluritrichloride; bromine under similar conditions combined additively to form the corresponding orange-yellow tribromide.

*4-Methoxytolyl-3-telluritrichloride.*—*p*-Tolyl methyl ether and tellurium tetrachloride did not interact appreciably in chloroform solution, but at higher temperatures condensation took place. Equal parts of the tetrachloride and *p*-tolyl ether with a trace of chloroform were heated on the water-bath until hydrogen chloride was no longer evolved. The resulting yellow liquid slowly yielded greenish-yellow crystals, which underwent partial hydrolysis in such solvents as moist benzene, chloroform and acetone. Accordingly these products were redissolved in dry chloroform and the pale yellow solution was saturated with hydrogen chloride. On concentrating the liquid in a vacuum desiccator, well-defined, yellow, rectangular plates separated, m. p. 135° (Found: Cl, 29.6.  $C_8H_9OCl_3Te$  requires Cl, 30.0%). The reduction of this and the following trichloride proceeded less readily than that of their foregoing isomeride.

*3-Methoxytolyl-(4 or 6)-telluritrichloride.*—Equal parts of tellurium tetrachloride and *m*-tolyl methyl ether with a little chloroform were heated on the water-bath until evolution of hydrogen chloride had ceased; the oily residue was then cooled until dark green crystals separated. When the crude material was dissolved in dry chloroform and the solution saturated with hydrogen chloride, no precipitation occurred, but slow evaporation in a vacuum desiccator furnished a yellowish-brown crystalline mass, m. p. 154° (Found: Cl, 28.2. Calc., Cl, 30.0%). This trichloride is much more soluble than its isomeride in organic media, but exposure to moisture leads to considerable hydrolysis.

Condensation between tellurium tetrachloride and each of the following:  $\beta$ -naphthyl methyl ether, monoethyl ethers of resorcinol and quinol, monomethyl ether of quinol, led to viscid, uncrystallisable products. No appreciable interaction was observed with *p*-nitroanisole, but a preliminary experiment with *p*-bromoanisole indicated a normal condensation to a *trichloride*, m. p. 184°; this was reducible by aqueous metabisulphite to a dark red oily ditelluride, which was brominated in chloroform solution to an orange-yellow *tribromide*, m. p. 153°.

*Interaction of Tellurium Tetrachloride and the Homologues of Acetic Anhydride.*

*Trichlorotelluripropionic Acid*,  $Cl_3Te \cdot CH(CH_3) \cdot CO_2H$ . Five g. of tellurium tetrachloride and 7 g. of propionic anhydride (3 mols.) in 38 c.c. of chloroform were heated under reflux for 4 hours. Hydrogen chloride was evolved slowly, and 0.3 g. of tellurium eliminated. The filtered liquid was concentrated in a vacuum desiccator, and chloroform added; a brown solid then separated (yield 4 g.). The product was extremely soluble in all organic

media and could not be freed by recrystallisation from tarry impurities. A halogen estimation on the crude material, obtained in white plates by allowing the viscous liquid from the foregoing condensation to remain in a vacuum desiccator for 4 weeks, gave Cl, 34.7 ( $\text{C}_3\text{H}_5\text{O}_2\text{Cl}_3\text{Te}$  requires Cl, 34.6%). This substance melted at 145–150° and on exposure to the atmosphere the crystals became liquid. A condensation with a large excess (6 mols.) of propionic anhydride gave a smaller yield of the trichloro-compound.

*Ditellurodipropionic Acid*,  $\{\text{Te}\cdot\text{CH}(\text{CH}_3)\cdot\text{CO}_2\text{H}\}_2$ .—Crude trichlorotelluripropionic acid was reduced with aqueous metabisulphite (2.5 mols.), and the yellow solution extracted with ether. The oily residue from the ethereal extract redissolved in chloroform to a solution which yielded a brick-red solid, m. p. 75°. The pale yellow *silver* salt was photosensitive and became brownish-black on exposure, the *copper* salt was a pale green precipitate decomposing at 175°, the soluble *potassium* salt separated from concentrated aqueous solution in brick-red plates blackening at 175°.

*Tribromotelluripropionic Acid*,  $\text{Br}_3\text{Te}\cdot\text{CH}(\text{CH}_3)\cdot\text{CO}_2\text{H}$ , resulted from the interaction of ditellurodipropionic acid and bromine in chloroform; it separated as a yellow oil which solidified to a bright yellow solid, m. p. 139–141° (Found: Br, 53.8.  $\text{C}_3\text{H}_5\text{O}_2\text{Br}_3\text{Te}$  requires Br, 54.4%). This tribromo-derivative dissolved readily in ether or acetone or in warm benzene, chloroform or ethyl acetate, separating from these solutions, on addition of light petroleum, as an oil which slowly solidified. When kept in a sealed tube, the yellow tribromo-compound changed into a greenish-black decomposition product.

Tellurium tetrachloride and *n*-butyric anhydride when boiled in chloroform solution slowly evolved hydrogen chloride, but the tarry product as extracted with acetone and other organic solvents remained oily. The acidic nature of this product was demonstrated by the formation of a yellow *silver* and green *copper* salt. Bromine in chloroform gave an oily additive product. Interaction between tellurium tetrachloride and isovaleric anhydride was attended by elimination of a considerable proportion of tellurium. From an experiment with monochloroacetic anhydride, the greater part of the tellurium tetrachloride was recovered.

The authors desire to express their thanks to the Government Grant Committee of the Royal Society and to the Research Committee of the University of Birmingham for grants which have helped to defray the expense of this investigation.

CXLI.—*The Behaviour of Mannose Diacetone on Methylation.*

By JAMES COLQUHOUN IRVINE and ANDREW FORRESTER SKINNER.

IN the course of a discussion on the application of the methylation process to the structural problems of carbohydrates, it was stated (Irvine and Oldham, J., 1925, 127, 2910) that the method is valid only if certain conditions are fulfilled. These need not be enumerated again, but obviously the fundamental requirement is that during alkylation methyl groups are introduced into the vacant hydroxyl positions without disturbing any substituting groups already present. Equally important is the condition that, once methyl groups have entered the non-glucosidic positions of a sugar chain, they should remain unaffected during the standard processes employed to hydrolyse glucosides, disaccharides or polysaccharides. So far, no authentic case has been encountered which indicates that the above primary conditions are not fulfilled. One apparent exception was, however, recorded by Freudenberg and Hixon (*Ber.*, 1923, 56, 2119), who converted mannose diacetone into a monomethyl derivative and subjected the product to mild hydrolysis in the hope that monomethyl mannose would be formed. Contrary to expectation, not only the unstable isopropylidene residues were removed, but the methyl group also was eliminated so that the final product consisted of mannose. The subject was reinvestigated by Levene and Meyer (*J. Biol. Chem.*, 1924, 59, 145), who varied the procedure by applying the silver oxide method of alkylation to mannose diacetone, but the monomethyl derivative obtained, whilst differing in optical activity from Freudenberg's product, displayed precisely the same instability towards acid hydrolysts.

These observations, although capable of simple explanation, have elicited some criticism of the principles underlying the researches associated with this laboratory, and it is advisable to clear up the situation. It was assumed, prematurely, that, as mannose diacetone has no effect on Fehling's solution, the reducing position of the parent sugar had been substituted by a ketonic residue. In such an event, one hydroxyl group should persist in the sugar chain and undergo methylation, giving, irrespective of the method employed, the same monomethyl derivative. This product, in turn, when treated with aqueous acid should give a reducing sugar, *viz.*, monomethyl mannose. Two views have been put forward to account for the fact that the methyl group is removed on hydrolysis, the first being that the stability of methylated sugars is not a general feature of these compound and is considerably less than our published papers

indicate. Alternatively, it has been suggested that, in the particular case under consideration, the entry of a methyl group had dislodged a ketonic residue from its initial attachment to the reducing position and, through subsequent rearrangement, had formed a derivative differing in type from the parent compound.

Either of the above explanations, if supported by convincing experimental evidence, would be damaging to the fundamental ideas underlying much of our work, but the suggestions are both highly improbable and opposed to experience. To the worker familiar with the properties of methylated sugars and glucosides, the apparently irregular behaviour of monomethyl mannose diacetone presents no difficulties whatsoever. The properties of the compound clearly show that it is *γ-methylmannoside diacetone*, and this could be formed only if mannose diacetone contained a labile hydrogen atom in the 1-position. That such is the case is shown by the fact that the compound forms a sodium derivative convertible into a monomethyl ether showing  $[\alpha]_D - 41^\circ$  in acetylene tetrachloride, whereas when methylation is effected directly by the silver oxide reaction the specific rotation of the product is widely different ( $[\alpha]_D + 23^\circ$ ). This is but an example of the general rule that when a reducing sugar is acted on by silver oxide and methyl iodide two stereoisomeric glucosides are produced, the  $\beta$ -variety being formed in excess. It follows that the monomethyl mannose diacetone obtained respectively by Freudenberg and by Levene differed merely in the relative proportions of two stereoisomeric substituted methylmannosides. From such compounds, again following a general rule, the alkyl group should be removed, as was the case, by hydrolysis. The only apparent irregularity is the extreme ease with which this group is lost, but even this feature is diagnostic and the explanation was already available. It has been known for a considerable time that  $\gamma$ -glucosides undergo hydrolysis with a facility comparable with that displayed by sucrose, and more recently (Irvine and Burt, J., 1924, 125, 1343)  $\gamma$ -methylmannoside has been shown to possess the same instability. Any confusion which may have arisen through the behaviour of mannose diacetone on methylation is due to attaching more importance to a single test, viz., the action of Fehling's solution, than to the numerous and more regular reactions of methylated sugars generally. Without additional experimental work it was possible to predict that mannose diacetone would (1) display mutarotation, (2) form the corresponding methylmannoside by the action of acid methyl alcohol, (3) undergo oxidation and reduction without removal of the acetone residues, and (4) condense with amino-bases.

In the interests of our general research programme we decided to

explore the case, but meanwhile Freudenberg has extended his work and has shown that mannose diacetone exhibits mutarotation and enters into condensation with ammonia (Freudenberg and Wolf, *Ber.*, 1925, 58, 300). More recently, Ohle and Berend (*ibid.*, p. 2950) have succeeded in oxidising mannose diacetone to a substituted mannonic acid, in which the ketonic residues persist, thus adding to the evidence that in the parent compound the reducing group is free. As our additional results are conclusive, and incidentally, have a bearing on the constitution of mannose diacetone, they are now submitted.

We have subjected mannose diacetone to the action of methyl alcohol containing 0.1% of hydrogen chloride, a methylating reagent

FIG. 1.

which is selective in the case of sugars, as it affects only the reducing position. Condensation proceeded readily and the optical changes involved, which are quoted in the experimental part, reveal that the substituted methylmannoside formed belongs to the  $\gamma$ -series. As anticipated, methylation proceeded without removing the acetone residues and the product was completely hydrolysed with the same facility as a  $\gamma$ -mannoside. Evidence was also obtained that mannose diacetone forms a phenylhydrazone, but as the product was a syrup and as, in the mannose series, aniline is a superior reagent to phenylhydrazine, the anilide was studied in greater detail. Mannose diacetone reacts in the cold with an alcoholic solution of aniline to give a well-defined crystalline *mannose diacetone anilide*. The polarimetric curve illustrating the change shows that two simulta-

eous reactions are involved and, following the general rule, the anilide displayed extensive mutarotation in alcoholic solution.

It will be observed that whereas during anilide formation the activity increases in the dextro-sense the compound when isolated is *laevorotatory*. In the preparation of mannoseanilide a similar anomaly is encountered.

The mutarotation of mannose diacetone in various solvents has also been studied, the observations being made on material which had been repeatedly crystallised, or preferably, sublimed at  $120^{\circ}/0.2$  mm. A number of interesting features were encountered, particularly in the case of aqueous solutions where the phenomenon is abnormal and is probably more correctly described as "pseudo-mutarotation." Using dry acetone as the solvent, the mutarotation remained suspended and consequently the initial value ( $[\alpha]_D + 38.4^{\circ}$ ) may be taken as a standard for the compound. The reaction was, however, catalysed by the addition of a trace\* of *N*/50-sodium hydroxide, the constant value  $+ 16.9^{\circ}$  being reached in 6 hours. A solution in acetylene tetrachloride showed practically the same range, but gave the initial specific rotation  $[\alpha]_D + 31.5^{\circ}$ , which diminished regularly to  $9.8^{\circ}$ . Incidentally, the value quoted by Freudenberg for the same solvent ( $+ 14.3^{\circ}$ ) is intermediate between these extremes and corresponds to the readings obtained 40 minutes after the solution was prepared. The change, as shown by the diagram reproduced below, was complete in 100 minutes and this comparatively rapid mutarotation in an anhydrous solvent suggests that in addition to the interchange of the hydrogen and hydroxyl of the reducing position other factors may be operative.

On the whole, the results quoted above are regular, but the use of absolute alcohol as the solvent gave a negative result, the initial value ( $[\alpha]_D + 15.9^{\circ}$ ) remaining constant and showing very little change on the addition of a trace of alkali. Reasons exist for the opinion that in this solvent the mutarotation is so rapid as to be undetectable and, in the circumstances, little success was anticipated in the case of aqueous solutions, particularly as only low concentrations are then possible. The result was, however, positive and the specific rotation diminished from  $+ 11.9^{\circ}$ , became *laevo*, and finally attained equilibrium when a small dextrorotation was just detectable. This consecutive fall and rise in activity shows that the mutarotation involves at least two reactions. If water plays a

\* Judging from published accounts, it would appear that experiments on mutarotation are frequently vitiated by the excessive use of alkali. In the sugar group particularly, this practice is regrettable, as prolonged changes in activity may thus be promoted which have no relationship to mutarotation in the accepted sense of the expression.

specific as well as a catalytic part in the changes, any compound thus produced must be unstable, as the original mannose diacetone was isolated from the solution by extraction with chloroform after mutarotation was complete. Additional information bearing on this point was obtained from the examination of a solution in 50% alcohol which had attained the permanent specific rotation of  $+8.5^\circ$ . On increasing the aqueous concentration to 75%, the activity was much reduced and ultimately vanished.

FIG. 2.

*Mutarotation of mannose diacetone.*

The combined results, when plotted on curves, suggest that the constitution of mannose diacetone is more complex than is generally supposed. As already stated, our opinion is that the compound is derived from  $\gamma$ -mannose, and this is supported by other results, obtained in this laboratory but still unpublished, which prove definitely that glucose diacetone is a derivative of  $\gamma$ -glucose. There remains, however, the problem as to why  $\gamma$ -glucose condenses with acetone to give a compound in which the reducing group is substituted while the same group, usually the most reactive in the molecule, remains free in the case of  $\gamma$ -mannose. For the time being, the formula for mannose diacetone which finds most favour represents the compound as :

Considering recent views as to the structure of the stable and unstable varieties of mannose, it is possible that the above constitution is approximately correct, and it is our intention to investigate the subject further. Meanwhile it may be said that Ohle's criticism of Haworth's conclusions as to the ring structure of mannose is not justified, as evidently the acetone derivatives of the sugar have no relationship with the amyleno-oxidic variety of the hexose.

### EXPERIMENTAL.

The mannose diacetone was prepared by the standard method and purified by recrystallisation from light petroleum (b. p. 40–70°) diluted with 20% of dry ether. After the second crystallisation the m. p. was 122°, and this remained unaltered on further crystallisation or on subliming the compound in a vacuum. A Zeisel estimation, carried out as a check on the purity of the reagents used in the preparation, gave a negative result and the absence of any action upon Fehling's solution was also confirmed.

#### *Rotation and Mutarotation of Mannose Diacetone.*

*Solvent, acetone.* As the compound displays suspended mutarotation in acetone, this solvent was employed in determining the standard specific rotation.

I. The mannose diacetone was recrystallised three times and thereafter sublimed by heating for 5 hours at 120°/0.2 mm.  $c = 1.016$ ;  $[\alpha]_D^{14} = +38.4^\circ$ . This value remained unchanged for 80 minutes.

II. In this experiment the sublimation process was omitted.  $c = 1.559$ .

Time from start.	$[\alpha]_D^{14}$ .	Time from start.	$[\alpha]_D^{14}$ .
8 minutes	+ 27.9°	4½ hours	+ 27.1°
25     "	27.9	8     "	27.2
75     "	27.5	24    "	26.9
150    "	27.1	30    "	26.8

On adding a trace of sodium hydroxide the specific rotation diminished steadily to the constant value + 16.9°, which was reached in 6 hours. The material recovered from this experiment melted at 123°.

*Solvent, acetylene tetrachloride.* This solvent was selected as it was employed by Freudenberg when he obtained the value  $[\alpha]_{H_2O, \text{yellow}} = +14.3^\circ$ . We find that when the mannose diacetone was recrystallised three times and dried at 80°/15 mm. before use, the maximum initial specific rotation observed was  $[\alpha]_{H_2O}^{15} =$

+26.2° and regular mutarotation ensued. Typical figures are given.  $c = 1.980$ .

Time from start.	$[\alpha]_D^{15^\circ}$ .	Time from start.	$[\alpha]_D^{15^\circ}$ .
5 minutes	+22.6°	60 minutes	+11.6°
15 "	18.6	75 "	10.0
20 "	17.1	90 "	9.6
40 "	14.1	100 "	9.1
50 "	12.6	24 hours	9.1

The above values were verified on four occasions and the figure quoted by Freudenberg corresponds with observations made 40 minutes after the first contact of solvent and solute.

A more striking result was obtained with mannose diacetone which had been sublimed by heating for 5 hours at 120°/0.2 mm.  $c = 0.509$ .

Time from start (mins.) . . . . .	10	15	25
$[\alpha]_D^{14^\circ}$ .....	+31.5°	+27.5°	+21.6°
Time from start (mins.) . . . . .	35	45	55
$[\alpha]_D^{14^\circ}$ .....	+15.7°	+11.8°	+9.8° (constant)

*Solvent, absolute alcohol.* Recrystallised material was used.  $c = 2.574$ . The initial specific rotation was +15.9° and this remained unaffected for 150 minutes. After adding a trace of sodium hydroxide the optical value diminished very slowly.

Time (mins.) .....	5	30	150	300	48 (hours)
$[\alpha]_D^{15^\circ}$ .....	+15.8°	+15.7°	+14.5°	+14.0°	+13.6° (constant)

The dissolved material was recovered and, after recrystallisation, proved to be unaltered mannose diacetone.

*Solvent, water.* Recrystallised material was used and, owing to the limited solubility, only dilute solutions were available. Mutarotation was exceedingly rapid and consequently the initial values varied considerably, but the most striking feature of the optical changes was the inversion of sign and the subsequent return to a small dextrorotation. This is illustrated in the following typical case.  $c = 0.4455$ .

Time from start.	$[\alpha]_D^{16^\circ}$ .	Time from start.	$[\alpha]_D^{16^\circ}$ .
5 minutes	+11.9°	1 hour	-5.6°
15 "	5.6	2 hours	-0.6
25 "	3.6	3½ "	Inactive
35 "	2.8	45 "	+1.1°

The end value remained constant for 8 hours after the addition of a trace of alkali.

Although the development of a levorotation was not observed on every occasion, the initial dextro-value always diminished and thereafter increased. By extraction with chloroform, the dis-

solved material was recovered and, after recrystallisation, was proved to be unchanged mannose diacetone.

*Solvent, 50% aqueous alcohol.* Freudenberg has already recorded that mannose diacetone preserves a constant specific rotation in this solvent for the first 24 hours and that thereafter the value falls to  $+9.2^\circ$ . For  $c = 1.2525$  and  $T = 13^\circ$  we found that in 3 days the end-point was  $[\alpha]_D + 8.5^\circ$  and that very little further alteration took place when a trace of dilute alkali was added. On halving the concentration by the addition of water, the liquid showed  $[\alpha]_D + 0.5^\circ$  and became inactive in the course of 2 hours.

*Condensation of Mannose Diacetone with Phenylhydrazine.*—A 3.5% solution of mannose diacetone was prepared in absolute alcohol containing recrystallised redistilled phenylhydrazine (1 mol. plus 10% excess). The solution was preserved at  $12^\circ$  in the dark, polarimetric readings being taken at intervals.

Time from start.	$[\alpha]_D^{12^\circ}$ .	Time from start.	$[\alpha]_D^{12^\circ}$ .
0 minute	$+18.0^\circ$	10 days	$+8.4^\circ$
2 days	13.3	14 "	9.8
4 "	8.7	19 "	12.7
6 "	4.2	28 "	15.5
7 "	7.0		

The results are typical of the condensation of a reducing sugar with the base, and indicate the superposition of an initial rapid reaction on a subsequent slower change. On isolation in the usual manner, the phenylhydrazone proved to be a syrup, which was not further examined.

*Condensation of Mannose Diacetone with Aniline.*—A 3.6% solution of mannose diacetone in absolute alcohol containing five times the theoretical amount of pure aniline was preserved in the dark at the temperature of the room. Polarimetric readings showed that two consecutive reactions then ensued.

Time from start.	$[\alpha]_D$ .	Time from start.	$[\alpha]_D$ .
0 minute	$+16.5^\circ$	10 days	$+50.5^\circ$
1 day	16.6	12 "	56.4
3 days	27.6	14 "	58.6
6 "	37.9	17 "	63.1

At this stage the crystalline product began to separate and the liquid after filtration was concentrated to a small bulk at  $15^\circ/15$  mm. Clusters of needles were thus obtained in excellent yield and, after purification from light petroleum, the product melted at  $114^\circ$  (Found: C, 64.7; H, 7.6; N, 4.2. Calc. for mannose diacetone anilide, C, 64.5; H, 7.5; N, 4.2%). Mannose diacetone anilide is laevorotatory, but, in common with sugar anilides generally, displayed extensive mutarotation in absolute alcohol.

Time from start.	$[\alpha]_D^{17}$ .	Time from start.	$[\alpha]_D$ .
5 minutes	-118.3°	50 hours	Inactive
15 "	118.3	4 days	+39.8°
50 "	106.9	5 "	50.2
180 "	88.7	6 "	72.8
5 hours	69.4	8 "	79.6
20 "	22.7	12 "	83.0
30 "	12.5		(constant)

The results when plotted on a curve showed a marked resemblance to those given by mannose anilide, although the whole of the rotations are shifted markedly in the dextro-direction. The anilide was recovered unchanged from the above solution.

*Condensation of Methyl Alcohol with Mannose Diacetone.*—A 3% solution of mannose diacetone in dry methyl alcohol containing 0.1% of hydrogen chloride was maintained at 17°, polarimetric readings being taken at intervals.

Time from start.	$[\alpha]_D^{17}$ .	Time from start.	$[\alpha]_D^{17}$ .
0 minute	+13.6°	8 hours	+18.9°
2 hours	16.0	24 "	21.1
3 "	17.1	48 "	21.7
4 "	17.9	72 "	21.7

The acid was removed with silver carbonate, and the filtrate taken to dryness in a high vacuum, the residue then remaining being extracted repeatedly with dry ethyl acetate in the cold. On removal of the solvent under diminished pressure a syrup was obtained which, as it reduced Fehling's solution slightly, was taken up in cold ether and filtered from a small quantity of reducing material. The ether was then evaporated and the syrup isolated by redistillation, a fraction, b. p. 115—125°/0.3—0.7 mm., being collected. The distillate consisted of a mixture of methylmannoside diacetone (64%) and unchanged mannose diacetone (36%). The conditions of the condensation with acid methyl alcohol were varied, and it was ascertained that when the reaction was continued until all the mannose diacetone had disappeared, the bulk of the product then consisted of  $\gamma$ -methylmannoside. This was isolated by solution in cold ethyl acetate, the syrup thus extracted being afterwards treated with ether to remove extraneous products. The mannoside was obtained as a colourless syrup which slowly crystallised owing to its spontaneous conversion into the  $\alpha$ -form.

CXLII.—*Ethyl Hydrogen Sulphate. Part II.*

By M. ABDUL HAMID, KIRPAL SINGH, and HORACE BARRATT DUNNICLIFF.

SEVERAL subjects not investigated by Dunnicliff and Butler (J., 1921, 119, 1384) have been studied.

*Preparation of Ethyl Hydrogen Sulphate.*—Attempts to prepare the pure ester have been made by the following methods :

1. By the action of hydrogen sulphide on lead ethyl sulphate (a) dry, (b) in alcoholic solution, and (c) suspended in ether. No action took place in the absence of water.

2. Passing ethylene into (a) sulphuric acid, (b) an ethereal solution of sulphuric acid, and (c) alcoholic sulphuric acid. Only very impure products were obtained.

3. Extraction of such sulphates as  $\text{Ag}_2\text{SO}_4 \cdot \text{H}_2\text{SO}_4$ ,  $\text{BaSO}_4 \cdot \text{H}_2\text{SO}_4$ , and  $\text{Li}_2\text{SO}_4 \cdot \text{H}_2\text{SO}_4$  gave a mixture of sulphuric acid and ethyl hydrogen sulphate in ether.

4. Barium ethyl sulphate,  $\text{Ba}(\text{C}_2\text{H}_5\text{SO}_4)_2 \cdot 2\text{H}_2\text{O}$ , was prepared in the ordinary way. On treatment with dry alcohol, the anhydrous salt,  $\text{Ba}(\text{C}_2\text{H}_5\text{SO}_4)_2$ , was formed. In order to start with an alcoholic sulphuric acid in which the free sulphuric acid was a minimum, 20% alcoholic sulphuric acid was taken after standing for a month. The percentage esterification of the sulphuric acid was 85. The free sulphuric acid was estimated. Barium ethyl sulphate in excess of the calculated amount required to react with the free sulphuric acid present was added to a weighed quantity of the alcoholic sulphuric acid and well shaken. The mixture was filtered and the filtrate heated with excess of barium ethyl sulphate under reduced pressure on a water-bath. When no more distillate was obtained, the residue in the flask was (a) filtered off or (b) extracted with dry ether in an apparatus of the Soxhlet type specially arranged for the extraction of liquids. It was hoped that the filtrate from (a) and the residue after driving off the ether from (b) would be free from sulphuric acid and probably from water and alcohol.

Among a large number of determinations of the equivalent weight of the ester so prepared, nine samples gave values which were within experimental error of the theoretical value, 126. The others were either high or low. The ester darkened on standing and the equivalent weight fell owing to the formation of free sulphuric acid. After some months, some preparations became black and free carbon was among the products of decomposition.

Attempts were made to determine the composition of several of the samples by combining the results of analyses by combustion,

estimation of sulphate by the barium sulphate method, and determination of esterification by the volumetric method. The greatest degree of purity obtained showed a yield of 84.5% of ester. A typical analysis was: Equivalent weight, 126.  $C_2H_5 \cdot HSO_4$ , 64.9;  $H_2SO_4$ , 13.7;  $C_2H_5 \cdot OH$ , 10.0;  $H_2O$ , 11.8; total, 100.4%.

5. By the action of dry hydrogen chloride on anhydrous barium ethyl sulphate (a) dry, (b) in anhydrous alcoholic solution, and (c) in ethereal solution. In the dry state no appreciable action was observed. In alcoholic and ethereal solution the hydrogen chloride reacted with the salt, giving insoluble barium chloride and ethyl hydrogen sulphate in solution. At first sulphuric acid was absent but, on concentration either by evaporation or water-bath or at the ordinary temperature in a desiccator, the ester decomposed. The solution, at first colourless, slowly turned yellow with increasing concentration and, long before the solvent was driven off, a strong test for sulphuric acid was obtained. This decomposition was not due to the presence of hydrochloric acid, because the same result was obtained in the presence of excess of barium ethyl sulphate. The potassium salt behaves in a similar manner.

All attempts to prepare pure ethyl hydrogen sulphate have failed. The ester appears to become more unstable with increasing concentration.

*Solubility of Ethyl Hydrogen Sulphate in Ether.*—Most books of reference state that ethyl hydrogen sulphate is insoluble in ether. Since pure ethyl hydrogen sulphate has not been prepared, it is difficult to say if this is so, as all ethereal solutions of the ester in ether contain some sulphuric acid. Determinations of the solubility of the ester at 30° in presence of a small percentage of sulphuric acid show that the concentration of the ethyl hydrogen sulphate diminishes as the concentration of free sulphuric acid rises. Extrapolation of the results indicates that the solubility of pure ethyl hydrogen sulphate in pure ether should be about 1.27 g. of ester per 100 g. of dry ether at 30°.

TABLE I.

*Solubility of Ethyl Hydrogen Sulphate in Ether containing free Sulphuric Acid at 30°.*

Free $H_2SO_4$ %	0.092	0.152	0.186	0.314	0.372	0.516	0.533
$C_2H_5 \cdot HSO_4$ %	1.125	1.061	0.999	0.818	0.722	0.509	0.470

These points lie practically on a straight line, but as the concentration of the sulphuric acid increases, the relationship is not so simple, e.g., when the concentration of sulphuric acid is 4.06%.

the concentration of the ester is 0.242%. If the solution were kept for some time, the concentration of the ester would increase on account of the interaction between ether and sulphuric acid. At the very low concentrations given in the table, the rate of esterification would be very slow and the total esterification very small. As the solutions were estimated immediately after they were formed, the line obtained by plotting the above points may be correctly described as a solubility graph. The fact that ethyl hydrogen sulphate is soluble in ether may be demonstrated by extracting ethyl hydrogen sulphate in a Soxhlet apparatus. The liquid in syphons over eventually separates into two layers, a lower one in ethyl hydrogen sulphate and an upper one poor in the ester. If the upper one be separated and allowed to evaporate, the ether first becomes cloudy and then a heavy layer of impure ethyl hydrogen sulphate separates.

*The Order of the Reaction between Ethyl Alcohol and Sulphuric Acid at High Concentrations of Acid.*—In the previous work, the velocity of the reaction at concentrations of sulphuric acid above 13.18% was not studied. The order of the reaction at concentrations of sulphuric acid between 60 and 75% has now been investigated. The practical difficulties encountered in this work were very considerable. At 18°, the reaction is very violent, so the experiments were carried out at 0°. In order to mix the interacting substances, alcohol which had been cooled to -5° was added slowly to super-cooled sulphuric acid. At the highest concentration, the acid was cooled to -10° and great care had to be exercised to prevent it from crystallising out. After the alcohol had been added there was no fear of this. The ingredients were thoroughly mixed, the flask being always immersed in the freezing mixture. When all the alcohol had been added, the reaction vessel was transferred to a bowl containing clean crushed ice. As soon as the temperature of the reaction mixture rose to 0°, the first portion of the reaction mixture was withdrawn in an ice-cold 1 c.c. pipette and run into a known quantity of standard caustic soda more than sufficient to neutralise it, and its weight was determined. The proportions in which the sulphuric acid and alcohol had been mixed in the reaction mixture were estimated after the experiment. The esterification was measured and the value of  $z$ , the time to be added to the observed time to compensate for the disturbed period, was calculated as previously described (*loc. cit.*, p. 1390).

The object was to obtain :

1. A minimal esterification during the disturbed period.
2. As large a difference as possible between the actual time of observation,  $t$ , and the correction,  $z$ , to be added.

3. A final total esterification several multiples of the esterification during the disturbed period.

The results in Tables II to IV show conclusively that, as in the case of low concentrations of sulphuric acid, the reaction is of the first order even when 1.44 molecules of sulphuric acid are mixed with one of alcohol, forming an alcoholic sulphuric acid containing 74.45% of sulphuric acid.

$x$  = quantity of ethyl hydrogen sulphate expressed as g.-mol. per 100 g. of mixture, and  $t$  = the actual time.

The mass-action coefficient obtained after 1 molecule of sulphuric acid had been allowed to interact with 1.05 molecules of alcohol at laboratory temperature for 25 days was 0.5650, and the ethyl hydrogen sulphate formed corresponded with 0.5787 g.-mol. These values are in agreement with (a) the "calculated" esterification (*loc. cit.*, p. 1387), which was 0.5595 g.-mol., (b) the variation in the value of the mass-action coefficient as explained in equation (3) (*loc. cit.*) and the general proposition that the ratio

$$\frac{\text{actual esterification obtained}}{\text{maximum possible esterification}} = 0.5787 \text{ (observed)}$$

is a minimum when equimolecular proportions of the reacting

compounds are employed. Claesson (*J. pr. Chem.*, 1879, **19**, 246) obtained the value 0.5710.

In some preliminary experiments it appeared that the final maximum esterification in an alcoholic sulphuric acid made by treating sodium hydrogen sulphate with dry alcohol was less than that found in an alcoholic sulphuric acid of the same strength made by mixing the constituents directly and that this was due to the presence of some sulphate of sodium in the first case. This has now been shown to be erroneous as instanced by the examples given below:

$\text{H}_2\text{SO}_4$ % in the alcoholic sulphuric acid containing sodium sulphate.	$\text{C}_2\text{H}_5\cdot\text{HSO}_4$ % found.	Theoretical % of $\text{C}_2\text{H}_5\cdot\text{HSO}_4$ for alcoholic $\text{H}_2\text{SO}_4$ .
9.46	10.16	10.08
12.86	13.87	14.06
43.50	44.16	44.36

### Summary.

All attempts to prepare pure ethyl hydrogen sulphate have been unsuccessful.

From determinations at  $0^\circ$  of the velocity coefficients of the reaction between sulphuric acid and alcohol in which the concentration of sulphuric acid is from 60 to 75%, it is shown that the reaction is of the first order.

The solubility of ethyl hydrogen sulphate in ether containing small quantities of sulphuric acid has been determined at  $30^\circ$ .

## CXLIII.—*The Reactivity of Alkyl Iodides with Sodium Benzyl Oxide. A Criticism.*

By LEONARD JAMES GOLDSWORTHY.

THE reactivity of alkyl iodides with sodium benzyl oxide and the effect of temperature on such reactions were studied by Haywood (*J.*, 1922, **121**, 1904), whose reaction mixture consisted of equal volumes of  $N/5$ -alcoholic solutions of sodium benzyl oxide and alkyl iodide. As the molecular ratio of ethyl alcohol to sodium benzyl oxide in such a mixture is about 170, it is extremely improbable that Haywood's velocity coefficients can be a measure of the rate of the reaction  $\text{C}_6\text{H}_5\cdot\text{CH}_2\cdot\text{ONa} + \text{RI} = \text{NaI} + \text{C}_6\text{H}_5\cdot\text{CH}_2\cdot\text{OR}$ . It is more likely that in such a mixture the concentration of sodium ethoxide is much greater than the concentration of sodium benzyl oxide, and that the velocity measured by Haywood was really that

of the reaction  $C_2H_5 \cdot ONa + RI = NaI + C_2H_5 \cdot OR$ . Although he remarked that alcoholysis "to a certain extent" is to be expected, Haywood apparently did not realise the probability that under the conditions of his experiments alcoholysis would be almost complete.

In order to put the matter to the test, the author mixed equal volumes of *N*/5-ethyl-alcoholic solutions of sodium ethoxide and ethyl iodide and compared the rate of the reaction in this mixture at 35° with the rate of the reaction in a mixture of equal volumes of *N*/5-ethyl-alcoholic solutions of sodium benzyl oxide and ethyl iodide. The velocity coefficients in the two experiments were practically identical. As there was a possibility that this result might have been due to coincidence, the reactivities of sodium benzyl oxide and sodium ethoxide being the same in ethyl-alcoholic solution, two further experiments were performed, in which *n*-butyl alcohol was used as solvent in the place of ethyl alcohol. Here again the velocity of the reaction in a mixture of equal volumes of *N*/5-butyl-alcoholic solutions of sodium butyl oxide and ethyl iodide was practically the same as the velocity in a mixture of equal volumes of *N*/5-butyl-alcoholic solutions of sodium benzyl oxide and ethyl iodide.

A final experiment was performed as a crucial test, the object of which was to isolate and examine the products of the reaction. A solution prepared by mixing equal volumes of 2*N*-ethyl-alcoholic solutions of sodium benzyl oxide and ethyl iodide was fractionally distilled after sufficient time had elapsed for the completion of the reaction (at 35°). If in this experiment no ethyl benzyl ether had been formed, the sole reaction being that between sodium ethoxide and ethyl iodide, 14.8 g. of ethyl ether should have been formed. Actually 11 g. of liquid boiling below 45° were collected and from this 6 g. of pure ethyl ether were obtained by further fractionation. Thus it is clear that even in a normal ethyl-alcoholic solution of sodium benzyl oxide and ethyl iodide the main reaction is that represented by the equation

In Haywood's experiments, in which the concentrations were tenth-normal, the amount of ethyl benzyl ether formed must have been negligibly small.

#### EXPERIMENTAL.

The ethyl alcohol used in these experiments was commercial absolute alcohol, dried by digesting with lime and calcium. The ethyl iodide (Kahlbaum's) was purified just before use by washing with dilute alkali and water, drying over calcium chloride, and distilling from silver powder.

The benzyl alcohol (Kahlbaum's) was redistilled before use. The *n*-butyl alcohol was purified by distillation, after treatment with lime.

All the instruments used were standardised with reference to standard instruments.

During the velocity determinations the temperature, kept constant by means of a thermostat provided with an Ostwald toluene regulator and stirrer, did not vary more than 0.05°. In the preparation of the *N*/5-ethyl-alcoholic solution of sodium benzyl oxide, a weighed quantity of benzyl alcohol was mixed with a measured volume of a standard alcoholic solution of sodium ethoxide, containing an equivalent quantity of the ethoxide. The mixture was then diluted to the calculated volume with alcohol. The solution of sodium benzyl oxide in butyl alcohol was similarly prepared. The rates of reaction were measured in the manner described by Haywood.

**Results.**—The velocity coefficients are calculated from the formula  $k = \frac{1}{t} \cdot \frac{x}{a-x} \cdot \frac{y}{C_0 a}$ , in which *x*, *y*, *t*, *a* and *C*<sub>0</sub> have the same significance as in Haywood's paper.

*N*/40-Hydrochloric acid was used in the titrations.

**1st Expt.** Equal volumes of *N*/5-sodium benzyl oxide (in ethyl alcohol) and *N*/5-ethyl iodide (in ethyl alcohol).

CXLIV.—*The Rate of Reaction between Formic Acid and Iodine in Aqueous Solution.*

By DALZIEL LLEWELLYN HAMMICK and MICHAEL ZVEGINTZOV.

It has been shown (Hammick, Hutchison, and Snell, J., 1925, 127, 2715) that the rate of reaction between bromine and formic acid is represented by the mass-action equation

$$dx/dt = k[\text{H}\cdot\text{COO}'][\text{X}]/\{1 + [\text{X}']/K_1\} \dots \dots (1)$$

in which  $[\text{X}]$  is the total concentration of free halogen  $\text{X}_2 + \text{X}'_3$ ,  $[\text{X}']$  the concentration of halogen ion, and  $K_1$  is the equilibrium constant  $K_1 = [\text{X}_2][\text{X}']/[\text{X}'_3]$ . For bromine,  $1/K_1$  is of the order of 10 and  $[\text{Br}']/K_1$  could not be neglected in comparison with unity. In chlorine and iodine, however, we have two extreme cases. For chlorine,  $K_1$  is large and  $[\text{Cl}']/K_1$  can be neglected; for iodine,  $K_1$  is small and has the value  $1.75 \times 10^{-3}$  at  $45^\circ$  (Fedotiev, *Z. physikal. Chem.*, 1909, 69, 22) and  $1.365 \times 10^{-3}$  at  $25^\circ$  (Jakowkin, *ibid.*, 1896, 20, 19). Hence in the case of iodine we may neglect unity in comparison with  $[\text{I}']/K_1$  and we should expect to find that, whereas the rate of reaction between chlorine and formic acid would be practically independent of chlorine-ion concentration, that between iodine and formic acid would be inversely proportional to the concentration of iodine ion. That is to say,

$$dx/dt = k[\text{H}\cdot\text{COO}'][\text{I}]/\{[\text{I}']/K_1\} \dots \dots (1A)$$

should represent the course of the reaction in the latter case. Iodine reacts at  $60^\circ$  at a convenient rate and results have been obtained at that temperature that confirm the conclusion arrived at above.

Iodine and formic acid, in the presence of potassium iodide, were mixed in a glass stoppered flask in a thermostat maintained at  $61.5^\circ \pm 0.25^\circ$ , the iodine being estimated from time to time with standard thiosulphate. In all experiments, the potassium iodide was present in excess (never less than 10 to 1) sufficient to eliminate perturbations due to the iodine ion produced during the reaction. A zero time-correction was obtained by plotting  $\log a/(a - x)$  against time and extrapolating to zero time. The unimolecular velocity coefficients given below have been corrected in this way.

By analogy with the reaction between bromine and formic acid, it is to be expected that iodine would react as follows:

An experiment was therefore carried out by mixing equal volumes of equivalent solutions of formic acid and iodine in presence of

excess of potassium iodide and measuring the rate of disappearance of the iodine. The results show that the reaction is bimolecular, as the above equation suggests.

TABLE I.

$[\text{H}\cdot\text{CO}_2\text{H}] = N/100$ .  $[\text{I}_2] = N/100$ .  $a - x$  = thiosulphate titre at time  $t$ .

$t$ (mins).	$a - x$ .	$1/(a - x) - 1/a$ .	$k \times 10^3$ (bimol. coeff.).
0.0	10.9	—	—
4.53	10.65	0.00215	4.45
10.08	10.4	0.00441	4.37
19.42	9.95	0.00826	4.51
25.6	9.7	0.01146	4.48

*Influence of Formic Acid Concentration on the Rate of Disappearance of Iodine.*—In Table II are the results of a series of determinations of the unimolecular velocity coefficient for two different concentrations of formic acid.

TABLE II.

$[\text{H}\cdot\text{CO}_2\text{H}]$ .	$[\text{KI}]$ .	$[\text{I}_2]$ .	$k \times 10^3$ .	
$N/3$	0.117N	0.011N	9.15	ratio = 1.34
$2N/3$	0.117	0.011	12.2	
$N/3$	0.234	0.011	4.65	" 1.37
$2N/3$	0.234	0.011	6.35	
$N/3$	0.17	0.016	5.85	" 1.45
$2N/3$	0.17	0.016	8.47	

Since formic acid obeys the dilution law, we have approximately  $\alpha^2/V = K_a$ , where  $\alpha$  is the degree of dissociation,  $V$  is the dilution, and  $K_a$  is the dissociation constant; hence, for any two dilutions  $V_1$  and  $V_2$ , we have  $\alpha_1/\alpha_2 = \sqrt{V_1/V_2}$ . Thus  $[\text{H}\cdot\text{COO}' ]_1/[\text{H}\cdot\text{COO}' ]_2 = (\alpha_1/V_1)/(\alpha_2/V_2) = \sqrt{V_2/V_1}$ . For the pairs of velocity coefficients given in Table II,  $V_2/V_1 = 1/2$  and hence  $[\text{H}\cdot\text{COO}' ]_2/[\text{H}\cdot\text{COO}' ]_1 = \sqrt{2} = 1.41$ . If the rate of reaction is proportional to  $[\text{H}\cdot\text{COO}' ]$  we should expect to find that doubling the concentration of formic acid would increase the velocity coefficient in the ratio of 1 to 1.41. The mean of the ratios in Table II is 1.39.

*Influence of Hydrogen-ion Concentration.*—Unimolecular velocity coefficients were determined in the presence of varying quantities of hydrochloric acid. The results of a series of determinations are summarised in Table III.

TABLE III.

$[\text{HCl}]$ .	$a$ .	$[\text{H}]$ .	$k \times 10^3$ .	$k \times [\text{H}] \times 10^3$ .
0.066N	0.844	0.06N	3.5	0.210
0.132	0.812	0.11	1.9	0.209
0.198	0.786	0.16	1.19	0.191

Under  $a$  are the activity coefficients of hydrochloric acid (Ellis, *J. Amer. Chem. Soc.*, 1916, 38, 535; Noyes, *ibid.*, 1917, 39, 2532).

These figures refer to acid at room temperature; in using them at 60°, we are, of course, assuming that the ratios of activity coefficients corresponding to different concentrations are independent of temperature. Under  $[H]$  are effective concentrations of hydrogen ion, calculated from the Law of Mixed Acids (Lewis, "System of Physical Chemistry," 1921, Vol. 1, p. 255) by the formula  $[H] = K_a/\alpha[HCl]$ ; the dissociation constant for formic acid,  $K_a$ , is taken as  $2.1 \times 10^{-4}$  (Ostwald, *Z. physikal. Chem.*, 1889, 3, 239); this value refers to 18° and hence values of  $[H]$  can only be regarded as relative. Nevertheless, the constancy of the product  $k \times [H]$  shows that the velocity of the reaction is inversely proportional to the effective concentration of the hydrogen ion and therefore directly proportional to the concentration of formyl ion.

*Influence of Iodine-ion Concentration.*—The concentration of iodine ion was varied between 0.117*N* and 0.350*N* by the addition of potassium iodide and was always in excess sufficient to mask the effect of the iodine ion produced in the course of the reaction. The results are in Table IV.

TABLE IV.  
 $[H \cdot CO_2H] = N/3$ .

$[I_2]$ .	$[KI]$ .	$k \times 10^2$ .	$\alpha$ .	$k \times \alpha \times [KI] \times 10^3$ .
0.012 <i>N</i>	0.117 <i>N</i>	0.915	0.735	0.786
0.11	0.234	0.465	0.689	0.750
0.11	0.351	0.328	0.663	0.762
0.16	0.170	0.585	0.710	0.733
0.0275	0.292	0.372	0.655	0.733
0.0335	0.351	0.330	0.663	0.768

The values for the activity coefficient,  $\alpha$ , are from McInnes and Parker (*J. Amer. Chem. Soc.*, 1915, 37, 1445) for potassium chloride in the presence of hydrogen ion, no data being available for the activity of the iodine ion. The close similarity of the potassium chloride and potassium bromide values renders the use of potassium chloride values justifiable. The figures do not refer to 60°, and hence are assumed to be only relatively correct. The product in column 5 shows that the rate of reaction is inversely proportional to the effective concentration of the iodine ion, as predicted by equation (1A).

The reaction between iodine and sodium formate in the presence of potassium iodide has been studied by Dhar (*J.*, 1917, 111, 726). He concludes that interaction takes place between iodine and formyl ions and notices the retarding influence of potassium iodide. He explicitly excludes, however, the possibility that this effect is due to disturbance of the equilibrium  $I_2 + I' \rightleftharpoons I'_3$ , and claims that the potassium iodide acts catalytically. He compares two cases in which "the concentrations of sodiumoformate are equal and according to

the mass-action equilibrium the velocity coefficients should be the same, since the ratio of the concentration of potassium iodide and iodine is the same in the two cases" (*loc. cit.*, p. 730). As a matter of fact, the ratio of the two velocity coefficients is  $k_1/k_2 = 0.00196/0.00378 = 0.52$ . If we now apply equation (1A) to the case of a velocity determination in which  $[\text{H}\cdot\text{COO}']$  and  $[\text{I}']$  are constant (sodium formate and potassium iodide were in excess in Dhar's experiments), we have on integrating,  $(1/t) \log a/(a-x) = k = K \cdot K_1 \cdot [\text{H}\cdot\text{COO}']/[\text{I}']$ . For two experiments in which  $[\text{H}\cdot\text{COO}']$  is the same in each, we have  $k_1/k_2 = [\text{I}']_2/[\text{I}']_1$ . Applying this to Dhar's examples, with the assumption that the potassium iodide is completely dissociated, we find  $k_1/k_2 = 2.7066/5.4132 = 0.50$ , in excellent agreement with the ratio given above. Thus Dhar's results do not, as he concludes, require us to regard the action of the potassium iodide as catalytic, but actually provide very good evidence in support of the view embodied in equations (1) and (1A) above.

## CXLV.—*The Complexity of the Solid State. Part III.* *The Behaviour of Pure Sulphur Trioxide. Part II.*

By ANDREAS SMITS and PIETER SCHOENMAKER.

CONTINUING our earlier publication on the behaviour of pure sulphur trioxide (J., 1924, 125, 2554) we first conclude the description of our investigation of the ice-like form. Tables VIII and IX of that paper contained the vapour pressures of the solid and the liquid phases of the ice-like form when in inner equilibrium up to  $49.75^\circ$ . We have since determined the vapour pressure of the liquid in inner equilibrium up to  $90^\circ$  with the following results :

$t$ .....	$57.1^\circ$	$65.4^\circ$	$74.0^\circ$	$80.9^\circ$	$90.2^\circ$
$p$ (mm. Hg) .....	1377.2	2041.0	2964.0	3985.5	5794.0

In order to find the point of intersection of the vapour-pressure curves of the solid and the liquid in inner equilibrium we have applied the method already used in the study of phosphorus ("Theory of Allotropy," p. 226; *Z. physikal. Chem.*, 1916, 91, 248). From the equation  $T \ln p = -Q/R + CT$ , it follows that on plotting  $T \ln p$  as a function of  $T$  a straight line will be obtained. The values of  $T \ln p$  for the temperature range  $0-90.2^\circ$  are in the

second column of Table I, and graphical representation gives two straight lines (see Fig. 5, p. 2565, of the earlier paper).

The two straight lines intersect in the triple point  $16.8^\circ$  and  $T \ln p = 1467$ , corresponding with  $p = 158.5$  mm. (Lighty, Berthoud, and Le Blanc found  $16.79^\circ$ ,  $16.85^\circ$ , and  $16.8^\circ$  respectively.) From the slope of the sublimation line, covering the first four temperatures of Table I, it follows that  $C$  for this line is 25.84, and hence the values of  $Q/R$  for the different observation temperatures may be calculated as shown in the third column of Table I. If the mean value of  $Q_{sg}/R$  is taken as 6000, the molecular heat of sublimation,  $Q_{sg}$ , is 11900 cal.

Similarly, the value of  $C$  for the liquid vapour pressure line is found to be 22.7, and the molecular latent heat of evaporation,  $Q_{lg}$ , based on the mean value of  $Q_{lg}/R$  (see Table I), is calculated to be 10100 cal. It further follows that the molecular latent heat of fusion,  $Q_{sl}$ , is 1800 cal. (Le Blanc calculated 2220 cal. from his determinations.)

From our determinations, it appears that the boiling point under a pressure of 760 mm. is  $44.8^\circ$  (compare Buff,  $46-47^\circ$ ; Schultz-Sellock,  $46^\circ$ ; Weber,  $46.2^\circ$ ; Lighty,  $44.88^\circ$ ; Berthoud,  $44.52^\circ$ ), and that the Trouton ratio  $Q_{lg}/T_b = 10100/317.8 = 31.8$ , as compared with the normal value 22. These results indicate that the liquid is more complex than the vapour, and that the solid and liquid phases differ but slightly in complexity. We shall return later to this phenomenon.

*The Insufficiently Dried, Low-melting, Asbestos-like Form.*

The region of the pseudo-system, in which the ice-form of sulphur trioxide is situated, is that of a dissociable compound of pseudo-components, related to each other as polymerides or isomerides, these terms being used in the widest possible sense (J., 1924, 125, 2554).

The ice-form of sulphur trioxide is one of the two metastable modifications. The other generally constitutes three-quarters of the pure sulphur trioxide in the bulbs supplied by Kahlbaum; it is

like asbestos in appearance and will be referred to as the low-melting, asbestos-like form.

For our more recent work, several bulbs provided with a septum (Fig. 1) were sent to the firm of Kahlbaum and filled with pure sulphur trioxide, the ends of the tubes *a* and *b* then being sealed. Such a bulb, unevacuated, was joined to a high-vacuum pump at *a* by a very short rubber tube connected with a small steel tube about 5 cm. in length, in such a way that *a* was inside the steel tube; by moving this tube the point *a* (previously scratched) could be broken. (To prevent the mercury in the pump from reacting with the sulphur trioxide, a U-tube cooled in liquid air was placed

in front of the pump.) After evacuation, the capillary tube *a* was sealed off.

A second T-piece with a septum,  $S_2$ , was now sealed to the delivery tube, a breaker of solid glass carefully placed on the septum  $S_1$  (Fig. 2), and the tube *c* sealed to a glass spring indicator, with the bulb *g* and the mantle *w* still connected through a capillary tube, *v*, as shown in Fig. 3. Bulb *g* was connected to a wide horizontal U-tube to which were sealed two or four vertical tubes, provided with capillaries, and a T-piece with septum,  $S_3$ , with breaker and bulb, *m*. The remaining connexion with the vessel *u* is evident from Fig. 3.

The whole apparatus was heated while a current of dry air was driven through every tube and vessel, and finally the capillary ends of these tubes and vessels were sealed off in succession. The sulphur trioxide bulb being cooled in liquid air, the rest of the apparatus was evacuated by connecting the delivery tube of vessel

*u*, which also was cooled in liquid air, with the high-vacuum pump. When a high vacuum had been reached, communication between the mantle *w* of the glass spring and the vessel *g* was stopped by sealing off the capillary tube *v*. The septum *S*<sub>1</sub> was then broken by shaking the apparatus. By evacuating again, sealing off the capillary *r*, and allowing the sulphur trioxide bulb to attain room temperature, a sufficient portion of the sulphur trioxide was distilled into *g*, this vessel being cooled to  $-80^{\circ}$  in a mixture of solid carbon dioxide and alcohol. The capillaries *p* and *q* were then sealed off.

The further manipulations necessary to make the apparatus ready for vapour-pressure measurements are described in J., 1924, 125, 2554.

FIG. 3.

A part of the sulphur trioxide, obtained in the foregoing way, was the ice-form, for we found the vapour-pressure line of this form to be as if it were in inner equilibrium. This was in complete agreement with the fact that the sulphur trioxide had not been dried by phosphorus pentoxide. After the ice-form had been distilled off by cooling tube *k* in liquid air and sealing, the vapour-tension line was determined again with the following results :

TABLE II.

Temp.	$p$ (mm. Hg).	$T \ln p$ .	$Q/R$ .	Temp.	$p$ (mm. Hg).	$T \ln p$ .	$Q/R$ .
0.2°	33.0	955.3	6574	20.25°	162.8	1494	6588
5.1	49.2	1083	6579	24.85	230.1	1620	6588
10.1	72.3	1212	6590	30.3	334.1	1761	6598
15.0	106.6	1345	6592				

The vapour pressures for the not intensively dried, liquid phase were the values employed in Table I.

If  $T \ln p$  is plotted against  $T$ , Fig. 4 is obtained, in which two straight lines intersect at  $32.5^\circ$  and  $T \ln p = 1823$  (i.e.,  $p = 398$  mm. Hg). This temperature is the melting point of the low-melting, asbestos-like form under this vapour pressure, if it is in inner equilibrium, or, in other words, if it behaves as a unary substance.

The triple point of the low-melting, asbestos-like form is therefore situated at  $32.5^\circ$  and 398 mm. Hg. The vapour-tension line for

this form indicates that the value of  $C$  in the formula  $T \ln p = -Q/R + CT$  is 27.56. The value of  $Q/R$  at each observation temperature is in Table II, and the mean value may be taken as 6590, whence  $Q_{SG} = 13000$  cal. Since  $Q_{LG} = 10100$  cal. (see p. 1109), it follows that  $Q_{SL} = 2900$  cal.

*The Intensively Dried, Low-melting, Asbestos-like Form.*

The method of intensive drying, as applied with the ice form, is very difficult to carry out in this case, since it is an arduous task to prepare the low-melting, asbestos-like form if the sulphur trioxide has been

intensively dried. We have therefore prepared the not intensively dried, low-melting, asbestos-like form and begun to dry it in the *solid* state, an operation which will take a very long time, perhaps several years, for completion.

In a preliminary trial phosphorus pentoxide was distilled into bulb *m* in the way previously described. The bulb was then evacuated, the delivery tube sealed off, the apparatus inverted, and the septum  $S_3$  broken by means of the breaker in tube *l*. The apparatus was again set upright; the large hole in the septum was thus freed, this being necessary for the drying to take place as rapidly as possible in the given circumstances. As we feared, the drying of the solid substance was exceedingly slow, the effect after months being inappreciable. Finally we tried once more to prepare

the intensively dried, low-melting, asbestos-like form from the intensively dried, ice-like form, but obtained the high-melting form.

*The High-melting, Asbestos-like Form.*

*The Intensively Dried, High-melting, Asbestos-like Form* (First part).—The apparatus for determining the vapour pressure of this form was filled in the way described in our first publication (*loc. cit.*), a bulb, containing pure sulphur trioxide, of the form shown in Fig. 2 being used. The storing apparatus having been filled with the intensively dried ice form (see Fig. 2, *loc. cit.*), the glass spring indicator was first filled with this form.

By distilling sulphur trioxide alternately from one vessel into another, the distilling vessel being at room temperature or slowly heated and the condensing vessel cooled in liquid air, it is possible to convert the ice form almost completely into the high-melting, asbestos-like form; the last traces of the ice form are removed by distilling into one of the tubes and sealing it off.

As shown in our first publication, the dried ice form of sulphur trioxide, as in the case of a mixture, exhibits a lower vapour pressure after a small portion has been distilled off. This phenomenon, first observed with violet phosphorus ("Theory of Allotropy," pp. 96, 213), is exhibited in a much higher degree by the high-melting, asbestos-like form. The intensively dried, high-melting, asbestos-like form, obtained in the way mentioned above, showed a very low vapour pressure, which remained constant at room temperature. At higher temperatures, however, the vapour pressure rises with a velocity which decreases with the time. The apparatus being kept at constant temperature, this phenomenon has been studied successively with the same filling at 30° and 40°, and with a new filling at 50°; the results are shown in Figs. 5, 6, and 7. In these figures the curves approach asymptotically a final value, indicated by a dotted line.

Calculating  $T \ln p$  from the final values of the vapour pressure at the three temperatures, we obtain the results shown in Table III.

TABLE III.

$t$ .	$p$ (mm. Hg).	$T \ln p$ .	$Q/R$ .
30°	120	1450	8246
40	290	1780	8236
50	650	2090	8246

The three points obtained by plotting  $T \ln p$  against  $T$  are collinear as shown in the lower line of Fig. 8.

The behaviour of the high-melting, asbestos-like form agrees completely with that of the ice-like form. There are only quanti-

tative differences, due to the higher temperatures at which the high-melting asbestos-like form had to be studied. The velocity of establishment of inner equilibrium in the intensively dried material being

FIG. 5.

FIG. 6.

FIG. 7.

imperceptibly slow at 18°, the initial preparation, highly disturbed by rapid evaporation, showed an abnormally low vapour pressure, which did not change. At higher temperatures, however, the

velocity becomes greater and is manifested in the vapour pressure, which increases until inner equilibrium is reached. Violet phosphorus shows exactly the same interesting behaviour (*Z. physikal. Chem.*, 1916, 91, 249).

From the vapour-pressure curves of the high-melting form, in inner equilibrium, and of the liquid (Table I), we can find the unary

FIG. 8.

melting point of the high-melting, asbestos-like form under its own vapour pressure, i.e., the triple point  $S + L + G$  of this form. The two lines obtained by plotting  $T \ln p$  against  $T$  for the solid and the liquid form (Fig. 8) intersect at  $t = 62.2^{\circ}$  and  $T \ln p = 2502$ , or  $p = 174.3$  cm. of mercury.

As in the case of the ice-like form and the low-melting, asbestos-like form, we can calculate here the heat quantities. Thus, using

Q Q

the relationship  $T \ln p = -Q/R + CT$ , we find  $C = 32.0$ . The mean value of  $Q/R$  for the three observation temperatures (see Table III) is 8240, so that  $Q_{\text{sg}} = 16300$  cal. Now we know that  $Q_{\text{lg}} = 10100$  cal. Hence  $Q_{\text{sl}} = 6200$  cal. We see that the molecular heat of sublimation and the molecular latent heat of fusion are greatest with the high-melting, asbestos-like form, which seems to be most complex.

*The High-melting, Asbestos-like Form, dried only by Distillation.*—Before continuing the description of our experiments with the intensively dried, high-melting, asbestos-like form, we wish to state here that, starting with the not intensively dried, metastable, ice-like form, freshly distilled from a bulb of pure sulphur trioxide, and carrying out the experiment in the way described above, but in an apparatus without phosphorus pentoxide, we have easily obtained the stable, high-melting, asbestos-like form dried only by distillation.

We have examined this form to see if we could determine directly the unary vapour-pressure line of the high-melting, asbestos-like form. This proved to be impossible, for the substance behaved almost exactly like that intensively dried by phosphorus pentoxide. As is mentioned in our first paper on this subject, the literature states that the substance we call the high-melting, asbestos-like form, not intensively dried, shows a very slowly rising vapour pressure. Now, as this substance was of course separated from the ice-like form by distilling off the latter, it was likely that this distillation process was sufficient to lead to the very dry state necessary for the existence of the high-melting, asbestos-like form. Our method of transforming the ice-like form into the high-melting, asbestos-like form is a distillation process repeated several times and therefore it was to be expected that our preparation would be extremely dry.

*The Intensively Dried, High-melting, Asbestos-like Form* (Second part).—We have already mentioned that in preparing the intensively dried, high-melting, asbestos-like form the last traces of all other forms are distilled off. In this process a part of the high-melting, asbestos-like form is evaporated also and the result is a high-melting, asbestos-like form of very low vapour pressure, constant at the ordinary temperature but rising perceptibly at temperatures above  $30^\circ$ .

We have studied this phenomenon more closely. In an apparatus filled with the intensively dried, high-melting, asbestos-like form which had stood some weeks in a thermostat at  $50^\circ$  the vapour pressure had risen to 591 mm. Hg., and was still rising very slowly. A part of the high-melting, asbestos-like form was now distilled off by cooling one of the condensing tubes in liquid air. After this tube

had been sealed off, and the apparatus replaced in the thermostat, the vapour pressure was found to have decreased enormously, namely, from 591 mm. to 37 mm. Hg. The vapour pressure, however, rose and readings made at intervals gave results which are represented graphically in Fig. 9.

The vapour pressure has risen above the initial pressure, in agreement with the fact that at the start the vapour pressure was still rising, although very slowly. The fact that the vapour pressure decreases so greatly on partial distillation proves that the high-melting asbestos-like form behaves as a mixed crystal consisting of at least two components differing largely in vapour pressure. These components must be pseudo-components, since after partial distillation the vapour pressure is not constant but rises, proving

FIG. 9.

that a more volatile part is formed from a less volatile part. Consequently the state for which the vapour pressure is abnormally low is a disturbed state of the stable, solid aggregation of the sulphur trioxide system.

As mentioned already, the unary melting point of the high-melting, asbestos-like form under its own vapour pressure is  $62.2^\circ$ , the pressure being 174.3 cm. Hg. Since it is possible to obtain different states of this high-melting asbestos-like form with very low vapour pressure it was important to determine the temperatures at which melting occurred. Since the glass spring is apt to be broken by a sudden rise of vapour pressure, the experiments were carried out very carefully, the temperature of the thermostat being raised slowly and continuously, so that each experiment lasted 2 or 4 days. Although this slow working is not favourable for producing the largest effect, the results in Table IV were obtained.

Thus the initial melting points lie respectively  $9^\circ$ ,  $19^\circ$  and  $26.5^\circ$  above the unary melting point of the high-melting, asbestos-like form under its own vapour pressure. With more rapid working it should not be difficult to realise still higher initial melting points.

TABLE IV.

Preparation.	Initial m. p.	Vap. press. (cm. Hg) at initial m. p.	$T \ln p.$	Vap. press. (cm. Hg) of the liquid if in inner equilibrium.
I.	71.0°	192	2601	266.0
II.	81.0	212	2711	400.2
III.	88.8	227	2796	642.7

A very remarkable phenomenon is that as soon as melting begins the vapour pressure rises so rapidly that it is very difficult to prevent the glass spring from being broken. This phenomenon had been expected, for we had already observed that, although the intensively dried liquid phase could behave as a mixture at relative low temperatures, at higher temperatures, *e.g.*, above 50°, the establishment of the inner equilibrium in the liquid took place rapidly. According to the theory of allotropy the liquid initially produced by the melting of a disturbed state of the high-melting, asbestos-like

FIG. 10.

form with a very low vapour pressure, due to the low concentration of the volatile pseudo-components, is a liquid, co-existing with this disturbed solid state, also having an abnormally low vapour pressure, since it contains little of the more volatile pseudo-component. Now, whilst the velocity of establishment of inner equilibrium in the solid, intensively dried, high-melting, asbestos-like form is slow even at, *e.g.*, 81°, inner equilibrium will be established with great rapidity in the liquid. For this state, the vapour pressure at 81° is 400.2 cm. Hg (value calculated by interpolation), so that, when melting begins at 81°, at a vapour pressure of 212 cm. Hg, the vapour pressure must rise considerably at constant temperature.

The determination of the temperature and pressure at which the disturbed solid state under consideration begins to melt is very important, for it is evident that these points, where a disturbed solid state co-exists with liquid and vapour (also not in inner equilibrium), are points on a three-phase line in the pseudo-system.

Though the equation  $d \ln p/dT = Q/RT^2$  does not hold for a

three-phase equilibrium, the curve of  $T \ln p$  plotted against  $T$  is a straight line, as Fig. 10 shows.

As is demonstrated in detail in the "Theory of Allotropy" (p. 18, Fig. 24; p. 28, Fig. 41), the unary melting point under vapour pressure is situated where the unary vapour pressure curve, *i.e.*, the vapour pressure curve of the liquid phase in inner equilibrium, meets a three-phase line for the co-existing solid, liquid, and vapour.

FIG. 11.

Plotting  $T \ln p$  against  $T$  both for the three-phase system and for the unary liquid system we obtain Fig. 11, showing the intersection of these lines at  $62.25^\circ$  and  $174.3$  cm. Hg. This is in complete agreement with our experiments mentioned on p. 1115.

*Initial Melting Points of the Highly Disturbed States of the High-melting, Asbestos-like Form.*

In the vapour pressure determinations of the disturbed states of the high-melting, asbestos-like form the rate of heating was very

slow, especially at higher temperatures, in order to prevent the glass spring from being broken. To ascertain at what temperatures melting would occur if the disturbed substance was heated less slowly, some tubes were filled with the intensively dried, high-melting, asbestos-like form, disturbed as much as possible by partial distillation, in the same way as was done in our vapour-pressure apparatus. After being sealed off, these tubes were placed in a stirred oil-bath, the temperature of which was slowly raised. The temperatures at which melting began are in Table V.

TABLE V.

Tube.	Initial m. p.	Vap. press. (cm.) at the moment melting began.	Vap. press. (cm.) of the liquid in inner equilibrium.
I.	65.0°	179.1	198.7
II.	77.0	203.7	344.7
III.	95.0	238.8	703.6

It is seen that initial melting points are realised up to 33° above the melting point of the same substance if in inner equilibrium. These experiments were dangerous, since, as has already been mentioned, the liquid formed establishes inner equilibrium and the pressure rises suddenly to relatively high values.

To demonstrate this we have inserted columns three and four in Table V. The third column shows the pressure at the moment the liquid is formed (the pressure on the three-phase line at the temperature considered here), and the fourth column shows the pressures reached when the liquid formed has established inner equilibrium. In the last case, the pressure rises from 3.14 atm. to 9.24 atm. Obviously the increase of vapour pressure takes place very rapidly and in fact caused a very serious explosion on one occasion.

#### *The Position of the Unary System in the Pseudo-system.*

In our first paper on this subject (*loc. cit.*) and in the previous pages of this paper we have described the investigations leading to our knowledge of the  $P$ - $T$  diagram of the unary system sulphur trioxide with regard to the equilibria in the vapour phases.

The schematical diagram is shown in Fig. 12.

Further it has proved that the intensively dried phases of sulphur trioxide behave like the phases of a mixture. The continuous change in the vapour pressure of the ice-like form caused by distillation enabled the region of the pseudo-system, to which this form belongs, to be studied. It is the region of a dissociable compound, forming mixed crystals which, if behaving as a unary substance, are a little richer in the more volatile pseudo-component than is the ordinary compound.

As regards the high-melting, asbestos-like form, this stable modification exhibits the phenomenon of falling vapour pressure on partial distillation even more strongly than the ice-like form, and by studying the states of different vapour pressure we found another part of the pseudo-system, namely, that to which the high-melting, asbestos-like form belongs. We realised also a part of a three-phase line for co-existing vapour-liquid-solid, the last phase of which is a mixed crystal of variable composition.

The unary, high-melting, asbestos-like modification is a mixed crystal of the same pseudo-components, with this peculiarity, that the pseudo-components are in inner equilibrium.

FIG. 12.

$S_{\alpha}$  = ice-like form;  $S_{\beta}$  = low-melting, asbestos-like form;  $S_{\gamma}$  = high melting, asbestos-like form.

As to the ice-like form, we were fortunate enough to be able to study the larger part of the three-phase line of this form, from which the conclusion could be drawn that the solid co-existing phase was a compound.

The three-phase line of the high-melting, asbestos-like form could only be studied to a small extent, and so far we do not know whether this form is a mixed crystal of a compound or a mixed crystal of the high-melting pseudo-component. For the present, this does not matter, and we will assume here the latter simple case.

The low-melting, asbestos-like form, which, as already stated, is easily obtained so long as the sulphur trioxide has not been intensively dried, does not appear or appears only in very small quantity if this has been intensively dried. The three-phase line to which the unary melting point under its own vapour pressure, i.e., the triple point, of this form belongs therefore cannot be studied until this form, prepared in the not intensively dried state, is intensively dried. This drying will take several years and therefore we

cannot say whether the low-melting, asbestos-like form is a mixed crystal of a compound or a mixed crystal of a second series of mixed crystals of the highest-melting pseudo-component.

Though the answer to this question will be very interesting, it can have very little influence on the pseudo-system and the situation of the unary system in it which can be deduced from our observations.

In one or two reviews of "The Theory of Allotropy" appears the criticism that the phenomenon of allotropy is regarded as being very complicated. Now it is most remarkable that by chance the first system that could be studied more closely, thanks to the ease of drying, not only gives a strong confirmation of the theory but also shows that the pseudo-system of the so-called simple substance sulphur trioxide is much more complex than the most complicated case dealt with in the theory mentioned above.

FIG. 13.

We will start with the  $P$ - $T$  diagram (Fig. 13). It is the diagram of a system of two pseudo-components in which two dissociable compounds appear. The minimum melting points of the compounds, however, are metastable, since the three-phase lines intersect at pressures situated above them.

The case we have to consider here is not one of the simple cases dealt with in the "Theory of Allotropy" (pp. 28, 34), but the much more complicated one following from these cases if compounds are formed.

$a$  is the triple point of the pseudo-component  $\alpha$ , and  $k$  is the triple point of the pseudo-component  $\beta$ . These points are connected by four three-phase lines,  $ae$  representing the three-phase line for the co-existing system  $\alpha$ -mixed crystals + liquid + vapour;  $egg'$  the three-phase line for the co-existing system  $\alpha\beta$ -mixed crystals + liquid + vapour;  $ghh'$  the three-phase line for the co-existing system

$\alpha\beta$ -mixed crystals + liquid + vapour; and  $hk$  the three-phase line for the co-existing system  $\beta$ -mixed crystals + liquid + vapour. We see that the greater part of the three-phase line  $ghh'$  represents metastable states.

The position of the unary system in this pseudo-system is given by thick lines. The line ABCDE is the vapour-pressure curve for the liquid in inner equilibrium. Where this curve meets a three-phase line of the pseudo-system a three-phase co-existence of the unary system appears. Every one of the three phases is in inner equilibrium or, in other words, there appears a unary melting point under its own vapour pressure (a unary triple point). The first meeting takes place at D, the stable unary melting point under its own vapour pressure. Further, the metastable part of the unary vapour-pressure line of the liquid still meets two metastable three-phase lines, one at C and the other at B. These points are metastable unary melting points under vapour pressure. At every unary melting point under vapour pressure, or triple point, three two-phase lines meet. The stable sublimation curve, D'D, the stable vapour-pressure curve of the liquid, DE, and the stable melting curve, DF, meet in the stable triple point and the three curves which meet at the two metastable triple points C and B are metastable.

This figure now represents substantially the  $P$ - $T$  diagram of the pseudo-system of sulphur trioxide and the position of the unary system in that pseudo-system. ABCDE is the vapour-pressure line of liquid sulphur trioxide in inner equilibrium. A'B is the vapour pressure line of the ice-like form in inner equilibrium, and the three-phase line  $egBg'$  that of the pseudo-system, which is a three-phase line for the co-existence of mixed crystals of a compound-liquid-vapour. C'C is the vapour pressure line of the low-melting asbestos-like form in inner equilibrium, and the three-phase line  $ghGh'$  that of a mixed crystal of a compound + liquid + vapour, but it is also possible that instead of a mixed crystal of a compound, series of mixed crystals of the  $\beta$ -pseudo-component are existing—which, however, does not change our diagram.

D'D is the vapour pressure line of the high-melting, asbestos-like form in inner equilibrium, and  $hDk$  is a three-phase line of the pseudo-system for the co-existing system mixed crystals of the  $\beta$ -pseudo-component + liquid + vapour.

It is possible that here, instead of mixed crystals of the  $\beta$ -pseudo-component, mixed crystals of another compound are co-existing, but as we do not know this, we will assume here the simplest case. Moreover, for an insight into the connexion of the pseudo- and unary systems this question is of little importance.

At two places now we have been able to penetrate the pseudo-

system, (1) in the region to which the ice-like form belongs, and (2) in the region to which the high-melting, asbestos-like form belongs.

By distilling off the intensively dried, ice-like form compositions different from that of the unary ice-like form could be obtained and so it was possible to determine a part of the three-phase line  $egBg'$ .

FIG. 14.

By distilling off the intensively dried, high-melting, asbestos-like form, enormously high effects were realised and states were obtained the vapour pressures of which were reduced up to  $1/15$  of the vapour pressure at inner equilibrium at the same temperature. In this connexion vapour-pressure lines could be realised lying far below the unary vapour-pressure line  $D'D$ .

This phenomenon enabled us, by continuing these curves, to

determine a part of the three-phase line  $kDk$  of the pseudo-system. Thus the curve  $Dk$  could be determined over a range of about  $30^\circ$ . The  $P$ - $T$  diagram considered here is a diagrammatic one. Drawing the observed curves of the most interesting part just as they have been found, we get the  $P$ - $T$  diagram in Fig. 14.

Finally we give diagrammatically the melting-point figure (Fig. 15) corresponding with the constant pressure indicated in the  $P$ - $T$  diagram (Fig. 13) by  $p_1$ .

Reference to the "Theory of Allotropy" (p. 36) will render this melting-point figure comprehensible at once.

In connexion with our  $P$ - $T$  diagram two compounds appear giving mixed crystals. The melting points of these compounds are situated in metastable regions. The line  $LL_1L_2L_3$  specifies the inner equilibria in the liquid at different temperatures. Where this line meets a melting-point curve of the pseudo-system a unary melting point appears. Three such meetings take place, one at  $L_1$ , a second at  $L_2$ , and a third at  $L_3$ . The co-existing phases at the unary stable melting equilibrium, indicated

by the liquid phase  $L_1$  and the solid phase  $S_1$ , represent the melting equilibrium of the high-melting, asbestos-like form.\* Similarly,  $L_2$  and  $S_2$  indicate the metastable co-existing phases of the low-melting, asbestos-like form at the metastable unary melting equilibrium, and  $L_3$  and  $S_3$  represent the same for the ice-like form. The lines  $S_1S_1'$ ,  $S_2S_2'$ , and  $S_3S_3'$  specify the inner equilibria of the

\* We prefer here to speak of melting equilibrium and not melting point, since in the  $T$ - $X$  diagram the melting phenomenon is indicated by two points, one representing the solid and the other the liquid phase.

stable and of the two metastable solid states at different temperatures, under constant pressure. Our  $P$ - $T$  and  $T$ - $X$  diagrams do not show a eutectic, which is most probable if  $\beta$  is a polymeride of  $\alpha$ .

It appears from our study of sulphur trioxide that the "Theory of Allotropy" has not represented the phenomenon as more complicated than it is. From the experiments of H. B. Baker and Mrs. Baker as well as our own, it was to be expected that a study of substances in an intensively dried state would offer the greatest chance of finding out something about the complexity of the so-called simple substances and we have found that the two first substances which could be obtained easily in an intensively dried state, namely, sulphur trioxide and phosphorus pentoxide, showed the complexity in a most distinct way.

Nature is very complex; and the old theory of allotropy is not satisfactory, for it cannot be assumed that we have studied accidentally the only substances showing complexity. We have studied the substances most easily dried, and we may expect that other substances in the intensively dried state will also show complexity, for there is little doubt that complexity is a general phenomenon.

In the next paper we shall deal with the results of our X-ray investigations.

#### *Summary.*

The investigation of the ice-like form of sulphur trioxide has been completed. The unary sublimation curve and the unary vapour-pressure line of the liquid having been determined, the heat quantities can be calculated. The unary triple point is at  $16.8^\circ$  and 158.5 mm. Hg.

The low-melting, asbestos-like form has been studied in the not intensively dried state, in which it is in inner equilibrium, so that here also the heat quantities can be calculated. The unary triple point of this form is at  $32.5^\circ$  and 398 mm. Hg.

The intensively dried, low-melting asbestos-like form cannot be prepared from the intensively dried, ice-like form; instead of the low-, the high-melting form always appears. The intensive drying of the low-melting asbestos-like form must be done with the substance in the solid state, and will take perhaps several years.

The high-melting, asbestos-like form has been studied closely in the intensively dried state. It exhibits more strongly than any other form the property of diminishing vapour pressure on distillation. A decrease from 59.1 to 3.7 cm. Hg has been observed.

The abnormally low vapour pressures remain constant at room temperature. But at higher temperatures the vapour pressure increases with a velocity which decreases with the time. This proves the velocity of the establishment of the inner equilibrium

to be imperceptibly slow at  $18^{\circ}$ . At higher temperatures, however, this velocity increases, and becomes manifest in the increasing vapour pressure, until inner equilibrium is reached. The vapour tensions asymptotically approach final values, being the values corresponding to inner equilibrium. The unary sublimation curve of this form has thus been found and the heat quantities have been calculated. The unary triple point of this form is at  $62.2^{\circ}$  and 174.3 cm. Hg.

In a second section the intensively dried, high-melting asbestos-like form has been considered more closely, and the phenomenon of diminishing vapour pressure on distillation studied in detail. The initial melting points (and the corresponding vapour pressures) of states of different low vapour-pressures lie up to  $33^{\circ}$  above the melting point of the same substance if in inner equilibrium.

The observed phenomena prove that the high-melting asbestos-like form is a mixed crystal of at least two pseudo-components differing widely in volatility and melting point.

Application of the theory of allotropy to these results enables the position of the unary system in the pseudo-system to be deduced. This position is given in a  $P$ - $T$  diagram and in a  $T$ - $X$  diagram and by its means the observed phenomena can easily be demonstrated.

This study shows most clearly that nature is very complex, and the old simple theory, being unsatisfactory, is to be replaced by the theory of allotropy.

## CXLVI.—*Preparation of Nickel Membranes for Ultrafiltration.*

By JOHN MANNING.

THE membranes which have hitherto been used for ultrafiltration have usually been prepared by impregnating filter-papers with nitrocellulose dissolved in acetic acid or in a mixture of ether and alcohol. They can neither be used at high temperatures nor with solvents such as acetone. In this communication are described membranes, prepared by the electrical deposition of nickel on fine nickel gauze, which can be used at high temperatures and in the presence of organic solvents.

The apparatus shown in the figure is made of nickel-plated phosphor-bronze. The two flanges are bolted together with the membrane between. The membrane alone could not stand the

high pressure involved and was therefore supported by a nickel disc through which several holes had been drilled. Various materials were tried as washers, but the most suitable was a pure silver-wire ring softened by annealing. This was flattened between the flanges when they were screwed together and made a very satisfactory joint. The apparatus could be used with pressures up to sixteen atmospheres.

*Ultrafilter.*  
A Screw for pressure gauge. B Holes for  $4\frac{3}{8}$ " bolts. C Silver ring. D Membrane. E Silver washers. F Perforated nickel support for membrane. G Asbestos compressed against glass tube. H Thick glass tube.

As a foundation for the membrane, fine nickel gauze (mesh 200) and, in later experiments, phosphor-bronze gauze was used.

In the early work, a nickel sheet of suitable size was made the anode in a solution which was agitated by using the cathode itself as a vertical stirrer. The solutions were similar to those used for ordinary nickel-plating, containing, for example, 120 g. of nickel sulphate, 22.5 g. of ammonium chloride, and 15 g. of boric acid per litre. With the current densities first used, smooth, even, and hard deposits were obtained, perforated with small holes. If the plating process was continued until these were filled in, the rest of the membrane became entirely impermeable. With high current densities, *i.e.*, 2 amps. per 4 sq. in., at 3.3 volts very irregular deposits were obtained. As the current density and *E.M.F.*

were decreased, the character of the deposit changed; it became less hard and darkened in colour and, at 0.3—0.5 amp. per 4 sq. in. at 0.9—1.1 volts, the resulting membranes were almost black and fairly regular. The suitability of the above membranes for ultra-filtration was tested by means of the following experiments.

A colloidal solution of silver in stearic acid, prepared by the reduction of silver stearate suspended in the acid (Giles and Salmon, *J.*, 1923, 123, 1600), was filtered at 140° under a pressure of 2 atmospheres. Perfectly clear stearic acid came through, the colloidal

metal being entirely retained as a blue deposit on the membrane. A second experiment was carried out with a solution in which only partial reduction had taken place, so that there was present a considerable excess of silver stearate. In this case, silver was found in the filtrate, which was colourless, showing that, although the colloidal metal had been retained, the silver stearate, which we believe to exist as simple molecules, passed through the membrane.

These membranes would also successfully filter arsenic sulphide and ferric hydroxide hydrosols, but they were not satisfactory with solvated organic colloids, such as gelatin in water, or nitro-cellulose in ether and alcohol. It seemed probable that filtration was taking place through a small number of holes, whilst the rest of the membrane was practically solid. These holes, which would retain inorganic solids and permit the passage of the solvent, became rapidly blocked up with gelatin. It was therefore necessary to obtain a more porous and open deposit, and experiments were carried out to determine the effect of changes in the composition of the plating bath on the character of the deposit.

The presence of nickel chloride is usually considered to give a soft deposit; consequently, membranes were prepared by plating in solutions of that salt (100 g. of nickel chloride, 20 c.c. of concentrated hydrochloric acid, and 1500 c.c. of water), hydrochloric acid being added to give a continuous evolution of gas at the cathode and thus increase the porosity of the deposit. At low current densities, the membranes were more smooth and even than with higher current densities, but contained green patches due to the high concentration of chlorine ions present; consequently, in later experiments, sulphuric acid was used instead of hydrochloric acid, and nickel sulphate was substituted for a part of the chloride. Table I shows the effect of varying the relative proportion of chloride and sulphate in the plating bath, the most effective membranes being obtained when the ratio of sulphate to chloride was 50 to 80.

The effect of varying the hydrogen-ion concentration on the nature of the membrane was also investigated. In one experiment, boric acid was used instead of sulphuric acid, in the hope that it would act as a hydrogen-ion regulator. Deposits in this case were hard with bright streaks and not efficient for filtration. In later experiments, the following plating mixture was used: 100 g. of nickel sulphate, 80 g. of nickel chloride, 20 g. of sodium acetate ( $3\text{H}_2\text{O}$ ), and 1500 g. of water. The membranes which were obtained were suitable for ultrafiltration and were much less brittle than those prepared from previous solutions. With a still larger proportion of acetate the membranes became greenish and

TABLE I.

The bath contained 1500 c.c. of water, 5 c.c. of concentrated sulphuric acid, and weights (g.) of nickel chloride and sulphate as indicated.

Current densities : 1.1 amps. down to 0.4 amp. per 4 sq. in. Potential difference : 3.5 volts for 1 hr. and 2 volts for about 18 hrs.

Bath.		Remarks on membranes.		
$\text{NiSO}_4$ .	$\text{NiCl}_2$ .	Appearance.	Thickness.	Filters
0	100	Black.	Flimsy.	Night blue.
20	100	Greenish.	Denser.	
40	80	"	"	Night blue and gelatin.
50*	80	Brown, sometimes greenish.	"	Night blue and cellulose acetate.
120	20	Irregular.		
120	0	No deposit from acidified solutions.		

\* The 3rd and 4th membranes prepared from this bath were much better than the first two. The bath was filtered and acidified with 5 c.c. of concentrated sulphuric acid before each successive plating operation.

still more pliable. In the next paragraph are described experiments carried out with these membranes.

*Ultrafiltration of Cellulose Acetate in Acetone and Water.*—Cellulose acetate was dried and dissolved in a mixture of acetone and water, the acetone having been purified by the method of Werner and Shipsey (J., 1913, 103, 1255). Solutions of known concentration were prepared in tightly-corked flasks and, to prevent evaporation, were transferred to the ultrafilter through glass tubing. The filtration of 3 to 5 c.c. took from 10—15 hrs. at a pressure of 10—14 atmospheres and, to avoid loss of acetone by evaporation, the filtrate was allowed to fall directly into a known weight of water. The acetone was estimated by Messenger's method (*Ber.*, 1888, 21, 3386). The results of three experiments are shown in Table II, the figures in the column "Cellulose acetate" showing the weight (g.) added to 100 g. of mixed acetone and water.

TABLE II.

Initial concentrations.			Concentrations after ultrafiltration.	
Cellulose acetate.	Acetone %.	Water %.	Acetone %.	Water % (by diff.).
3.25	74.9	25.1	75.5	24.5
5.41	68.0	32.0	68.3	31.7
3.73	71.1	28.9	71.7	28.3

The analytical error is about 1%.

The concentration of the acetone would be expected to fall on

account of its volatility, but, on the other hand, there appears to be a slight increase in concentration in the filtrate, indicating apparently that water is taken up by cellulose acetate (from these mixtures, at any rate) to a greater extent than acetone.

*Ultrafiltration of Sodium Stearate.*—Solutions of sodium stearate of concentrations lying between  $N/2$  and  $N/6$  were ultrafiltered at a temperature between  $80^{\circ}$  and  $90^{\circ}$ , the whole ultrafilter being surrounded by an electric oven. In every case, only a negligible amount of stearic acid penetrated the membrane, whilst the alkalinity of the filtrate was always less than  $0.01N$ , indicating that membrane hydrolysis had not taken place to any considerable extent.

Solutions of casein and gelatin were also successfully filtered by means of this membrane. In the case of  $0.5\%$  gelatin sols, extremely small quantities of gelatin passed through the filter at  $16^{\circ}$ , but, on raising the temperature to  $45^{\circ}$ , the gelatin almost entirely passed through. This means that the particles present at the higher temperature are too small to be retained. If we accept the view, which will be discussed in a later communication, that the difference between gelatin at these two temperatures is due to the secondary linking up of particles, then the primary particles of gelatin are considerably smaller than is usually believed.

*Determination of Size of Pores.*—One of Bechhold's methods for the determination of the size of pores depends on the minimum air pressure which will produce bubbles through the membrane covered 1 mm. deep with water.

Some irregularities in the membranes were detected by this method, one or two large holes usually being found. In a particular case, at a pressure of 3.5 atmospheres there was bubbling at one hole, at 4 atmospheres at 5 holes, and at 4.8 atmospheres the bubbling became general. In view of the results obtained, it seems probable that these large holes are very quickly blocked up during filtration. It was observed many times that initially the colloid came through, but was retained after the first few drops.

The finest membranes obtained contained pores of between  $50-80\ \mu$ , the size increasing as the nickel sulphate content of the plating bath increased, until the average size of the pores was  $300\ \mu$ , for a bath containing 90 g. of nickel sulphate, 80 g. of nickel chloride, 1500 g. of water, and 5 c.c. of concentrated sulphuric acid.

### *Summary.*

Membranes have been prepared by nickel plating on bronze or nickel gauze which are capable of retaining most colloids on ultrafiltration. They can be used at high temperatures, and with

solvents which will attack the usual membranes. The average size of the pores can be controlled by varying the plating bath, so that they can be used for fractional filtration.

The author is indebted to the Department of Scientific and Industrial Research for a grant which enabled the above work to be carried out, and also to Mr. C. S. Salmon, who suggested the subject and continually gave very valuable advice in the course of the experiments.

KING'S COLLEGE, LONDON.

[Received, January 29th, 1926.]

## CXLVII.—*Ring-chain Tautomerism. Part XV. The Phenol-succineins and -glutareins.*

By SIKHIBHUSHAN DUTT.

IN a previous paper (Dutt and Thorpe, J., 1924, 125, 2524) it was shown that the effect of increasing complexity of the substituents R and R<sub>1</sub> in fluoresceins and rhodamines, derived from  $\alpha$ -disubstituted succinic and  $\beta\beta$ -disubstituted glutaric acids, of the following constitutions

Succinylfluoresceins; X = OH.

Succinylrhodamines; X = NMe<sub>2</sub>.

Glutarylfluoresceins; X = OH.

Glutarylrhodamines; X = NMe<sub>2</sub>.

is to diminish the tetrahedral angle ( $\theta$ ) between the directions of the two remaining valencies of the substituted carbon atom; the stability of the lactone ring is thereby progressively increased, and consequently the amount of open-chain coloured quinonoid derivative produced by the action of alkalis and acids on these compounds progressively diminishes. The results of that research, which were based on spectroscopic data, were in complete accord with the results obtained by Thorpe and his collaborators, working on the same problem from other points of view.

The phenolsuccineins (I) and phenolglutareins (II),

where  $RR_1$  represent HH, MeMe, MeEt, EtEt, and the *cyclohexane* residue, have now been prepared and their absorption maxima determined. The results obtained are in complete agreement with those found in the cases of the corresponding fluoresceins and rhodamines (*loc. cit.*) and thus serve to confirm the generalisation stated above.

Like phenolphthalein, the phenol-succineins and -glutareins described in this paper are all colourless, crystalline substances which dissolve in alkalis with a bright pink colour, the mechanism of transformation from the colourless (I) to the coloured form (III) being the same as in the cases of the fluoresceins and rhodamines, *viz.*, fission of the lactone ring and formation of a quinonoid substance. The red quinonoid form is stable only in alkaline solution, the stability being due to salt formation at the carboxyl group, and on acidification reverts to the original colourless lactone form.

Green and Perkin have shown (J., 1904, 85, 398) that the gradual disappearance of the deep pink colour produced by treating phenolphthalein with an excess of alkali is due to the formation of a carbinol salt,  $(ONa \cdot C_6H_4)_2C(OH) \cdot C_6H_4 \cdot CO_2Na$ , produced by hydration of the quinonoid form,  $ONa \cdot C_6H_4 \cdot C(C_6H_4 \cdot O) \cdot C_6H_4 \cdot CO_2Na$ . On acidifying the colourless solution of the carbinol salt, the free carbinol is obtained, which spontaneously loses water and is reconverted into the original lactone.

In presence of alkali, the phenolsuccineins and, very much more rapidly, the phenolglutareins undergo changes similar to the above, only a slight excess of alkali being necessary to produce them. In fact, the normal red quinonoid salts of the phenolglutareins are unstable in solution even in the absence of an excess of alkali. These salts, which have an alkaline reaction in solution, probably dissociate into the monoalkali salts and alkali hydroxide:

The liberated alkali then brings about hydration at the quinonoid linking, the carbinol derivatives being formed. The red quinonoid forms, however, are more stable in very dilute solution.

The *carbinol* derivative of phenolglutarein,

has been isolated as a colourless, crystalline substance. It is stable under ordinary conditions, but is converted into the lactone by the action of heat or dehydrating agents, such as concentrated hydrochloric or sulphuric acid, anhydrous zinc or aluminium chloride, and stannic chloride. The *carbinol* derivative of phenol- $\beta$ -methylglutarein is very unstable and, although capable of isolation, passes into the lactone in the course of a few minutes. No carbinol derivative could be isolated from any of the remaining phenol-succineins or -glutareins.

The rate of hydration of the phenolglutareins under the influence of alkali, the end-point being where the red solution became colourless, was, under exactly similar conditions, slowest in the case of phenolglutarein, and progressively increased with the complexity of the substituents in the glutaric acid residue.

From the table (p. 1139) showing the relative rates of hydration of the various phenolglutareins in different concentrations of alkali, it will be seen that in dilute solution the rate is almost unaffected by the concentration of the alkali, thus proving that the change is a unimolecular one. The hydration of the phenolsuccineins was so slow and irregular that trustworthy measurements could not be made.

Stannic chloride is the only agent that has been found to bring about the condensation of phenol with succinic and glutaric acids and their substituted derivatives in the desired direction and in a satisfactory manner; with fused zinc chloride and with hydrogen chloride, the yields obtained are practically valueless. Strong sulphuric acid and phosphorus oxychloride produce the diphenyl esters of these acids, and anhydrous aluminium chloride produces complex pyrone derivatives which are probably similar in constitution to *o*-phenolphthalein anhydride.

#### EXPERIMENTAL.

*Phenolsuccinein*.—The preparation of this compound is attended with difficulty on account of the ease with which it becomes hydrated to the carbinol derivative and subsequently further decomposed into simpler substances. Dilute alkalis effect this change very quickly; even long contact with water, dilute alcohol, or dilute acids brings about the same transformation. The effect is quickened

by heating. But once the compound has been isolated and dried, the rate of hydration becomes very much slower. After a trial of various methods the following was adopted for the preparation of this compound :

A mixture of 12 g. of succinic acid, 25 g. of phenol, and 13 c.c. of stannic chloride was heated on the steam-bath for 4 hours, the melt treated with pure dry ether, and the insoluble salmon-coloured crystalline compound filtered off and washed with absolute alcohol-ligroin (1 : 3 by vol.). The almost colourless residue, containing tin salts, was dissolved in cold absolute alcohol, dry hydrogen sulphide passed through the solution, the excess of the gas removed by carbon dioxide, and the filtered solution concentrated in a vacuum at the ordinary temperature; addition of light petroleum then precipitated *phenolsuccinein* in colourless needles. This compound and the succeeding ones are described in the tables.

*Phenol-as-dimethylsuccinein*.—A mixture of *as*-dimethylsuccinic acid (1 mol.), phenol (2 mols. plus 20% excess), and stannic chloride (1 mol. plus 20% excess) was heated on the steam-bath for 4 hours, the melt poured into water, and the excess of phenol distilled in steam; the condensation product solidified, on cooling, to a mass of crystals in a matrix of brittle, dark brown, resinous matter. The latter was removed by washing the finely-powdered product with absolute alcohol-ligroin (b. p. 70—80°); the almost colourless crystalline residue recrystallised from alcohol (animal charcoal) in long, colourless, silky needles.

Phenolsuccineins were obtained from *as*-methylethyl-, *as*-diethyl-, and *as*-cyclohexane-succinic acids by exactly similar methods.

*Phenolglutarein*.—The rapid hydration of this compound and subsequent decomposition into simpler substances make its preparation exceedingly difficult.

The *lactone form* was obtained from a mixture of glutaric acid (13 g.), phenol (25 g.), and stannic chloride (13 c.c.) by the method for preparing phenolsuccinein. It crystallised from absolute alcohol-ligroin in colourless, silky needles.

*Quinonoid form*. The ethereal filtrate in the preceding preparation was shaken with concentrated hydrochloric acid to remove tin salts, the ether distilled off, and the residue, after addition of an equal volume of 50% sulphuric acid, distilled in steam until phenol ceased to pass over. The red, sticky substance in the distilling flask was extracted with ether, the ethereal solution dried, diluted with ligroin, and allowed to evaporate at the ordinary temperature. After a month, the gummy residue had partly solidified, with separation of small crystals. These were spread

on a porous plate, washed free from the sticky mother-liquor with absolute alcohol-ligroin (1:4 by vol.), and recrystallised from ether; glistening, red prisms were thus obtained which, on heating, decomposed without melting. The substance changed into the colourless lactone form after contact with concentrated hydrochloric acid for several days or when its solution in concentrated sulphuric acid was poured into ice-cold water (Found: C, 71.5; H, 5.8.  $C_{17}H_{16}O_4$  requires C, 71.3; H, 5.7%).

*Carbinol form.* The sticky mother-liquor was extracted from the porous plate by sodium carbonate solution, in which it dissolved with a bluish-red colour, but the solution soon became colourless. On acidification, a colourless solid was precipitated which crystallised from dilute alcohol in glistening, white needles, m. p.  $220^{\circ}$  (Found: C, 67.3; H, 5.8.  $C_{17}H_{18}O_5$  requires C, 67.5; H, 5.9%).

The carbinol can also be prepared by dissolving the quinonoid or the lactone form in aqueous sodium carbonate or hydroxide and, after the dark red colour has disappeared, acidifying the solution with hydrochloric acid. An alkaline solution of the carbinol quickly decomposes in contact with air; from the products of decomposition phenol and *p*-hydroxybenzoic acid have been isolated.

*Phenol- $\beta$ -methylglutarein.*—Only the lactone form of this compound was obtained by the method for preparing phenolglutarein. The carbinol derivative was obtained by keeping a solution of the lactone in dilute aqueous sodium hydroxide until the pink colour had disappeared, and then acidifying with dilute hydrochloric acid, filtering off the precipitated lactone, and extracting the filtrate with ether; on rapidly evaporating the ether in a current of air, the carbinol was obtained as a colourless, crystalline substance which in the course of about 15 minutes changed completely into the lactone. Immediately after isolation, it dissolves in aqueous sodium hydroxide, forming a colourless solution, but in a few minutes this begins to exhibit the red colour of the quinonoid form. Under no conditions could the carbinol be obtained in a stable form.

*Phenol- $\beta\beta$ -dimethylglutarein.*—A mixture of 16 g. of  $\beta\beta$ -dimethylglutaric acid, 25 g. of phenol, and 13 c.c. of stannic chloride was heated on the steam-bath for about 4 hours; after cooling, the dark red melt was dissolved in moist ether. The ethereal solution was thoroughly washed with ice-cold dilute hydrochloric acid, water, and sodium bicarbonate solution, and then shaken with a saturated solution of sodium carbonate for 3 hours. The aqueous layer was separated, acidified with hydrochloric acid, and distilled in steam

to remove phenol. The yellow, sticky residue was extracted with ether, the ether evaporated, and the residue thus obtained was acetylated by boiling with twice its volume of acetic anhydride and a few drops of pyridine. The excess of anhydride was decomposed with water, and the viscous acetyl derivative dissolved in ether. The ethereal solution was repeatedly extracted with a 5% solution of sodium hydroxide until the extract was no longer pink. The ether was then evaporated, and the residual acetyl derivative hydrolysed by dissolving it in concentrated sulphuric acid and pouring the solution on to ice. The lactone was precipitated in pinkish-white flocks, which were filtered off, washed with water, dissolved in ether, the ethereal solution shaken with sodium bicarbonate solution, decolorised with animal charcoal, dried, and then allowed to evaporate at the ordinary temperature. Large, white, cubical crystals were obtained which were freed from the adhering sticky matter by washing with absolute alcohol-ligroin and then recrystallised from ether or dilute alcohol; large, transparent, silky prisms were thus obtained (yield about 1.3 g.).

Phenolglutareins were obtained from  $\beta\beta$ -methyleneethyl-,  $\beta\beta$ -diethyl-, and  $\beta$ -cyclohexane-glutaric acids in similar ways to the above.

*Decomposition of Phenolglutarein by Alkali.*—Phenolglutarein (5 g.) was dissolved in 200 c.c. of 10% sodium hydroxide solution, and the mixture heated under reflux for about 3 hours. The solution was diluted with water, acidified with hydrochloric acid, and distilled in steam until phenol ceased to pass over. The residual liquid, after cooling, was extracted with ether, and from the ethereal extract 0.7 g. of *p*-hydroxybenzoic acid, m. p. 213°, was obtained.

The steam distillate, which had an acid reaction, was neutralised with sodium carbonate and extracted with ether. After the evaporation of the ether, a small quantity of a liquid smelling strongly of phenol was obtained which gave all the reactions of this substance. The aqueous mother-liquor, on evaporation to dryness, yielded about 1 g. of a solid which was qualitatively shown to be a mixture of sodium butyrate with smaller quantities of sodium acetate and succinate.

Phenolsuccinein, on treatment with sodium hydroxide, behaved in an exactly similar manner. Substituted phenol-succineins and -glutareins do not yield *p*-hydroxybenzoic acid on treatment with alkali but decompose into phenol and aliphatic acids in the manner described in J., 1924, 125, 2529, for the corresponding resorcinol derivatives.

The decomposition of phenolglutarein by alkali may be represented as follows :

The succineins and glutareins are fairly easily soluble in alcohol, acetone, acetic acid, or benzene and insoluble in water or ligroin.  $\alpha$  is the absorption maximum (wave-lengths) for dilute aqueous solutions.

#### *Phenolsuccineins.*

## CXLVIII.—*Synthesis in the Thianthren Series.* *Part II.*

By MONMOHAN SEN and JÑANENDRA NATH RÂY.

THE method described in Part I (J., 1921, 119, 1959) has been applied in the synthesis of other thianthren derivatives. The reaction is apparently a general one, but difficulties are encountered in purifying the product. *Tetramethylthianthren* (I) has been obtained in the crystalline form and characterised by the preparation of its *disulphone*.

From guaiacol, *dimethoxydihydroxythianthren disulphide* (II) was obtained, the crystalline yellow sodium salt of which is sparingly soluble in water. The similar disulphide previously isolated (*loc. cit.*) was very unstable. The remarkable stability of the present compound may possibly be due to its acquiring a *p*-quinonoid constitution (III); the sodium salt forms an orange solution in water.

In view of the use of thioaniline in the dye industry, it appeared that diaminothianthren might be a valuable intermediate, and some azo-compounds derived from this base have been prepared.

#### EXPERIMENTAL.

**1:4:5:8-Tetramethylthianthren (I).**—When dry aluminium-mercury couple (from 0.3 g. of aluminium foil) was added to a mixture of *p*-xylene (6 c.c.) and sulphur monochloride (4 c.c.), the reaction became vigorous in a few minutes and hydrogen chloride was copiously evolved. The mass soon solidified almost completely and carbon disulphide (8 c.c.) was then introduced and the mixture kept at 40° during an hour. The solvent was decanted, the product decomposed with ice, and the colourless precipitate washed successively with yellow ammonium sulphide, aqueous sodium sulphite, and water, dried, and crystallised from boiling nitrobenzene. The crystals were extracted with boiling carbon disulphide, and dissolved in nitrobenzene, the last trace of sulphur being then removed by treatment with copper powder. The filtrate from the copper sulphide deposited the pure substance in colourless needles, m. p. 242° (Found: S, 23.1; C, 70.6; H, 5.8.  $C_{16}H_{16}S_2$  requires S, 23.5; C, 70.5; H, 5.8%).

The substance exhibits the normal behaviour of thianthren and dissolves in concentrated sulphuric acid to a green solution which is decolorised on dilution with water, the original compound being precipitated.

The *disulphone* was obtained by repeatedly evaporating the thianthren with an excess of nitric acid (*d* 1.4) on the steam-bath. The product was precipitated with water, washed, and crystallised from glacial acetic acid, separating in needles, which did not melt below 290° (Found: S, 18.7.  $C_{16}H_{16}O_4S_2$  requires S, 19.0%).

**3:7-Dimethoxy-2:6-dihydroxythianthren Disulphide.**—To a solution of 6.2 g. of guaiacol in 10 c.c. of carbon disulphide, 4 c.c. of sulphur monochloride, dissolved in 10 c.c. of the same solvent, were added and the amalgam prepared from 0.4 g. of aluminium was quickly introduced. The solution became deep green and a vigorous reaction ensued. After being kept at room temperature

for an hour, the mixture was warmed at 40° for some time, the carbon disulphide evaporated off, and the residue treated with water. The red oil thus obtained was dissolved in alkali. The filtered solution slowly deposited glistening, yellow leaflets. These were filtered off, dissolved in water, and the thianthren derivative precipitated by carbon dioxide. The yellow solid thus obtained crystallised from boiling alcohol in yellow, silky scales, m. p. 202° (Found: S, 33.9.  $C_{14}H_{12}O_4S_4$  requires S, 34.4%). The yield was poor.

The substance was easily acetylated by boiling with an excess of acetic anhydride and a few drops of pyridine. The *diacetyl* derivative crystallised from alcohol in needles, m. p. 165° (Found: S, 27.7; C, 47.5; H, 3.6.  $C_{18}H_{16}O_6S_4$  requires S, 28.0; C, 47.3; H, 3.5%).

*Azo-compound from Diazotised Diaminothianthren and  $\beta$ -Naphthol.*—A solution of 2 g. of diaminothianthren (*loc. cit.*, p. 1964) in 200 c.c. of water and 1 c.c. of concentrated hydrochloric acid was treated at 0° with 0.44 g. of sodium nitrite and thereafter with an alkaline solution of 0.9 g. of  $\beta$ -naphthol. The solid precipitated on acidification was crystallised from boiling benzene (Found: N, 10.6.  $C_{32}H_{20}O_2N_4S_2$  requires N, 10.1%). The deep red dye produced a dull shade on unmordanted cotton.

*Tetrazo-compound from Diaminothianthren and Resorcinol.*—Diaminothianthren hydrochloride (2 g.) was diazotised and then coupled with 0.17 g. of resorcinol in alkaline solution. The dye obtained on acidification could not be crystallised, and therefore it was purified by precipitation from an alkaline solution. The reddish-brown product did not melt below 250° (Found: N, 11.4.  $C_{24}H_{16}O_4N_4S_2$  requires N, 11.5%).

*Thianthren-2 : 6-bis(diazoaminobenzene-4'-sulphonic Acid,*

—A solution of 1.1 g. of sulphanilic acid in water containing sodium hydroxide was diluted to 200 c.c., made faintly acid, and slowly treated with a diazotised solution of 2 g. of diaminothianthren. The mixture was filtered after a time, and the filtrate made alkaline and then acidified with acetic acid. The reddish-brown dye thus precipitated was dried (Found: N, 12.8.  $C_{24}H_{18}O_6N_8S_4$  requires N, 13.6%).

Thianthren derivatives were obtained by the general method in the following cases, but the products could not be isolated free from sulphur: bromobenzene, *p*-chlorophenol, *p*-cresol, quinol dimethyl ether, *p*-tolyl methyl ether, and resorcinol dimethyl ether. The case of bromobenzene is interesting, because, unlike that in

iodobenzene (*loc. cit.*), the halogen atom is not displaced in the reaction.

We wish to thank Dr. A. F. Titley of Oxford for a gift of pure *p*-xylene.

### CXLIX.—*The Hydrates of Chromic Nitrate.*

By JAMES RIDDICK PARTINGTON and SIDNEY KEENLYSIDE  
TWEEDY.

IN the course of investigations on chromium salts, it was necessary to prepare crystals of chromium nitrate. Chromic hydroxide, precipitated from cold, saturated chrome alum solution, and washed with hot water, was dissolved in the least possible quantity of cold nitric acid (about 4*N*; compare Loewel, *J. Pharm. Chim.*, 1845, 7, 321, 401). The dark green dichroic solution thus obtained was allowed to crystallise in an open dish; after a few days it turned violet, and was then transferred to a stoppered bottle. Some three months later, it had deposited reddish-violet crystals and reverted to its original green colour. The crystals were not deliquescent and appeared through the microscope to be octahedral. After drying between filter-paper, they gave Cr, 11.2, 11.15; N, 9.0, 9.0% (determined by reduction with Devarda's alloy; very low results are obtained if the reaction is not allowed to finish in the cold after the initial warming necessary to start it) [ $\text{Cr}(\text{NO}_3)_3 \cdot 12\frac{1}{2}\text{H}_2\text{O}$  requires Cr, 11.2; N, 9.1%]. Large crystals were also grown.

The "normal" chromic nitrate described in text-books (*e.g.*, Roscoe and Schorlemmer, 1923, vol. ii, p. 1084) forms deliquescent rhombohedra,  $\text{Cr}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ . By allowing a solution of chromic hydroxide in dilute nitric acid to evaporate spontaneously, Halse (*Chem.-Ztg.*, 1912, 36, 962) obtained from a violet solution crystals of a hydrate,  $\text{Cr}(\text{NO}_3)_3 \cdot 7\frac{1}{2}\text{H}_2\text{O}$ , m. p. about 100°, which he considered to be identical with a brown, crystalline hydrate obtained by Jovitschitsch (*Monatsh.*, 1912, 33, 9), who heated ignited chromic anhydride with nitric acid (*d* 1.4) in a sealed tube for 1½ hours at 160°. It seems, however, that the crystals obtained by Halse are identical with those obtained by us and contain  $12\frac{1}{2}\text{H}_2\text{O}$ . Our crystals turned black (viewed by reflected light) at 95° and melted to a dark green liquid at 104–105°. Halse remarks that these crystals, since they are formed by the action of an acid on a hydr-

oxide, should be considered as the "normal" form of chromium nitrate in preference to the nonahydrate, which is only obtained under special conditions.

On one occasion, in a repetition of Halse's experiment, the liquid evaporated to a dark green syrup which retained its colour both on boiling and on dilution. Attempts were made to precipitate the green form of chromic nitrate from the syrup. Anhydrous ether and ether mixed with nitric acid were ineffectual, but addition of excess of absolute alcohol threw out a light green precipitate which, after drying between filter-paper, had a m. p. about 74°. No precipitation occurred on the addition of 96% alcohol. A quantity of the substance is being prepared with a view to future investigation.

We repeated Jovitschitsch's preparation with pure chromic anhydride prepared by the action of sulphuric acid on potassium dichromate (Traube, *Annalen*, 1848, 66, 165) and purified by grinding with concentrated nitric acid, draining and heating at 80° in a current of dry air. The bomb tubes used in the preparation of the nitrate are very liable to burst during the heating. On only one occasion a brown solution was obtained which deposited brown crystals on keeping in a vacuum desiccator over potassium hydroxide. On all other occasions, the ordinary blue-violet dichroic solution of chromic nitrate was obtained, which yielded crystals of the nonahydrate. The factors controlling the production of the brown solution were not discovered. The brown crystals gave a brownish-green dichroic aqueous solution; the filtrate obtained after precipitating with ammonia was pale yellow, indicating that a small portion of the chromium is present in the crystals as chromate [Found: Cr, 13.3. Calc. for  $\text{Cr}(\text{NO}_3)_3 \cdot 7\frac{1}{2}\text{H}_2\text{O}$ : Cr, 13.9%]. No crystals were available for checking this figure, or for determining the nitrogen.

Jovitschitsch remarks that the brown crystals on drying over potassium hydroxide and even over calcium chloride lose both nitric acid and water; later, he says that, after 5 days over calcium chloride,  $\text{Cr}(\text{NO}_3)_3 \cdot 4\frac{1}{2}\text{H}_2\text{O}$  is formed. We kept 0.2522 g. of the crystals over sodium hydroxide; after 4 days they turned a dull violet and weighed 0.2222 g., this weight remaining constant for 12 days [Found: Cr, 15.1; N, 12.35. Calc. for  $\text{Cr}(\text{NO}_3)_3 \cdot 4\frac{1}{2}\text{H}_2\text{O}$ : Cr, 16.3; N, 13.1%].\* None of these figures is to be regarded as final.

The viscosities,  $\eta$ , of solutions of the nonahydrate of chromium nitrate (Kahlbaum's pure; see below) were determined by the

\* Dr. A. D. Mitchell has pointed out to us that the values found are very nearly those required for  $\text{Cr}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$ .

comparative flow method at 18° and 25°. The modified Ostwald viscosimeter described by Martin was used (*Bull. Soc. chim. Belg.*, 1925, 34, 81); we have found this instrument to give very consistent results. The viscosimeter was standardised with freshly-prepared conductivity water obtained from a Bousfield still and stored in a Pyrex flask; water similarly prepared was used for making the solutions. Each viscosity ratio represents at least a dozen consecutive identical time readings or else the mean of a dozen or more readings the extreme variation of which is 0.5 second. The time of flow for water was 31.5 seconds at 25° and 36.5 seconds at 18°.  $w$  is the weight of anhydrous salt in 100 g. of water.

Temperature 18°.			Temperature 25°.		
$w$ .	$\eta/\eta_{H_2O}$ .	$\eta$ .	$w$ .	$\eta/\eta_{H_2O}$ .	$\eta$ .
29.11	1.8219	0.01948	25.37	1.6428	0.01498
26.58	1.7055	0.01823	18.58	1.4048	0.01281
23.62	1.5616	0.01669	12.61	1.2302	0.01122
19.73	1.4247	0.01523	10.98	1.1984	0.01093
15.07	1.2841	0.01373	8.99	1.1508	0.01050
9.56	1.1422	0.01221	6.05	1.1032	0.01006
7.16	1.0960	0.01172	5.93	1.0952	0.00999
4.99	1.0582	0.01131	3.58	1.0556	0.00963
3.55	1.0308	0.01102	3.18	1.0476	0.00953
			1.91	1.0238	0.00934

Measurements at higher dilutions are unsatisfactory with the method used.

The figures given in the third and sixth columns represent the absolute viscosities, obtained by multiplying  $\eta/\eta_{H_2O}$  by  $\eta_{H_2O}$ . Thorpe and Rodger (*Phil. Trans.*, 1894, 185, 397) give 0.00891 and 0.010563 dyne/cm.<sup>2</sup> at 25° and 18°, respectively, for  $\eta_{H_2O}$ ; we have used the more recent values determined by Leroux (*Ann. Physique*, 1925, 4, 163), namely, 0.00912 and 0.01069 dyne/cm.<sup>2</sup>, the former figure being calculated on the assumption that the viscosity varies linearly with the temperature over the range 23.2° to 26.4°, for which  $\eta = 0.00949$  and 0.00883 dyne/cm.<sup>2</sup>, respectively. The above values for the viscosities of chromium nitrate solutions lie on smooth curves.

Kahlbaum's pure chromic nitrate crystals,  $Cr(NO_3)_3 \cdot 9H_2O$  (Found: Cr, 13.0; N, 10.7. Calc.: Cr, 13.0; N, 10.5%), freed from adhering nitric acid by pressing between filter-paper, melted to a dark green liquid at 66–66.5°; there were no signs of fusion at the previously recorded m. p., 36.7° (Ordway, *Amer. J. Sci.*, 1850, 9, 30). The fused salt on cooling passed through an indefinite pasty stage extending from about 37° to 20°, and gradually changed in colour to a greyish-green. On continual stirring, the temperature rose to 30–33° and slow crystallisation set in. The crystals were violet. These temperatures are slightly different from

those recorded by Ordway, who found that the green liquid first deposited crystals at  $24^{\circ}$ , the temperature rising gradually to  $34^{\circ}$ . A crystal picked out of the green paste melted sharply at  $66.5^{\circ}$  and was evidently, therefore, a crystal of nonahydrate. Apparently no transition to a second hydrate takes place at the m. p.

Chromic nitrate nonahydrate crystals may be readily prepared by dissolving violet chromic chloride in slightly more than the theoretical quantity of hot strong nitric acid and storing in a vacuum desiccator over sodium hydroxide. If excess of the chloride is used, the product contains small quantities (0.1%) of chlorine. No chromic chloride nitrate similar to that prepared by Schiff by dissolving basic chromic chloride in nitric acid (*Annalen*, 1862, 124, 177) was obtained.

An X-ray examination of chromium nitrate and other chromium salts is being undertaken. It is expected that information of importance for the theory of co-ordination will be obtained with the three isomeric hexahydrates of chromic chloride, all of which have been prepared.

#### *Summary.*

1. The solution obtained by dissolving chromic hydroxide in nitric acid yields crystals of  $\text{Cr}(\text{NO}_3)_3 \cdot 12\frac{1}{2}\text{H}_2\text{O}$ , m. p.  $104-105^{\circ}$ , and not  $\text{Cr}(\text{NO}_3)_3 \cdot 7\frac{1}{2}\text{H}_2\text{O}$ , as previously described.

2. The viscosities of some chromic nitrate solutions at  $18^{\circ}$  and  $25^{\circ}$  are recorded.

3. Chromic nitrate nonahydrate crystals melt at  $66-66.5^{\circ}$ , no transition to a second hydrate occurring at this temperature.

4. Chromic nitrate nonahydrate crystals may be prepared by dissolving violet chromic chloride in hot nitric acid and allowing the solution to crystallise in a vacuum desiccator.

In conclusion, one of the authors (S. K. T.) wishes to express his gratitude to the Advisory Council of the Department of Scientific and Industrial Research for a personal grant.

*Hæmoglobin.*

A LECTURE DELIVERED BEFORE THE CHEMICAL SOCIETY ON  
FEBRUARY 11TH, 1926.

By JOSEPH BARCROFT, C.B.E., M.A., F.R.S.

IN making some remarks to-night about one of the subjects dearest to my heart, namely, hæmoglobin, I wish to disabuse you at the outset from any idea that my primary object is to inform you—far otherwise—hæmoglobin is to me a query mark—an unanswered question—a Will-o'-the-wisp—something which one day you think you have grasped only to find the next that its real essence has eluded you. You recollect what Thackeray said about George IV : “To make a portrait of him at first seemed a matter of small difficulty. There is his coat, his star, his wig, his countenance simpering under it : with a slate and a piece of chalk I could at this very desk perform a recognisable likeness of him. And yet after reading of him in scores of volumes, and hunting him through old magazines and newspapers, having him here at a ball, there at a public dinner, there at races and so forth, you find you have nothing—nothing but a coat and wig and a mask smiling below it—nothing but a great simulacrum. . . . I look through all his life and find but a bow and a grin—I try and take him to pieces, and find silk stockings, padding stays, a coat with frogs and a fur collar, a star and a ribbon, a pocket handkerchief prodigiously scented, one of Truefitt's best nutty-brown wigs reeking with oil, a set of teeth and a huge black smock under-waistcoat, more under-waistcoats and under that nothing.” And so in my more despondent moments it seems to be with hæmoglobin. Its colour fascinates you, you crystallise it only to find that it crystallises in innumerable forms, you determine its osmotic pressure to find that may be anything, you redissolve the crystals to find that the material has altered as the result of crystallisation. Is the attempt to pursue hæmoglobin worth while? Well, gentlemen, at the end of this lecture you may answer that question as you will. For my part it is just here that the analogy with “The first gentleman in Europe” breaks down, for you must remember that Thackeray went on : “I own I once used to think it would be good sport to pursue him, fasten on him, pull him down. But now I am ashamed to mount and lay good dogs on to summon a full field and then to hunt the poor game.” Hæmoglobin never can appear poor game to the biologist, for the life of the warm-blooded animal—yours and mine—depends upon its existence, there is no other substance which is capable of transporting oxygen

in just the same amount and in just the same way. How nature discovered the pieces from which to effect the synthesis must ever be a fascinating subject of inquiry to the biologist—and to find out what those pieces are and in what way the synthesis has been effected he must digress from his own proper sphere into that of chemistry. Yet as ribbons, wigs, and stars go, those of George IV were probably more interesting than most, and if I at once disclaim the objects of telling what hæmoglobin really is, and make it clear that I am merely trying to pass an hour by discussing some of its more superficial properties, it may be that you will find these a little interesting, even if you regard the methods of the biologist as being at one time crude and at another clumsy, and his presentation of a chemical problem naïve and amateurish.

### I.

The time-honoured conception of hæmoglobin was that it consisted of two moieties united in some unknown way. These were called hæmatin and globin, the latter being a protein, the former a substance containing iron. It was supposed further that these could be broken the one from the other by acid or alkali. Within the last two years the position as put forward above has been gone into in considerably greater detail. Let us start with hæmoglobin and work backwards. If in the presence of a reducing agent hæmoglobin be made alkaline, a substance, hæmochromogen, is formed with a characteristic spectrum, which possesses a band of great density in the region of  $\lambda 560$ . This substance was assumed to be hæmatin, in the reduced form and in alkaline solution. That is to say, it was assumed to be protein-free. This conception appears to be incorrect, for we can obtain hæmochromogen, not analytically, but synthetically, the best starting point being a substance called hæmin.

Hæmin is made by adding glacial acetic acid to dried blood in the presence of sodium chloride and is a well-defined crystalline substance to which the formula  $C_{34}H_{35}O_3(?)N_4Fe.HCl$  was given by Hoppe-Seyler. From it, *in the presence of a reducing agent*, the base hæm,  $C_{34}H_{35}O_3N_4Fe(?)$ , may be liberated by the addition of sodium hydroxide. According to the old conception, this base should have been hæmochromogen, but it is not so, having a quite different and ill-defined spectrum. One further step is necessary to produce hæmochromogen, namely, the addition of globin to the hæm. Therefore we obtain the following scheme (Scheme 1).

The conception put forward above opened up an entirely new field for discovery, in which three principal facts may be emphasised.

First, that globin is only one of a great many substances which

will perform the same function, thus forming a whole group of hæmochromogens. Nicotine, pyridine, hydrazine, ammonia,

albumin, etc., all perform the same rôle, that is, when added to hæm, which has a comparatively indistinct spectrum, they yield substances producing spectra with the typical characteristics of that of hæmochromogen, and it must be remembered that the spectrum of hæmochromogen is the most typical and best defined of all blood spectra. We therefore may now extend our scheme as follows :

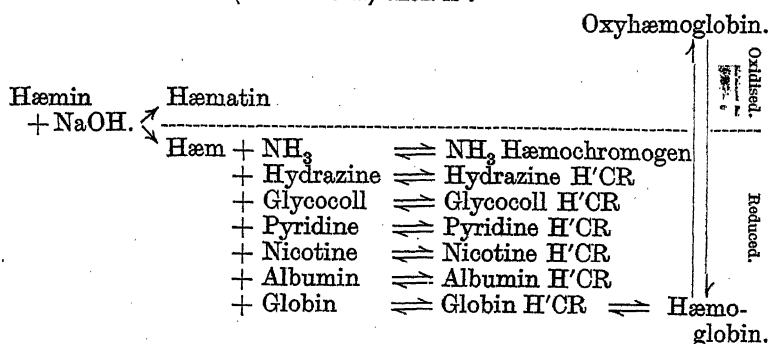

Secondly, whilst all these substances yield hæmochromogens with spectra of the same type, there are appreciable differences between the actual spectra of the different members of the family; in one the bands will be a little towards the red, in another a little towards the blue—but so little that casual observation would not show the difference.

Thirdly, all these hæmochromogens seem to be kept *in statu quo* as the result of balanced action, and here it may be noted that for the production of most of them a great preponderance of the components is necessary. The globin hæmochromogen stands nearly but not quite alone in so far as the action is almost complete.

The globin compound has as well other distinctive properties; it is one of the few hæmochromogens which are soluble in a high degree, and, but chiefly, the globin compound stands alone, in

that it and it only can form a hæmoglobin. Anson and Mirsky, by regulation of the hydrogen-ion concentration, obtained hæmoglobin from globin hæmochromogen. Robin Hill has been at great pains to obtain the analogues from other hæmochromogens, but without success.

The final scheme (Scheme III) then is :

SCHEME III.

## II. Cytochrome.

It is not possible to leave the subject of hæmochromogen without making a digression for the purpose of discussing cytochrome. Here, as in the case of hæmochromogen, let the name cytochrome stand for a spectrum, at all events until we can get something more concrete to which we may attach it.

This spectrum was first described by McMunn,<sup>1</sup> but its true significance has only recently been brought to light by the work of Keilin,<sup>2</sup> who has kindly consented to demonstrate it to-night. It may be seen well in the wing-muscle of the bee, in the onion, in yeast, in aerobic bacteria, and, indeed, it may be regarded as of more or less universal occurrence in forms of life which have contracted the oxygen habit. In these there is reason to suppose that it acts as a catalyst, in contrast to hæmoglobin, which acts as a carrier, but pervading both the animal and the vegetable kingdom; it is far more widely distributed than either hæmoglobin or chlorophyll. Not only so, but cytochrome appears in forms of life than which none are more primitive.

This spectrum has never been seen outside a cell; all attempts to extract the cytochrome have ended in changing the spectrum—moreover, it is only seen in the reduced condition—shake yeast with air, the spectrum disappears, to return on permitting the yeast to reduce itself—expose the wing-muscle of the bee to the atmosphere, the spectrum disappears, to return on the exclusion of oxygen by a coverslip.

Superficially this spectrum presents the appearance of possessing four bands, which may be designated as *a*, *b*, *c*, and *d*; of these *c* is the most conspicuous (see Fig. 1).

To say that this spectrum has four bands is only a partial statement of the facts, for the band *d* may be resolved into three overlapping bands which I will call *x*, *y*, and *z*. Thus on any picture

FIG. 1.\*

which shows the relative absorption at different parts of the spectrum there are six summits. This is shown crudely in the figure. It must not be supposed that this figure is drawn from accurate spectrophotometric observations; the positions of maximum density only have been measured with care. So far as the relative densities of the various bands are concerned, the figure simply is a rough

\* Figs. 4, 7, 8, 9, 10, 11, 12, and 13 are reproduced by permission from the *Proceedings* of the Royal Society, and Figs. 5 and 6 from the *Journal of Physiology*.

representation of the impression one gets from the observation of varying concentrations of the material.

To obtain a better understanding of the cytochrome spectrum, let us turn to alkaline extracts. An extract of yeast in potassium hydroxide gives a spectrum also with six summits, but which has only three bands, because those which correspond to  $b$  and  $c$  have become merged into a single band with two summits. The summits in the spectrum of the potassium hydroxide extract I will call  $a_K$ ,  $b_K$ ,  $c_K$ ,  $z_K$ ,  $y_K$ , and  $x_K$ , respectively, representing  $a$ ,  $b$ ,  $c$ ,  $z$ ,  $y$ , and  $x$ .

If one goes further and makes an acetone extract, which is then made alkaline, only four summits appear; they are  $b_K$ ,  $c_K$ ,  $y_K$ , and  $z_K$ , respectively,  $a_K$  and  $x_K$  being absent. If one goes still further and dries the yeast, makes an aqueous extract of the dry yeast, and renders that alkaline, two more bands,  $b_K$  and  $y_K$ , drop out and one is left with  $c_K$  and  $z_K$  only. And now we have something very familiar; it is none other than a typical hæmochromogen spectrum. The simplest interpretation of the cytochrome spectrum is that it is a mixture of the spectra of three hæmochromogens A, B, and C, of which A is responsible for bands  $a$  and  $z$ , B for bands  $b$  and  $y$ , and C for bands  $c$  and  $x$ , and this interpretation is rendered the more likely by the fact that in different cytochromes the relative intensities of the bands vary. But in this respect the bands are associated in pairs; thus  $a$  and  $z$  may be exaggerated, relatively to the rest, or  $b$  and  $y$  may be, but not  $a$  and  $y$  or say  $c$  and  $z$ , or  $a$  or  $b$  or  $c$  alone.

### III. *Metallic Porphyrin Compounds.*

Some allusion should here be made to the work of Robin Hill,<sup>4</sup> who has investigated the compounds of various metals with porphyrin. Porphyrin unites with a great number of metals—iron, nickel, cobalt, manganese, zinc, copper, silver, potassium and others. The compounds formed are all on the *hæm* level, if I may put it that way, but of these, only three have the power of being readily oxidisable and reducible. These are the compounds of cobalt, iron, and manganese, *i.e.*, the hæmatins as well as the hæms of these metals can be obtained.

It is remarkable and perhaps significant that, whilst none of these substances has any nitrogenous compound attached, they all, with one exception, have spectra which suggest hæmochromogen rather than hæm. The one exception is the iron compound, and, further, it is the only one to which nitrogenous compounds such as pyridine and globin will attach themselves and thus form true hæmochromogens. Not that the iron-porphyrin compound is precisely the same as hæm, or that the derived hæmochromogens are precisely the same as those formed from blood—the spectral bands are nearer the blue;

presumably the original porphyrins are not the same as that in the hæm obtained from blood.

#### IV. *Equilibrium Constants of Compounds of Hæmoglobin with Oxygen and Carbon Monoxide.*

The curve which represents the equilibrium between oxygen and blood is, as was shown by Christian Bohr,<sup>5</sup> S-shaped in character (Fig. 2, B). This contour adds greatly to the biological value of hæmoglobin and for that reason it was an object of speculation to Bohr himself—as it has been to all his successors—as to what

the underlying significance of the inflexion might be. A simple equilibrium of the type

would, of course, be represented by a rectangular hyperbola.

In 1911, Roberts and I<sup>6</sup> found that a dialysed solution of hæmoglobin of considerable purity yielded an equilibrium curve which approximated very much to the hyperbolic type, and we hazarded the view that if complete purity were obtained the curve would actually become a hyperbola (Fig. 2, H). This view met with a general, but as it seems a premature, acceptance; for, on later occasions with I think purer and certainly more concentrated

solutions, we failed to obtain the hyperbolic form, and at Harvard, Adolph and Ferry,<sup>7</sup> with a very perfect technique of its kind, asserted that in no circumstances was the curve anything but S-shaped. I used the phrase "a very perfect technique"—perhaps this phrase was wrong. I should have said a technique which more nearly reached our ideals. Our ideals were: a solution which contained the minimum of impurity and the maximum of hæmoglobin. With regard to the latter point, of course the greater the concentration of hæmoglobin the easier and more trustworthy becomes the gas analysis.

FIG. 3.

The conceptions put forward by Adair<sup>8</sup> indicated the probability of our ideal being wrong. They suggested that the fundamental equilibrium curve was to be obtained from the investigation of solutions not stronger but more dilute than that used by Roberts and myself. The study of such solutions required an entirely new technique. The relative concentrations of hæmoglobin and oxyhæmoglobin in dilute solution can be determined only by some spectroscopic method, and even that is very difficult to do and can be done only for the middle portion of the curve. The pressures of oxygen involved are so small as to demand very exact and difficult analyses of the atmosphere to which the hæmoglobin is exposed, if the equilibrium be struck at room temperature. On the other hand, if the equilibrium be struck at 35–40°, the gas analysis

becomes easy, but the hæmoglobin becomes unstable. If we review these difficulties in order, we find that the spectroscopic analysis becomes easy when we study the analogous reaction :

The difficulties of gas analysis by ordinary methods are, however, seemingly insuperable, for the pressures of carbon monoxide

FIG. 4.

involved are counted in thousandths of a millimetre. Fortunately, it has proved possible at 15° to work out a method—almost audacious in its simplicity—which has enabled us to avoid gas analysis and by a single spectroscopic measurement to estimate the concentrations of all the reacting substances in the above equation. This technique will be demonstrated by my colleague, Dr. Selig Hecht, of Harvard. With its aid we have succeeded in the last fortnight or so in obtaining the curve shown in Fig. 3. Between the limits of 0 and 25

thousandths of a millimetre pressure of carbon monoxide (above which limits the method has not so far proved accurate) the curve is nearly, though not quite, hyperbolic in form.

It would seem that at last we are really within sight of the fundamental curve and in a position to push forward and discover the effects on this curve of increasing the concentration of hæmoglobin, of the salts, and of alterations in the concentration of hydrogen and hydroxyl ions in the solution.

I need only remind you that the effect of increasing alteration of hydrogen-ion concentration is to reduce the affinity of oxygen (or carbon monoxide) for hæmoglobin proportionately over the whole curve.

FIG. 5.

*The Temperature.*—The same may be said of the effect of temperature. The curves in Fig. 4 show the equilibrium of oxygen and hæmoglobin in blood at various temperatures. They are taken from a research by W. E. Brown and A. V. Hill.<sup>9</sup>

Their work has been followed by that of Maçela and Seliskar,<sup>10</sup> who have determined the temperature coefficients of the hæmoglobin, in dilute solution and under constant conditions of hydrogen-ion concentration, of several forms of life. It is remarkable, and again of great biological interest, that the hæmoglobin of man has a temperature coefficient of about 5 for its equilibrium with oxygen (Fig. 5), and that of the frog has a temperature coefficient of only about 2.5 (Fig. 6). Whether human hæmoglobin serves man better by having so high a temperature coefficient is difficult to say, but it would be quite unsuited to the needs of the frog.

V. *The Velocity Coefficients of the Reactions of Hæmoglobin with Oxygen and Carbon Monoxide.*

The sensitiveness of the equilibrium constant of the reactions

to temperature, hydrogen-ion concentration, etc., naturally leads to the inquiry how are the velocity coefficients of the separate phases of the reaction affected by the conditions under which the reaction takes place. If, for instance, a rise of temperature tends to

FIG. 6.

dissociate oxygen from hæmoglobin, is this because the velocity coefficient,  $k$ , of the reaction

is increased or the velocity coefficient,  $k'$ , of the reaction

is diminished, or are both velocities increased but in different proportions—the state of affairs which would seem most probable *prima facie*—or what? Before the war, A. V. Hill and I made a few experiments on this subject, but it was clear that our experimental methods were quite inadequate—our scheme in general depended on the bubbling of oxygen or nitrogen through hæmoglobin solutions. The actual velocities of the chemical reactions which took place were of so high an order as compared with the rates at which the

gases passed into or out of the solution that the results which we obtained depended merely on the extent to which we were able to

FIG. 7.

“ring the changes” on the physical, as opposed to the chemical, processes involved.

Within the last four years the velocity coefficients of the various

phases of the reactions of hæmoglobin with oxygen and with carbon monoxide have been studied by Hartridge and Roughton<sup>11</sup> with what appears to me to be amazing success. Such a study, of course, demands the most meticulous consideration of detail, and if I treat their method in a very general way it is because the discussion of the details, once embarked upon, would occupy more than the whole time at my disposal.

Let us commence, then, with the consideration of the reaction :

To carry out our purpose, it is necessary that one or other of the substances produced, the hæmoglobin or the oxygen, should be removed from the sphere of action as fast as it is formed. For this purpose, the procedure is briefly as follows.

The apparatus (Fig. 7) is schematically in the shape of a Y made of tubing—along the limbs of the Y enter on one side a dilute solution of the oxide of hæmoglobin, on the other water containing a concentration of sodium hyposulphite to absorb the oxygen, it being ascertained that the sodium hyposulphite does not reduce the oxide by double decomposition. At the junction of the tubes there is a mixing chamber, in which the mixing is so rapid and intimate as to be completed in a time which is negligible compared with the one-hundredth part of a second. The rate at which these fluids are driven through the apparatus is so great that the reaction in the lower limb of the Y may be followed with the eye. The fluid, which emerges red from the mixing chamber, is seen to become purple as it passes down the tube. The degree of reduction may be estimated at any point along the tube by the reversion spectroscope, whilst the time taken for the process is calculated from the velocity of flow of the fluid along the tube, the fluid being in turbulent motion.

In the world in which we now are, this reaction is relatively slow; and, as Fig. 8 shows, it obeys the "rules of the game" inasmuch as the curve obtained by plotting the logarithm of the concentration of the oxyhæmoglobin against the time is a straight line.

The reaction :

presents much greater difficulties for two reasons. The first is the technical one that it takes place enormously faster, the second is the theoretical one that it has not proved practicable to remove the oxide as it is formed and therefore it is only when the first portions of oxide are forming that the reaction appears with its full velocity. However, just because the disruption of the oxide is slow

as compared with its formation, and because we know the velocity of the disruption, we can correct for it by a process of calculation.

To determine the velocity of oxidation, solutions of hæmoglobin and of oxygen in sufficient concentration to oxidise it are driven at such a velocity that they traverse the lower limbs of the Y at the rate of about 600 cm. per second, and over the first few centimetres the chemical change may be seen with the eye, the hæmoglobin turning from violet to red as the oxide forms. The measurements are made with the reversion spectroscope. The time, as before, is measured by the rate at which the fluid travels from point to point, and the degree of oxidation by spectroscopic examination of the fluid from point to point along the tube.

FIG. 8.

The actual result achieved in an experiment is illustrated by Fig. 9. Here you will see that one-quarter of the whole oxidation takes place in about two-thousandths of a second. To ascertain the figure with an accuracy of but 10% required a certainty of two ten-thousandths of a second in the estimation of the time.

Having said so much about Hartridge and Roughton's method, let me pass to the consideration of their results. Taking first the oxidation, its velocity coefficient possesses properties that are worth noting, the most remarkable of which is that temperature appears to have no effect upon it. Of course I mean temperature within rather narrow limits, for hæmoglobin will not stand heating above about 45°. What the theoretical explanation of this phenomenon may be is a matter which I shall leave to you who know much

more about such things than I do. It would be explained according to the authors on the assumption that all the molecules of oxygen which impinged upon the hæmoglobin molecule—at whatever temperature—adhered to it. The second property, and one which is of great interest to physiologists, is that alteration of the hydrogen-ion concentration of the medium in which the hæmoglobin is dissolved is also without marked effect upon the velocity coefficient of the oxidation phase of the reaction.

It follows, therefore, that the now well-known effects of hydrogen-ion concentration and temperature on the equilibrium constant must

FIG. 9.

be almost entirely the reflexion of the effects of these conditions on the *reduction* phase, and to this we shall now turn.

Experiments on sheep's hæmoglobin indicate that the velocity coefficient of the reduction phase has a temperature coefficient of 3.8 for an alteration of 10°, which, as a matter of fact, corresponds to that of the equilibrium constant of the reaction

The effect of hydrogen-ion concentration is restricted to a small region between  $p_{\text{H}} = 7.8$  and about  $p_{\text{H}} = 5.5$ , i.e., within 1.2 on each side of the isoelectric point. Within this region the effect is very great and fully accounts for the properties which blood exhibits (Figs. 10 and 11).

To revert, however, to the original proposition of whether the value of the equilibrium constant as determined does or does not agree

FIG. 10.

*Abscissæ = Time in seconds. Ordinates = logarithm of oxyhaemoglobin percentage; numerals on left of ordinate axis indicate corresponding value of oxyhaemoglobin percentage.*

FIG. 11.

*Abscissæ =  $p_H$  of solution. Ordinates = value of reduction velocity coefficient. Squares represent results obtained in experiment on one sample of blood. Circles represent results obtained in experiment on another sample of blood.*

with the quotient of the velocity coefficients, the following table, which summarises the results of four such comparisons, shows, I

think, as good an agreement as can be looked for from experiments of so high a degree of difficulty.

*The Comparison of K with  $k'/k$ .*

No. of Expt.	$p_{\text{H}}$ .	Temp.	Mean value of $k'$ .	Mean value of $k$ .	Value of $K$ .	
					Calculated from $K = k'/k$ .	Observed from dissociation curve.
I.	7.7	17.5°	2875	17.5	164	218
II.	7.2	18.9	2550	17.3	148	112
III.	10.0	15.1	3145	4.5	700	730
IV.	10.0	17.3	3540	8.1	438	336

The values of  $k'$ ,  $k$ , and  $K$  were subject individually to possible experimental errors of  $\pm 20\%$ ,  $\pm 10\%$ , and  $\pm 15\%$ , respectively.

A parallel set of observations has been carried out on the velocity coefficient of the reactions

Of these, the velocity coefficient of the association phase is of the same order as that of the corresponding reaction for hæmoglobin and oxygen; but the velocity coefficient of this dissociation phase is of quite a different order from that of the reduction phase of oxy-hæmoglobin.

Being in possession of the values of  $k$  and  $k'$  for the reactions

respectively, we should be able to calculate the corresponding coefficients for the reaction

or, as it is more correctly written,

But at this point a most interesting discrepancy has appeared. The hæmoglobin appears to be much more reactive towards carbon monoxide if this gas is presented to it within about one-tenth of a second after the removal of the oxygen than it is subsequently. Whether, in that tenth of a second some tautomeric change takes place, or, if not, what the alternative may be, is still under investigation, so there we must leave the matter.

VI. *The Importance of the Protein.*

Within recent years the point of interest with regard to hæmoglobin has been shifting. Formerly, it was entirely centred upon the relation of the oxygen to the hæmatin, and this interest extended to the significance of the pyrrole group and the possible connexion with chlorophyll. Little progress has been made in this direction; the researches of Willstätter more particularly have turned men's minds rather away from the pyrrole group; on the other hand, the protein moiety of hæmoglobin has in one way or another been steadily receiving more recognition. The points of importance with regard to the protein may be considered under two main groups, those which embrace the proportion of hæmoglobin as an amphoteric electrolyte, and those which have to do with its specificity.

(a) *Hæmoglobin as an Amphoteric Electrolyte.*—Hæmoglobin acts as an acid in alkaline solution and as a base in acid solution. The former action has been studied in much greater detail than the latter. In strict parlance one should, I suppose, speak of hæmoglobinic acid and of sodium or potassium hæmoglobinate—the latter being the form in which hæmoglobin exists for the most part in human blood.

This very important fact at once raises a number of points such as :

( $\alpha$ ) The number of dissociable sodium atoms for each atom of iron.

( $\beta$ ) The strength of the acid.

( $\gamma$ ) Effect on the strength of the acid of oxidising the hæmoglobin.

( $\delta$ ) The repercussion of the above considerations on the system in which hæmoglobin is found in the blood, which contains also sodium bicarbonate, sodium chloride, and carbonic acid. This system becomes complicated by the fact that the hæmoglobin is in corpuscles, the envelopes of which appear to be relatively impermeable to kations as compared with anions. This system is of paramount importance to the physiologist, but to the chemist it is so special a case that I shall pass very lightly over it.

$\alpha$ . Very different views have been held as to the number of gram-atoms of sodium which could dissociate from 16,800 grams of hæmoglobin (the weight which contains 56 grams of iron and unites with 32 grams of dissociable oxygen). The matter recently formed the subject of an exhaustive research by the workers in Dr. Van Slyke's laboratory,<sup>12</sup> who have come to the conclusion that the number was much higher than had formerly been supposed. Their estimate is 12.

$\beta$  and  $\gamma$ . Hæmoglobin in the reduced form is a very weak acid. In the oxidised form it is, according to A. V. Hill, some seventy

times as strong, and is then of the same order of strength as sodium bicarbonate.

8. It follows that when hæmoglobin is oxidised in the presence of sodium bicarbonate the sodium becomes redistributed, the hæmoglobin taking more, and therefore the amount of sodium bicarbonate decreases whilst the amount of free carbon dioxide increases. On the other hand, the addition to the system of carbon dioxide or any other acid will attract sodium from the hæmoglobin and tend to release the oxygen, which has less affinity for the free acid than for the sodium hæmoglobinate.

The scheme put forward by Hill<sup>13</sup> to explain these facts is that hæmoglobin may be regarded as

whilst oxyhæmoglobin in the presence of sodium bicarbonate is

(b) *Specificity*.—That the hæmoglobins which are derived from different species of animals, and even from different members of the same species, differ may be shown in a number of ways. That they differ in crystalline form has been known for a long time, and the crystallographic differences have formed the subject of a work, monumental in bulk, by Reichert and Brown.<sup>14</sup> Moreover Landsteiner and Heidelberger,<sup>15</sup> in a very elegant research on the solubility of hæmoglobin, have shown that the difference between one form and another is sufficiently great to render them more or less independently soluble. After a solution has been saturated with the hæmoglobin of one animal, it is still capable of dissolving some at all events of the hæmoglobin of another.

Moreover the spectra are slightly different, the bands being shifted a little towards the red or towards the blue from one hæmoglobin to another. This is true, not only of the bands of oxyhæmoglobin, but also of carboxyhæmoglobin. One band, known as the  $\alpha$ -band, has been studied in some detail. In the case of human blood, when carbon monoxide is bubbled through a solution of oxyhæmoglobin this band moves 54 Å.U. towards the blue. In the slang of the laboratory, we say the band has a "span" of 54 Å.U. Most forms of hæmoglobin have a lesser span. Now let me put before you a remarkable and hitherto unexplained relationship, which at present

exists on quite an empirical basis. It merely has been "observed to be so" in the cases which have been tested.

We may express the equilibrium point of the reaction which takes place when carbon monoxide is passed into oxyhæmoglobin as follows:—<sup>16</sup>

FIG. 12.

With different hæmoglobins,  $K$  differs. Now let me show you the relation of  $K$  to the "span." I do not wish to insist that the relation is in the strict sense linear. We may be on a very flat curve or near the point of inflexion of an S-shaped curve. What I want to emphasise is that *there is a relation*. It would be simple to explain this relation on the hypothesis that there are a limited number of hæmoglobins, say two, which in different animals are mixed together in different proportions. This simple explanation seems to be negatived by the fact that if the hæmoglobin be crystallised and redissolved the solution presents the same properties as the original solution or as the fluid left above the crystals.

On the other hand, no attempt to find any spectroscopic or other differences, either in the hæms or the hæmins derived from these

various hæmoglobins, has been successful. In the present state of our knowledge one must attribute this very interesting specific feature to the globins.

### VII. *Osmotic Pressure and Molecular Weight.*

And now I come to that part of the subject in which hæmoglobin appears to be in its most illusive mood. The thing which we most want to know about it is perhaps its molecular weight, and in this audience the confession of ignorance on that point is a confession not untinged with shame. We know as a starting point that the least possible molecular weight—that which contains 56 grams of iron—would be somewhere about 16,700. If then we call the molecular weight  $(16,700)_n$ , what is the value of  $n$ ?

We turn to some indirect method. What is to be said about the osmotic pressure? I may pass rather rapidly over the work of Hüfner and Gansser,<sup>17</sup> who came to the conclusion that the osmotic pressure of a 1% solution of hæmoglobin would be 10 mm. of mercury—a result which would give a value of  $n = 1$ . By what happy accident Hüfner and Gansser arrived at this result is likely to remain a mystery. Weymouth Reid,<sup>18</sup> in a research which is too little quoted, concluded that 3 was the nearest whole number to his determinations of  $n$ . Roaf<sup>19</sup> made the material but rather depressing discovery that  $n$  might appear to be almost anything—less than unity, for instance—according to the circumstances in which the measurements were made. It has remained for Adair<sup>20</sup> to reduce to some sort of order the apparently chaotic readings which were found. The possibilities of adsorbed salts, of variable ionisation of the hydrogen or sodium ions, of membrane potentials, of polymerisation of the hæmoglobin, of the onset of putrefaction, of the attainment of a true equilibrium, etc., all had to be taken into account. Take the last two considerations, the attainment of equilibrium and the avoidance of putrefactive changes. In ordinary circumstances it proved quite impossible to complete a measurement in which a satisfactory equilibrium was attained before the solution ceased to be above suspicion. This difficulty was overcome by working at  $0.6^\circ$ , at which temperature a hæmoglobin solution remains good indefinitely. The time factor looms almost as large in Adair's determinations as in those of Hartridge and Roughton. The latter measure events which take place in a fraction of  $1/1000$  of a second; Adair's osmometric determinations each require a fraction of a year. The work is being carried on in the Low Temperature Station at Cambridge, where Sir Wm. Hardy kindly allows Adair to set up his osmometers (Fig. 13). Such work must be very slow, but already enough information has been

FIG. 13.

Osmometer, Type D (left), with straight column of solution for measuring pressure. Scale in centimetres. Osmometer, Type O (right), for high pressures with mercury manometer: (1) A rigid collodion tube, 20 c.c. capacity, in jar holding 500 c.c. of outer liquid. (2) Rubber connexion. The glass tube from (2) to (3) is filled with liquid paraffin. Beyond (3) there is water. (4) Rubber connexion with clip (not shown here). (5) Glass T tube, with water down to level B. (6) Glass rod in rubber tube, for adjusting the pressure. (7) Glass tube, open to air, or fitted with a soda-lime tube. W = level of outer liquid; B = level of mercury in manometer limb, 6 mm. in diameter; L = level of mercury in manometer limb, 0.7 mm. in diameter. Above the mercury at L there is a drop of lactic acid.

obtained to be of considerable interest. Adair will show you a model in which the osmotic pressure in a 1% solution of hæmoglobin is represented vertically whilst the hydrogen-ion concentration and the saline concentration of the solvent are the horizontal co-ordinates. Over a great part of this model the conditions may be varied without any change in the osmotic pressure of the hæmoglobin, which pressure works out pretty regularly at 2.6 mm. of mercury. This figure is given if the solution is not more than 4% hæmoglobin or is not of less saline concentration than 0.01 molar. Where a different and higher osmotic pressure than 2.6 is given per 1% of hæmoglobin, as in cases where the concentration of Hb is more than 4% (Fig. 14)

FIG. 14.

or the pigment is dissolved in salt solution of greater dilution than 0.01M (Fig. 15), Adair finds a cause which satisfies him. If we accept his estimate, the value of  $n$  would be 4 and the molecular weight of hæmoglobin about 68,000. A substance of this molecular weight, it may be said incidentally, would depress the freezing point of water about 0.00001°.

And now we are face to face with the final puzzle. How are we to reconcile an equation

with the form of equilibrium curve as obtained?

In considering this question I will leave out two factors each of which may produce an appreciable secondary effect on the shape of the curve. These are the alteration in hydrogen-ion concentration produced on oxidation and the effect of the great concentration in

which the hæmoglobin is found, say, in the red corpuscle. These apart, we may consider the reaction as being either

or it may follow what physiologists call the "all or none" principle, there being no possibility of intermediate oxides between  $\text{Hb}_4$  and

FIG. 15.

Conditions. Concentration of Hb less than 4%.

o Solution in distilled water.

x Solution of saline concentration greater than 0.01M.

$\text{Hb}_4\text{O}_8$ . The latter hypothesis yields a curve of the S-shaped form with which we are familiar in the case of blood.

In the case of successive oxidations, if the equilibrium constants of the four reactions are in the ratios of 4 : 3 : 2 : 1, i.e., if each oxygen may be regarded as of the same value and uninfluenced by the presence or absence of the others, a curve of the hyperbolic form would be produced such as has been obtained in the case of carbon monoxide and a dilute solution of hæmoglobin of relative purity. It may here be remarked that the "all or none" conception may be

regarded as a special case of the conception of successive oxides, the case in which the equilibrium constants of the intermediate oxides have not got finite values, and that being so, it is possible to produce any curve of the general type given by the equation

$$y/100 = Kx^n/(1 + Kx^n),$$

where  $n$  is between 1 and 4, by suitably arranging the equilibrium constants of the successive reactions. But we have now passed entirely into the domain of speculation. We know of no reason why the actual factors which do alter the inflexion of the curve should so affect the equilibrium constants of the successive oxidation equilibria, and no one has claimed to have isolated any of the intermediate oxides, or to have obtained anything but the most nebulous evidence of their existence.

Yet so long as the physical basis of the inflexion fails to be understood the dream of the physiologist will be unfulfilled, for the inflexion of the curve is the biologically important fact about it. One day the enigma will be solved, until then we can but strive on in the sure and certain hope that "Nature never has betrayed the heart that loved her."

CL.—*A Theory of Colour on the Basis of Molecular Strain. The Effect of Chromophoric Superposition.*

By SIKHIBHUSHAN DUTT.

THE visible colour of substances is due to selective absorption of certain of the electro-magnetic vibrations causing the sensation of white light and the transmission of the remainder. In the present paper an attempt is made to show that selective absorption is due to molecular strain, such strain being imparted to the molecule by the distortion of the normal valency directions produced by any of the following causes :

- (a) Formation of a double or triple bond.
- (b) Formation of a cyclic from an open-chain compound.
- (c) Unequal distribution of the masses attached to the atom.

The amount of strain is roughly proportional to the angular displacements of the valency directions of the atoms.

Strain in a molecule can be intensified by loading, the greatest effect being obtained when the load is in close proximity to the centre of strain. The farther the load is from this centre, the less is its effect.

The effect produced when two sources of strain are in close proximity in a molecule is much greater than that produced when they are remote from each other, because in the former case the intervening single linking also assumes a comparatively strained condition, thereby increasing the total rigidity of the molecule. The two strains produce the greatest effect when they originate in the same atom ; they have scarcely any mutual effect, each operating independently of the other, when they are situated at atoms separated by more than one single linking.

The position of the absorption maximum of a dye, the molecule of which contains two different and distantly situated chromophores, is approximately the mean of the positions of the maxima of the two components of the dye, each containing one chromophore. For example, the absorption maximum of the dye

is at  $\lambda$  5570, and those of its components, benzeneazodimethylaniline and malachite-green, are at  $\lambda$  5040 and  $\lambda$  6190 respectively (mean,  $\lambda$  5615). A dye containing several chromophores of the same kind has almost the same absorption maximum as the dye containing only one such chromophore. Hence, in each of these two cases, the effects of the strains, situated in distant positions in the molecule, are independent of each other.

## EXPERIMENTAL.

*Azotriphenylmethane Dyes. Series I. Dyes containing One or Two Azo-groups attached to One Benzene Nucleus.*

These dyes were obtained by oxidising the leuco-bases formed by condensing mono- and bis-azobenzaldehydes with dimethylaniline.

*Preparation of Azobenzaldehydes.*—The following mono- and bis-azobenzaldehydes were prepared by diazotising the substance named first in the bracket and coupling the product with the second-named substance. *p*-Aminobenzaldehyde was diazotised as described in D.R.-P. 85233 of 1895, and *m*-aminobenzaldehyde in concentrated hydrochloric acid. The coupling with phenol was done in 10% sodium hydroxide solution. The coupling with aniline or dimethylaniline was done in a mixture of concentrated hydrochloric and glacial acetic acids, which were thereafter gradually neutralised with sodium carbonate.

Monoazobenzaldehydes: (1) Benzeneazobenzaldehyde,

prepared by the method described in Beilstein's "Organische Chemie," Vol. IV, p. 1068. (2) *p*-Hydroxybenzeneazobenzaldehyde,  $(p)\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{N:N}\cdot\text{C}_6\text{H}_4\cdot\text{CHO}(p)$  (*p*-aminobenzaldehyde; phenol). (3) *p*-Dimethylaminobenzeneazobenzaldehyde,

(*p*-aminobenzaldehyde; dimethylaniline). (4) *p*-Aminobenzeneazobenzaldehyde,  $(p)\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{N:N}\cdot\text{C}_6\text{H}_4\cdot\text{CHO}(p)$  (*p*-aminobenzaldehyde; aniline). (5) *p*-Hydroxybenzeneazo-*m*-benzaldehyde,  $(p)\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{N:N}\cdot\text{C}_6\text{H}_4\cdot\text{CHO}(m)$  (*m*-aminobenzaldehyde; phenol). (6) *p*-Dimethylaminobenzeneazo-*m*-benzaldehyde,

(*m*-aminobenzaldehyde; dimethylaniline). (7) *p*-Aminobenzeneazo-*m*-benzaldehyde,  $(p)\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{N:N}\cdot\text{C}_6\text{H}_4\cdot\text{CHO}(m)$  (*m*-aminobenzaldehyde; aniline). (8) Benzeneazosalicylaldehyde,

(aniline; salicylaldehyde). This substance is identical with the compound prepared by Borsche (*Ber.*, 1900, 33, 1325) from benzeneazophenol, chloroform, and sodium hydroxide. (9) *p*-Hydroxybenzeneazosalicylaldehyde,  $(p)\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{N:N}\cdot\text{C}_6\text{H}_3(\text{OH})(p)\cdot\text{CHO}(m)$  (*p*-aminophenol hydrochloride; salicylaldehyde). (10) *p*-Methoxybenzeneazobenzaldehyde,  $(p)\text{OMe}\cdot\text{C}_6\text{H}_4\cdot\text{N:N}\cdot\text{C}_6\text{H}_4\cdot\text{CHO}(p)$ , prepared by treating (2) with methyl sulphate and 3% sodium hydroxide solution. (11) 2:4-Dihydroxybenzeneazobenzaldehyde,

(*p*-aminobenzaldehyde; resorcinol). (12) 2:3:4-Trihydroxybenzeneazobenzaldehyde,  $\text{C}_6\text{H}_2(\text{OH})_3\cdot\text{N:N}\cdot\text{C}_6\text{H}_4\cdot\text{CHO}(p)$  (*p*-aminobenz-

aldehyde; pyrogallol). Bisazobenzaldehydes: (13) *p*-Hydroxybenzeneazobenzeneazobenzaldehyde,

(No. 4, diazotised as described in D.R.-P. 85233; phenol).

(14) *p*-Dimethylaminobenzeneazobenzeneazobenzaldehyde,

(No. 4; dimethylaniline). (15) *p*-Hydroxybenzeneazobenzeneazo-*m*-benzaldehyde,  $(p)\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{N}\cdot\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{N}\cdot\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{CHO}(m)$  (No. 7, diazotised in concentrated hydrochloric acid; phenol). (16) *p*-Dimethylaminobenzeneazobenzeneazo-*m*-benzaldehyde,

(No. 7; dimethylaniline).

No diazoamino-compound was formed in the preparation of substances 4 and 7.

Substances 2, 11, 12, and 13 were crystallised from glacial acetic acid, and substances 3—8, 10, and 14—16 from alcohol. Substance 9 separated in an amorphous form from acetic acid.

Some properties of the azo-aldehydes are given in Table I.

TABLE I.  
*Azobenzaldehydes.*

Azo-aldehyde.	Appearance.	M. p.	N % (theor. % in brackets).
2	Golden-yellow spangles with metallic lustre.	199°	12.5 (12.3)
3	Glistening, red prisms.	170	16.9 (16.6)
4	Yellowish-brown prisms.	158	18.5 (18.7)
5	Orange-yellow prisms.	164—165	12.2 (12.3)
6	Brownish-yellow needles.	116	16.8 (16.6)
7	Yellow prisms.	85—87	18.3 (18.7)
8	Golden-yellow needles.	128	12.1 (12.3)
9	Dark brown powder.	117—120	11.9 (11.6)
10	Bright yellow needles.	130—131	11.4 (11.7)
11	Microscopic, red needles.	Above 300	11.2 (11.6)
12	Microscopic, brown needles.	„	11.1 (10.8)
13	Glistening, brownish-yellow needles.	190	17.3 (16.9)
14	Dark red needles.	142—143	19.2 (19.6)
15	Glistening orange-yellow prisms.	135	16.7 (16.9)
16	„ „ „	128—129	19.8 (19.6)

*General Method of Condensation of Azobenzaldehydes with Dimethylaniline, and Preparation of the Corresponding Azotriphenylmethane Dyes.*—A solution or suspension of the azobenzaldehyde (1 mol.) and dimethylaniline (2 mols.) in ten times their volume of a mixture of equal parts of concentrated hydrochloric and glacial acetic acids was heated under reflux for periods of time varying from 3 to 12 hours, the end of the reaction being shown by the production of a clear solution and the change in colour from dark red to pale yellow.

The solution was poured into water, made alkaline with sodium carbonate, and every trace of dimethylaniline removed by distillation in steam. The white precipitate of the leuco-base was dissolved in dilute hydrochloric acid and reprecipitated from the filtered solution with sodium carbonate. In most cases the leuco-base could not be further purified or crystallised, owing to oxidation, and was therefore directly oxidised to the dye.

The oxidation was carried out by heating a solution of the leuco-base in sufficient 50% acetic acid with slightly more than the theoretical quantity of freshly precipitated and moist manganese dioxide (prepared by quantitative precipitation of potassium permanganate in warm water with alcohol) on the steam-bath for about 1 hour, with frequent stirring. After filtration, the solution of the colouring matter was treated with excess of saturated sodium acetate solution, and the precipitated dye was washed with water, dried, and crystallised from various solvents such as chloroform-ligroin, benzene, acetic acid, alcohol, and acetone, chloroform-ligroin (1 : 2) being the best solvent for the purpose. The substances thus obtained were acetates of the corresponding carbinol bases, and crystallised in glistening prisms or leaflets with a coppery lustre. They are generally sparingly soluble in water or benzene, moderately easily soluble in dilute mineral acids, alcohol, acetone, or acetic acid, very soluble in chloroform or pyridine, and insoluble in ligroin. They dye wool in various shades, from reddish-violet to deep blue.

*Series II. Azotriphenylmethane Dyes containing Two Azo-groups attached to Two Benzene Nuclei.*

Dyes of this series were prepared by tetrazotising *pp'*-diaminotriphenylmethane and its substitution products, coupling the products with dimethylaniline (2 mols.) in the usual manner, and oxidising the leuco-bases thus formed.

1. *pp'*-Diaminotriphenylmethane,  $\text{CHPh}(\text{C}_6\text{H}_4\cdot\text{NH}_2)_2$ , was obtained by O. Fischer's method (*Annalen*, 1881, **206**, 147).

2. *p*-Hydroxy-*p'**p''*-diaminotriphenylmethane,  
 $\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{CH}(\text{C}_6\text{H}_4\cdot\text{NH}_2)_2$ .

—An intimate mixture of *p*-hydroxybenzylideneaniline (1 mol.), aniline hydrochloride (1 mol.), and concentrated hydrochloric acid (5 mols.) was heated in a sealed tube for 6 hours. The product was diluted with water, filtered, and the filtrate rendered alkaline with sodium carbonate solution. The resulting white precipitate, after being washed with water, crystallised from pyridine-alcohol in colourless needles, not melting at  $295^\circ$ . It dissolved very easily in dilute acids to pale yellow solutions, and was found to contain

two amino-groups by titration with  $N/2$ -sodium nitrite (Found: N, 9.3.  $C_{19}H_{18}ON_2$  requires N, 9.7%).

3. *p*-Dimethylamino-*p*'*p*''-diaminotriphenylmethane,

—*p*-Dimethylaminobenzaldehyde (5 g.), aniline (7 g.), and strong hydrochloric acid (50 c.c.) were boiled under reflux for about 5 hours. The leuco-base was isolated as in the above instance. It crystallised from alcohol in colourless leaflets, m. p. 152°. It was very soluble in dilute acids and was found to contain two amino-groups by the standard method (Found: N, 13.6.  $C_{21}H_{23}N_3$  requires N, 13.2%).

*General Method of Preparation of the Dyes of this Series.*—The diaminotriphenylmethane (1 mol.) in excess of dilute hydrochloric acid was treated with sodium nitrite (2 mols.), and the tetrazo-solution added to dimethylaniline (2 mols.) dissolved in strong hydrochloric or glacial acetic acid. On gradual neutralisation of the acid with sodium carbonate, the azo-dye separated. After being washed and crystallised from alcohol or glacial acetic acid, the leuco-base in hot glacial acetic acid was oxidised to the carbinol by freshly precipitated manganese dioxide in the usual manner. The dyes thus obtained are yellow, but the leuco-bases are brown. They dissolve in concentrated hydrochloric acid with a pink colour, whilst in ordinary solvents the colour is yellow.

*Series III. Azotriphenylmethane Dyes containing Three Azo-groups attached to Three Benzene Nuclei.*

These dyes were obtained by tetrazotising *p*-benzeneazo-*p*'*p*''-diaminotriphenylmethane and its substituted derivatives, and coupling the products with dimethylaniline in the usual way. The leuco-bases thus obtained are unaffected by oxidation. In behaviour they are all similar to simple azo-dyes like benzeneazodimethylaniline. They are all yellow, but dissolve in concentrated hydrochloric acid with a red colour.

1. *p*-Benzeneazo-*p*'*p*''-diaminotriphenylmethane,

—This substance was obtained by heating benzeneazobenzaldehyde (1 mol.) with aniline (2 mols.) and concentrated hydrochloric acid (10 mols.) in a sealed tube at 200° for 6 hours. It crystallises from alcohol in brownish-yellow needles, m. p. 174°, and is very easily soluble in dilute acids (Found: N, 14.5.  $C_{25}H_{22}N_4$  requires N, 14.8%).

2. *p*-4-Dimethylaminobenzeneazo-*p*'*p*''-diaminotriphenylmethane,

—*p*-Dimethylaminobenzeneazobenzaldehyde (6 g.), 5 g. of aniline,

30 c.c. of strong hydrochloric acid, and 20 c.c. of glacial acetic acid were heated under reflux for about 3 hours until the colour of the solution had changed from dark crimson to pale yellow. The solution was poured into water and made alkaline with sodium carbonate; the precipitate produced, after being filtered off, washed and dried, crystallised from benzene in brownish-yellow needles, m. p.  $165^{\circ}$  (Found: N, 17.0.  $C_{27}H_{27}N_5$  requires N, 16.6%).

3. *p*-4-Hydroxybenzeneazo-*p*'*p*''-diaminotriphenylmethane,

—This substance was prepared from *p*-hydroxybenzeneazobenzaldehyde (1 mol.) and aniline (2 mols.) in a similar way to the above. It crystallised from alcohol in yellow aggregates, m. p.  $162$ – $163^{\circ}$  (Found: N, 14.5.  $C_{25}H_{22}ON_4$  requires N, 14.2%).

*Series IV. Dyes containing Different Kinds of Chromophores.*

For the preparation of the following dyes of the mixed type, all the diazotisations or tetrazotisations were carried out in cold strong sulphuric acid solution with the theoretical quantities of sodium nitrite. The sulphuric acid solutions were then diluted with ice-water and coupled with the required quantities of dimethylaniline in the usual manner:

(1) Azo-oxazine dye: *Nile-blue-2-azodimethylaniline* (formula I), from diazotised Nile-blue A; dark violet, microscopic needles from chloroform-benzene (N found, 15.4; theo., 14.9%).

(2) Azo-thiazine dye: *Lauth's violet-2:7-bisazodimethylaniline*

(II), from tetrazotised Lauth's violet; brownish-yellow powder from pyridine (N found, 19.7; theo., 19.2%).

(3) Azo-safranine dyes: (a) *Safranine-2-azodimethylaniline* (IIIa), from diazotised phenosafranine hydrochloride; dark violet needles from alcohol (N found, 20.4; theo., 20.1%). (b) *Safranine-2:7-bisazodimethylaniline* (IIIb), from tetrazotised phenosafranine hydrochloride; brownish-yellow needles from alcohol (N found, 19.3; theo., 19.7%).

(4) Azo-indamine dye: *Indamine-3-azodimethylaniline* (IV), from diazotised phenylene-blue; violet, microscopic needles from chloroform (N found, 21.5; theo., 21.3%).

(5) Azo-indigoid dyes: (a) *Indigotin-5-azodimethylaniline* (Va), from diazotised 5-aminoindigotin; violet needles with silky lustre from pyridine (N found, 17.3; theo., 17.1%). (b) *Indigotin-4:4'-bisazodimethylaniline* (Vb), from tetrazotised 4:4'-diaminoindigotin (*Monatsh.*, 1905, 62, 1262); brownish-yellow, microscopic needles from acetic acid (N found, 19.3; theo., 19.2%).

(6) Azo-thioindigoid dye: "*Thioindigo*"-5:5'-*bisazodimethylaniline* (VI), from tetrazotised 5:5'-diaminothioindigo (D.R.-P. 240805); light brown, amorphous powder (N found, 14.5; theo., 14.2%).

#### *Series V. Reduplication of the Same Chromophore.*

A. *The Azo-group.*—1. *Benzeneazobenzeneazobenzeneazoaniline*,  $\text{Ph}\cdot\text{N}_2\cdot\text{C}_6\text{H}_4\cdot\text{N}_2\cdot\text{C}_6\text{H}_4\cdot\text{N}_2\cdot\text{C}_6\text{H}_4\cdot\text{OH}$ . *Benzeneazobenzeneazoaniline* (*Ber.*, 1888, 21, 2145) (1 mol.) was diazotised in cold concentrated hydrochloric acid solution, and the product coupled with phenol (1 mol.), dissolved in excess of sodium hydroxide, in the usual manner. The final product crystallised from glacial acetic acid in bright yellow prisms, m. p. 248° (Found: N, 20.4.  $\text{C}_{24}\text{H}_{18}\text{ON}_6$  requires N, 20.7%).

2. *Benzeneazobenzeneazobenzeneazoaniline*,  
 $\text{Ph}\cdot\text{N}_2\cdot\text{C}_6\text{H}_4\cdot\text{N}_2\cdot\text{C}_6\text{H}_4\cdot\text{N}_2\cdot\text{C}_6\text{H}_4\cdot\text{NH}_2$ ,  
 was obtained by coupling diazotised *benzeneazobenzeneazoaniline* (1 mol.) with aniline (1 mol.) dissolved in the minimum quantity of strong hydrochloric acid and, after thorough stirring, adding an excess of sodium acetate. The product crystallised from alcohol in yellow leaflets, m. p. 194°. No diazoamino-compound was formed (Found: N, 24.4.  $\text{C}_{24}\text{H}_{19}\text{N}_7$  requires N, 24.2%).

3. *Benzeneazobenzeneazobenzeneazodimethylaniline*,  
 $\text{Ph}\cdot\text{N}_2\cdot\text{C}_6\text{H}_4\cdot\text{N}_2\cdot\text{C}_6\text{H}_4\cdot\text{N}_2\cdot\text{C}_6\text{H}_4\cdot\text{NMe}_2$ ,  
 was prepared in a similar way to the above by using dimethylaniline in place of aniline. It crystallised from alcohol in orange leaflets, m. p. 218° (Found: N, 22.8.  $\text{C}_{26}\text{H}_{23}\text{N}_7$  requires N, 22.6%).

4. *Benzeneazobenzeneazobenzeneazobenzeneazophenol*,

was obtained by diazotising benzeneazobenzeneazobenzeneazoaniline (1 mol.) in cold strong sulphuric acid solution and coupling the product with phenol (1 mol.), dissolved in excess of sodium hydroxide, in the usual way. It crystallised from nitrobenzene in brownish-yellow prisms, not melting at  $290^\circ$  (Found: N, 22.3.  $\text{C}_{30}\text{H}_{22}\text{ON}_8$  requires N, 22.9%).

5. *Benzeneazobenzeneazobenzeneazodimethylaniline*,

was prepared by adding diazotised benzeneazobenzeneazobenzeneazoaniline (1 mol.) to dimethylaniline (1 mol.), dissolved in concentrated hydrochloric acid, and, after thorough stirring, adding an excess of sodium acetate. It crystallised from pyridine in orange-yellow prisms, not melting at  $290^\circ$  (Found: N, 23.2.  $\text{C}_{32}\text{H}_{27}\text{N}_9$  requires N, 23.4%).

B. *The Diphenylmethane Group*.—1. *Bistetramethyldiaminodiphenylmethane*,  $(\text{NMe}_2 \cdot \text{C}_6\text{H}_4)_2\text{CH} \cdot \text{CH}(\text{C}_6\text{H}_4 \cdot \text{NMe}_2)_2$ . A mixture of 10 g. of glyoxal, 22 g. of dimethylaniline, and 50 c.c. of fuming hydrochloric acid was heated in a sealed tube at  $180^\circ$  for 8 hours. The product was diluted with water, rendered alkaline with sodium carbonate, and distilled in steam until no more dimethylaniline passed over. The residue, which solidified on cooling, was ground up, washed with water, and its solution in dilute hydrochloric acid was decolorised by boiling with animal charcoal and sulphurous acid. The filtered solution on treatment with dilute sodium hydroxide gave a white precipitate of the leuco-base, which was filtered off, washed, and dried on a porous plate; it crystallised from ether in colourless needles, m. p.  $96-98^\circ$ , which became brownish-violet on exposure to air (Found: N, 11.4.  $\text{C}_{34}\text{H}_{42}\text{N}_4$  requires N, 11.1%).

2. *Bistetramethyldiaminodiphenylcarbinol (diacetate)*,

The above leuco-base was dissolved in sufficient 50% acetic acid, slightly more than the calculated quantity of freshly precipitated manganese dioxide added, and the mixture thoroughly stirred. The solution, dark green at first, on warming on the steam-bath became brilliant violet-blue. After heating for about an hour, it was filtered, cooled, and treated with an excess of saturated sodium acetate solution. The precipitated colouring matter was filtered off, washed, and dried; it crystallised from chloroform-ligroin in dark violet-blue needles with a coppery lustre which dissolved in organic solvents and dilute acids with a violet-blue colour (Found: N, 9.3.  $\text{C}_{38}\text{H}_{46}\text{O}_4\text{N}_4$  requires N, 9.0%).

C. *The Triphenylmethane Group*.—1. *leuco-Dimalachite-green*,  $(\text{NMe}_2\cdot\text{C}_6\text{H}_4)_2\text{CH}\cdot\text{C}_6\text{H}_4\cdot\text{C}_6\text{H}_4\cdot\text{CH}(\text{C}_6\text{H}_4\cdot\text{NMe}_2)_2$ . *p*-Bromoleucomalachite-green [m. p.  $128^\circ$ , obtained from *p*-bromobenzaldehyde (1 mol.) and dimethylaniline (2 mols.), concentrated hydrochloric acid at  $200^\circ$  being used as the condensing agent] was intimately mixed with an equal weight of very fine copper bronze, and the mixture heated at  $210$ – $220^\circ$  in an atmosphere of hydrogen. In 1 hour, a reaction took place which was indicated by the loss of metallic lustre of the bronze powder. After heating for about 4 hours, the melt was dissolved in dilute hydrochloric acid, the solution filtered, the filtrate decolorised with animal charcoal and sulphur dioxide, and the leuco-base precipitated with dilute sodium hydroxide. It could not be crystallised and was a white powder, m. p.  $135$ – $138^\circ$ , which readily became green on exposure to air (Found: N, 8.2.  $\text{C}_{46}\text{H}_{50}\text{N}_4$  requires N, 8.5%).

2. *Dimalachite-green (diacetate)*,

prepared by oxidising the above leuco-base with manganese dioxide, could not be crystallised and was obtained as a brilliant green powder which dissolved in organic solvents and dilute acids with a deep green colour (Found: N, 7.6.  $\text{C}_{50}\text{H}_{54}\text{O}_4\text{N}_4$  requires N, 7.2%).

D. *The Pyronine Group*.—*Dipyrone G* (formula VII). Glyoxal (1 mol.), dimethyl-*m*-aminophenol (4 mols.), and strong hydrochloric acid (10 mols.) were heated together on the steam-bath for about 12 hours under reflux in a current of carbon dioxide. The product was diluted with water, and the leuco-base precipitated with sodium carbonate. As it could not be purified in this state, being very easily oxidised in the air, it was repeatedly dissolved in dilute hydrochloric acid and reprecipitated with sodium carbonate before being converted into the dye. This conversion was done by dissolving the leuco-base in cold strong sulphuric acid and adding

slightly more than the calculated quantity of sodium nitrite, with vigorous stirring. The solution became dark red and small steel-  
s s\*

blue needles began to separate. After 1 hour, the solution was poured into ice-water, and the dye precipitated by adding a concentrated solution of sodium chloride. It came down in fine steel-blue needles with a golden iridescence, and was filtered off, washed with a little water, and dried. Its solutions in water and in organic solvents have a brilliant pink colour (Found : N, 9.6.  $C_{34}H_{36}O_2N_4Cl_2$  requires N, 9.3%).

E. *The Phthalein Group.*—*Difluorescein* (VIII) was obtained by condensing pyromellitic acid with-resorcinol (4 mols.) according to the method (J., 1906, 89, 1787) by which the corresponding compound was prepared from mellitic acid. It is a dark yellow, amorphous substance, not melting at  $300^\circ$  (Found : C, 69.5; H, 3.4.  $C_{34}H_{18}O_{10}$  requires C, 69.6; H, 3.0%).

F. *The Oxazine Group.*—*Di-Meldola's blue* (IX). *p*-Nitrosodimethylaniline hydrochloride ( $4\frac{1}{2}$  mols.) and 2 : 7-dihydroxynaphthalene (1 mol.) were heated together in alcoholic solution under reflux for 24 hours. The black crystalline colouring matter that had separated was filtered off, washed with alcohol and water, and dried. It was a black, crystalline powder, dissolving in organic solvents with a dark green colour (Found : N, 11.6.  $C_{26}H_{22}O_2N_4Cl_2$  requires N, 11.3%).

G. *The Azine Group.*—1. *Phenazineazine* (X) was obtained by condensing 2 : 3-diaminophenazine (Ber., 1889, 22, 356) with *o*-benzoquinone in concentrated sulphuric acid solution. It crystallises from nitrobenzene, and also sublimes on careful heating, in bright yellow needles which do not melt at  $290^\circ$  (Found : N, 19.7.  $C_{18}H_{10}N_4$  requires N, 19.8%).

2. *Phenazineazineazine* (XI) was obtained by condensing 2 : 3-diaminophenazine with 2 : 3-dihydroxyphenazine (Ber., loc. cit.) in cold strong sulphuric acid solution containing 30% of sulphur trioxide. It crystallises from nitrobenzene in microscopic yellow

needles which do not melt at  $290^{\circ}$  (Found: N, 21.6.  $C_{24}H_{12}N_6$  requires N, 21.8%).

*Series VI.*

*A. Malachite-green with a Bridge Linking between Two Benzene Nuclei.*—1. 3 : 3'-Tetramethyldiaminodiphenyl,

3 : 3'-Dinitrodiphenyl (*Ber.*, 1901, **34**, 2177) was reduced with tin and hydrochloric acid in the usual way, the tin precipitated with hydrogen sulphide, and the filtered solution evaporated to dryness. The hydrochloride of 3 : 3'-diaminodiphenyl, thus obtained in long, colourless, silky needles, was dissolved (10 g.) in 150 c.c. of water, and 60 g. of methyl sulphate were added, about 5 g. at a time with vigorous shaking, during an hour, the solution being neutralised from time to time with 10% sodium hydroxide solution; methylation was complete when excess of sodium hydroxide failed to precipitate any amino-compound. The yellow crystalline chromate of the quaternary base precipitated from this solution by a strong aqueous solution of chromic acid was filtered off, washed with water, and treated in aqueous suspension with sulphur dioxide. The dark green solution thus obtained was boiled to drive off the excess of sulphur dioxide and rendered strongly alkaline with ammonia, the precipitated chromium hydroxide washed with water, and the filtrate and washings were evaporated to dryness. The residue was extracted with absolute alcohol, and the extract, after being distilled on the steam-bath until no more alcohol came over, was heated at  $250^{\circ}$  in a vacuum for  $\frac{1}{2}$  hour; only a small, pale yellow distillate, however, was obtained. The distillate and the residue were dissolved in hot dilute hydrochloric acid and the solution was decolorised with animal charcoal. From the filtered solution dilute aqueous sodium hydroxide precipitated a solid, which crystallised from alcohol in clusters of colourless needles, m. p.  $126-128^{\circ}$ , easily soluble in dilute mineral acids (Found: N, 11.5.  $C_{16}H_{20}N_2$  requires N, 11.8%).

2. *The leuco-base, 3 : 6-tetramethyldiamino-9-phenylfluorene (XII).* A solution of 3 : 3'-tetramethyldiaminodiphenyl (1 mol.) and benzal chloride (1 mol.) in dry carbon disulphide was heated under reflux with powdered anhydrous aluminium chloride (2 mols. plus 10% excess) for about 6 hours. The carbon disulphide was distilled off, the dark brown aluminium compound decomposed with water, and the white residue filtered, washed, and extracted with very dilute acetic acid (in which 3 : 3'-tetramethyldiaminodiphenyl is insoluble). The extract was rendered alkaline with sodium carbonate, and the precipitated leuco-base filtered off and washed with

TABLE II.

*Absorption Maxima of Azotriphenylmethane Dyes.*

The dye whose symbolical formula is in the first column was prepared from the aldehyde, the reference number of which is in the second column.  $\alpha$  denotes the absorption maximum of the dye in alcoholic solution containing 1 mol. of HCl, and in the last column are its found and theoretical (in brackets) percentages of nitrogen. A =  $C_6H_5 \cdot N \cdot N \cdot$  or  $\cdot C_6H_4 \cdot N \cdot N \cdot$ , B =  $C_6H_5$  or  $C_6H_4$ , etc., C = methane carbon atom, and R and R' respectively =  and

water. It could not be crystallised and melted at 92—94° (Found: N, 8·7.  $C_{23}H_{24}N_2$  requires N, 8·5%).

3. *The dye (acetate) (XIII).* The above leuco-base was oxidised in 50% acetic acid solution with freshly precipitated manganese dioxide in the usual manner. It was obtained from chloroform-ligroin as a dark green, crystalline powder, which formed dark green solutions in organic solvents and dilute acids (Found: N, 7·5.  $C_{25}H_{26}O_2N_2$  requires N, 7·2%).

B. *Phenolphthalein with a Bridge across two Benzene Nuclei (XIV).*

—A mixture of 9 g. of 3:3'-dihydroxydiphenyl (Ber., 1894, 27,

2107), 7.5 g. of phthalic anhydride, and 15 g. of anhydrous aluminium chloride was heated at 200° for 5 hours. The product was powdered, extracted with boiling water, the residue dissolved in hot aqueous sodium carbonate, the solution filtered, and the filtrate acidified; the dye was thus obtained in pale purple flocks. It crystallised from glacial acetic acid (animal charcoal) in colourless needles, not melting at 285°. It dissolved in alkalis with a bluish-red colour (Found: C, 75.7; H, 4.0.  $C_{20}H_{12}O_4$  requires C, 75.9; H, 3.7%).

TABLE III.

*Absorption Maxima of Azotriphenylmethane Dyes (Series II and III).*

These dyes were prepared by tetrazotising the amines referred to in the second column, coupling the products with dimethylaniline (2 mols.), and oxidising the final products.  $\alpha$  is now the absorption maximum of the dye in conc. HCl.

My best thanks are due to Professor J. F. Thorpe, F.R.S., for the kind interest he has taken in this work, to Professor A. Fowler, F.R.S., for permission to use his quartz spectrograph, and to the Chemical Society for a grant which has defrayed part of the expense of this research.

IMPERIAL COLLEGE, SOUTH KENSINGTON. [Received, October 30th, 1925.]

# CLI.—*Studies on the Walden Inversion. Part X.* *The Reaction between Water and the Phenylchloro- acetate and Phenylbromoacetate Ions.*

By ALLAN MILES WARD.

RACEMISATION may be effected by two processes apparently distinct, namely (1) without displacement of groupings, and (2) during group-displacement. Catalytic racemisation falls under case (1). The generally accepted mechanism of (1) is that the racemisation is due either (*a*) to a tautomeric change, or (*b*) to an equilibrium existing between the original substance and the products formed by its dissociation, one of which is unsaturated at the asymmetric centre (compare Lowry, *Rep. Brit. Assoc.*, 1904; McKenzie and Widdows, *J.*, 1915, **107**, 702; McKenzie and Wren, *J.*, 1919, **115**, 602; Walden, "Optische Umkehrerscheinungen," 1919, V Kapitel). By such a mechanism the resulting mixture of optical isomerides, if not quite inactive, must contain an excess of the isomeride initially present, a Walden inversion thus being impossible. This statement, however, would not be applicable in the case of asymmetric catalytic racemisation (McKenzie and Smith, *Ber.*, 1925, **58**, 894). On the other hand, racemisation of type (2) may be effected by the occurrence of two simultaneous reactions, whereby both *d*- and *l*-isomerides of the product are formed as follows:

The two reactions, which may be identical from the ordinary kinetic standpoint, proceed with velocities, the coefficients of which,  $k_1$  and  $k_2$ , may be equal or different. The relative values of  $k_1$  and  $k_2$  might vary largely according to the experimental conditions, so that in some cases  $k_2$  would be negligible in comparison with  $k_1$ , when only one isomeride would result. When  $k_1$  and  $k_2$  become equal, the product would be entirely racemic; whilst, depending on the relative values of  $k_1$  and  $k_2$ , a complete range of intermediate activities of either sign is possible. By such a mechanism a Walden inversion may thus be effected. This view has been suggested in

various forms many times previously (compare Fischer, *Annalen*, 1911, 381, 126; Werner, *ibid.*, 1912, 386, 68), and the experiments of Holmberg, whereby active products of either sign are produced from a given initial material, provide a proof for the case in which the mechanisms of the production of the two isomerides differ when deduced from the ordinary kinetic standpoint. Thus the kinetic results (Holmberg, *J. pr. Chem.*, 1913, 87, 456) show that the conversion of sodium or silver *l*-bromosuccinate into malic acid proceeds through an intermediate stage, since definitely established as malolactone. If this reaction is carried out in acid solution, the product from *l*-bromosuccinic acid is *r*- and *l*-malic acids, whilst in alkaline solution *r*- and *d*-malic acids are formed. Holmberg represented this by the following scheme:

This scheme closely resembles the one used above, but the mechanism of the production of the malic acids from the lactone is not discussed, and appears to be more allied to Phillips's investigations (J., 1923, 123, 22; Kenyon, Phillips, and Turley, J., 1925, 127, 399; Phillips, *ibid.*, p. 2563) than to the present work, the reaction probably taking place by the fission of one or other of the bonds in malolactone as indicated in positions (a) and (b)

In the subsequent experiments on the xanthosuccinic acids and the thiolmalic acids (Holmberg, *J. pr. Chem.*, 1913, 88, 553; *Arkiv Kemi, Min., Geol.*, 1916, 6, No. 1; 1916, 6, No. 8; Holmberg and Lenander, *ibid.*, 1917, 6, No. 17) evidence from kinetic results shows the reaction to proceed both by direct substitution of the halogen and also *via* the lactone, and from experiments with the reactants in various concentrations, the following mechanism was put forward for the conversion into the thiolmalic acids (and similarly for the xanthosuccinic acids):

The mechanisms for the production of the stereoisomeric thiolmalic acids (and xanthosuccinic acids) are here kinetically different, whereas in the present investigation the mechanisms are the same from the ordinary kinetic point of view.

Considered on a quantitative basis, the reaction (*e.g.*)

in order to fulfil the conditions of the above mechanism, must (from the results of kinetic measurements) be one of a simple order, and the value of  $k$  thus calculated will be equal to  $k_1 + k_2$ , whilst, from the results of measurements of the change of rotation of the solution of the active substance with time under the same conditions as employed for the inactive, the same value of  $k$  should result. To test these considerations the conversion of sodium *l*-phenylchloroacetate into sodium *r*- and *l*-mandelate has been carried out. The action of water on *l*-phenylchloroacetic acid, of water on sodium *l*-phenylchloroacetate, and of aqueous sodium hydroxide on sodium *l*-phenylchloroacetate was first studied by McKenzie and Clough (J., 1908, 93, 811; 1909, 95, 777), who found that the mandelic acid produced was laevorotatory and that extensive racemisation occurred in these changes. The kinetics of the conversion of *r*-phenylchloroacetic acid and its sodium salt in aqueous solution, and also of the sodium salt in aqueous caustic soda solution, have been investigated (Senter, J., 1915, 107, 908), and it was shown that each of the above reactions is one and the same, namely, the reaction of water with the phenylchloroacetate ion. The best value for the velocity coefficient for the conversion of sodium *r*-phenylchloroacetate in aqueous sodium hydroxide solution at 25° was considered to be 0.00146, where time is measured in minutes, but the values of  $k$  actually found (*loc. cit.*, p. 914) at 25° for the sodium salt ( $N/10$ ) were

(a) in caustic soda ( $N/10$ ), 0.00138, 0.00142, 0.00145,

(b) „ „, ( $N/5$ ), 0.00134, 0.00134, 0.00138.

Thus the reaction here dealt with is  $\text{PhCHCl}\cdot\text{CO}_2' + \text{H}_2\text{O}(\text{excess}) \rightarrow \text{PhCH}(\text{OH})\cdot\text{CO}_2' + \text{NaCl}$  from the kinetic point of view. Table I gives the results of the corresponding polarimetric experiment, which was carried out as follows. To 150 c.c. of aqueous sodium hydroxide (0.1858*N*) at 24–85° were added 2.3037 g. of *l*-phenylchloroacetic acid with  $[\alpha]_{\text{D}}^{25} = -191.5^\circ$  in benzene (resolved by the method of McKenzie and Clough, *loc. cit.*, except that the morphine salt was

decomposed by dilute aqueous ammonia). The acid rapidly dissolved to a clear, colourless solution, which was maintained at 24.85°. Samples were withdrawn at the times shown in Table I, and their rotations determined, using a 2-dcm. tube and the yellow mercury line.

17	0.11			
Mean			0.0016	Mean 0.00161

The values of  $k$  differential (column 4) are obtained from the formula

$$k = \frac{\delta\theta}{\delta t} \cdot \frac{2}{\theta_{t_2} + \theta_{t_1} - 2\theta_\infty}$$

where  $\theta_{t_2}$  and  $\theta_{t_1}$  are consecutive observations,  $\delta\theta = \theta_{t_2} - \theta_{t_1}$  and  $\delta t = t_2 - t_1$ . The values of  $k$  thus calculated are irregular, as is only to be expected, since a small error in the determination of  $\theta$ , causes, by this method, a large variation in the coefficient. No drift in value, however, occurs, and the applicability to this case is thus shown of the integrated form (column 5) for a unimolecular reaction, namely,  $k = \frac{2.3}{t} \log_{10} \frac{\theta_0 - \theta_\infty}{\theta_t - \theta_\infty}$ .

This method of calculation does, however, suffer from the defect that great importance is placed on the value of  $\theta_0$ , but the mean value of  $k$  obtained by both methods is substantially the same. A duplicate determination using an acid with  $[\alpha]_{D^{780}} - 188^\circ$  gave  $k = 0.00160$ .

It would thus appear that the mechanism is in the main as postulated, but the divergence between the values of the coefficients

as thus calculated and those of Senter (*loc. cit.*) remains to be accounted for. The following experiment on sodium *l*-mandelate showed that under the conditions of the preceding experiments mandelic acid does not undergo catalytic racemisation, at least with any speed comparable with that of the displacement here studied. To 1.3865 g. of *l*-mandelic acid with  $[\alpha]_{D}^{15} - 159^\circ$  in water, was added a mixture of 50 c.c. of sodium chloride (0.2020*N*) and 50 c.c. of aqueous sodium hydroxide (0.1858*N*) at 24.85°. The solution was maintained at this temperature, and samples were withdrawn at intervals and their rotations determined, the yellow mercury line and a 2-dcm. tube being used. The results are shown below:

Time (hours)	0.10	2.05	12.05	30.5	50.0	3 days	9 days
Rotation ...	-3.25°	-3.43°	-3.35°	-3.43°	-3.44°	-3.44°	-3.44°

Thus no contributory factor here arises to produce the difference in the two values. There remains the slight possibility that the coefficient for sodium *l*-phenylchloroacetate is not the same as that for sodium *r*-phenylchloroacetate, but this was disposed of by carrying out experiments (a) and (b) below.

(a) To 1.4822 g. of *l*-phenylchloroacetic acid, with  $[\alpha]_{D}^{24} - 188^\circ$  at 24.85°, were added 100 c.c. of sodium hydroxide (0.2010*N*). Samples of 10 c.c. were withdrawn at times shown, and titrated against sulphuric acid ( $1.037 \times N/20$ ), phenolphthalein being used as indicator.

(b) This experiment was carried out simultaneously with (a), and the conditions were identical, except that 1.5816 g. of *r*-phenylchloroacetic acid were used.

The results are in Table II, *k* being equal to  $2.3/t \cdot \log_{10} a/(a-x)$ .

TABLE II.

<i>l</i> -Acid.			<i>r</i> -Acid.		
Time.	Titre.	<i>k</i> .	Time.	Titre.	<i>k</i> .

Mean 0.00130			Mean 0.00131		

It thus appears certain there is a divergence between the values of *k* as determined from titres and from optical measurements, and this may be satisfactorily accounted for by assuming that, in addition to the displacement racemisation of the phenylchloro-

acetate ion, there is a simultaneous catalytic racemisation of this ion, so that the completed scheme would become:

If  $a$  is the initial concentration of  $d$ -chloro-compound,  $b$  the initial concentration of  $l$ -chloro-compound,  $x$  and  $y$  the amounts of  $d$ - and  $l$ -chloro-compounds respectively changed in time  $t$ ,

$$\text{then } dx/dt = k_1(a - x) - k_1(b - y) + (k_2 + k_3)(a - x) \quad (1)$$

$$\text{and } dy/dt = k_1(b - y) - k_1(a - x) + (k_2 + k_3)(b - y) \quad (2)$$

Integration of (1) and (2) gives

$$x = a - \frac{a+b}{2} e^{-(k_2+k_3)t} - \frac{a-b}{2} e^{-(2k_1+k_2+k_3)t} \quad (3)$$

$$\text{and } y = b - \frac{a+b}{2} e^{-(k_2+k_3)t} + \frac{a-b}{2} e^{-(2k_1+k_2+k_3)t} \quad (4)$$

For the hydroxy-compounds, if  $w_d$  and  $w_l$  are the concentrations of  $d$ - and  $l$ - forms, respectively, present at time  $t$ ,

$$\text{then } dw_d/dt = k_2(a - x) + k_3(b - y) \quad (5)$$

Substituting in (5) the values of  $x$  and  $y$  in (3) and (4) and integrating

$$\begin{aligned}
 w_d = & -\frac{a+b}{2} e^{-(k_2+k_3)t} - \frac{k_2-k_3}{2k_1+k_2+k_3} \cdot \frac{a-b}{2} \cdot e^{-(2k_1+k_2+k_3)t} \\
 & + \frac{(k_1+k_2)a + (k_1+k_3)b}{2k_1+k_2+k_3}
 \end{aligned}$$

Similarly

$$\begin{aligned}
 w_l = & -\frac{a+b}{2} e^{-(k_2+k_3)t} - \frac{k_3-k_2}{2k_1+k_2+k_3} \cdot \frac{a-b}{2} \cdot e^{-(2k_1+k_2+k_3)t} + \\
 & \frac{(k_1+k_3)a + (k_1+k_2)b}{2k_1+k_2+k_3}
 \end{aligned}$$

Thus at any time  $t$ , the observed rotation of the solution ( $\theta_t$ ) is equal to the rotation of the chloro-compounds + the rotation of the hydroxy-compounds, i.e.,  $\theta_t = D_{CH}(a - x) - (b - y) + D_{OH}(w_d - w_l)$ , where  $D_{CH}$ ,  $D_{OH}$  are the rotations of unit concentrations

of *d*-chloro- and *d*-hydroxy-compounds, respectively, under the given conditions, *i.e.*,

$$\theta_t = D_{Cl}(a-b)e^{-(2k_1+k_2+k_3)t} + D_{OH} \cdot \frac{(k_2-k_3)(a-b)}{2k_1+k_2+k_3} \{1 - e^{-(2k_1+k_2+k_3)t}\}.$$

In the present case,  $a = 0$ , so that

$$\theta_t = -D_{Cl} \cdot b \cdot e^{-(2k_1+k_2+k_3)t} - D_{OH} \cdot b \cdot \frac{k_2-k_3}{2k_1+k_2+k_3} \{1 - e^{-(2k_1+k_2+k_3)t}\} \quad (6)$$

To evaluate  $k_1$ ,  $k_2$  and  $k_3$ , we have from (6) when  $t = 0$ ,

$$\theta_0 = -D_{Cl} \cdot b = -4.52 \text{ (Table I)} \quad . \quad . \quad . \quad (7)$$

and when  $t = \infty$ ,

$$\theta_\infty = -D_{OH} \cdot b \cdot \frac{k_2-k_3}{2k_1+k_2+k_3} = -0.11 \text{ (Table I).}$$

Substituting in (6),

$$\begin{aligned} \theta_t &= -4.52e^{-(2k_1+k_2+k_3)t} - 0.11 + 0.11e^{-(2k_1+k_2+k_3)t} \\ &= -4.41e^{-(2k_1+k_2+k_3)t} - 0.11, \end{aligned}$$

$$\text{i.e.,} \quad e^{(2k_1+k_2+k_3)t} = \frac{-4.41}{\theta_t + 0.11} = \frac{\theta_0 - \theta_\infty}{\theta_t - \theta_\infty},$$

$$\text{therefore} \quad 2k_1 + k_2 + k_3 = \frac{2.3}{t} \log_{10} \frac{\theta_0 - \theta_\infty}{\theta_t - \theta_\infty} = 0.00161 \text{ (Table I)}$$

and  $k_2 + k_3 = 0.00130$  (Table II), so that  $k_1 = 0.000155$ .

Further, from the data on p. 1188, 2.054 g. of mandelic acid ( $= 2.3037$  g. of phenylchloroacetic acid) have rotation  $-3.39^\circ = -D_{OH} \cdot b$ .

Therefore from (7),  $-0.11 = -3.39 \frac{k_2-k_3}{0.00161}$ , so that  $k_2 - k_3 = 0.000052$ , whence  $k_2 = 0.000676$  and  $k_3 = 0.000624$  and  $\theta_t = -4.41e^{-0.00161t} - 0.11$ .

For comparison with the observed values of  $\theta_t$ , those values thus calculated are shown in column 3, Table I.

The divergence between the coefficients from the corresponding titration and optical experiments is thus satisfactorily accounted for by assuming that besides the displacement racemisation, there is also a catalytic racemisation.

It becomes of interest to review in the same way the results of McKenzie and Walker (J., 1915, 105, 1685) on the conversion of *l*-phenylbromoacetic acid and its sodium salt in aqueous and aqueous caustic soda solutions, in conjunction with the corresponding kinetic experiments of Senter and Tucker (J., 1916, 107, 690). The experiments of Senter and Tucker on the reactions between *l*-phenylbromoacetic acid and its sodium salt, and also

between aqueous caustic soda and sodium *r*-phenylbromoacetate, showed that the main reaction in each case consists of the interaction of water and the phenylbromoacetate ion, exactly as for phenylchloroacetic acid. From the results on the bromo-acid, it was considered that in this case water also reacts with the undissociated acid, the reaction between water and the ion being some 120 times faster than between water and the undissociated acid. The main reaction here dealt with is, therefore,  $\text{PhCHBr}\cdot\text{CO}_2' + \text{H}_2\text{O}(\text{excess}) \rightarrow \text{PhCH}(\text{OH})\cdot\text{CO}_2'$ . As for the chloro-acid, the rate of reaction is thus dependent on the hydrogen-ion concentration, and development of hydrogen ions during the reaction causes a marked falling off in the value of the velocity coefficient. McKenzie and Walker found in some of their experiments that the reaction between water and *l*-phenylbromoacetic acid gave *d*- and *r*-mandelic acids, whilst in other cases *l*- and *r*-acids resulted, and to account for this the following scheme was put forward (*loc. cit.*, p. 1689):

The changes of rotation involved in the cases on which this theory is based were very small. Thus from the data in Table I (*loc. cit.*, p. 1693) the change is from  $-0.02^\circ$  to  $+0.04^\circ$ . Assuming that the *l*-rotation due to the mandelic acid when (I) is complete is  $-0.02^\circ$ , if no racemisation at all took place in (II) and (III), then the rotation of the *d*-mandelic acid would be  $+0.02^\circ$ , and could not be  $+0.04^\circ$  by this mechanism, although a difference of  $\pm 0.02^\circ$  is within the limits of experimental error. If, however, it is assumed that (II) and (III) proceed at all, extensive racemisation would undoubtedly accompany both stages, so that for practical purposes the resultant mandelic acid would be optically inactive. Furthermore, these processes must be assumed to continue indefinitely, and by the above mechanism complete racemisation must ultimately result, but in the first experiment quoted (*loc. cit.*, p. 1692), the mandelic acid isolated after 3 weeks had  $\alpha_D + 0.16^\circ$ ,  $[\alpha]_D + 4.7^\circ$ , whilst in the second experiment, the mandelic acid isolated after two months at  $25^\circ$  had  $\alpha_D + 0.31^\circ$ ,  $[\alpha]_D + 5.2^\circ$ . It does not appear justifiable to base any accurate comparison on the third experiment (*loc. cit.*, p. 1692), in which an optically impure phenylbromoacetic acid ( $[\alpha]_D - 70^\circ$ ) was used, when it was found that the rotation of the solution before isolation of the product was  $\alpha_D - 0.16^\circ$ , and of the mother-liquors after isolation was  $\alpha_D - 0.45^\circ$ ; the rotation of

the mandelic acid isolated (= 18.2% of theory) is not recorded, and the rotations of the solutions in this case might well be due to some impurity present initially in the partly racemic phenylbromoacetic acid used. Thus it does not appear that McKenzie and Walker's scheme is correct. Also no explanation is apparent for the almost complete racemisation in stage (I). On the other hand, if the mechanism of the reaction is assumed in the main to be

where  $k_1$  and  $k_2$  are nearly equal, closer agreement between theory and experiment is obtained. In some cases, according to the conditions,  $k_1$  may be greater than  $k_2$ , corresponding with the production of a final dextrorotation, whilst if  $k_1$  is less than  $k_2$ , then the solution will remain levorotatory. This explanation is only tenable if the change of sign of rotation is in accord with the displacement effect as determined by titration, and whereas McKenzie and Walker's experiments showed the displacement to be complete before a final steady rotation value was obtained, the following experimental results did not confirm this.

*Reaction between Water and r-Phenylbromoacetic Acid at 25°.*

Water (250 c.c.) was added to *r*-bromo-acid (1.3438 g. =  $N/40$  and 2.5088 g. =  $1.867N/40$ , respectively); in the case of the  $N/40$  solution, 72 minutes elapsed before the solution was homogeneous, whilst for the  $1.867N/40$  solution, 173 minutes were required. These times are reckoned as zero in each set of results. Samples (10 c.c.) were withdrawn and titrated against sodium hydroxide solution (1.011 $N/40$ ), with phenolphthalein as indicator. The results are in Table III,  $k_1$  and  $k_2$  being calculated from the usual unimolecular formula.

The theoretical final titres are 19.78 c.c. and 36.93 c.c., respectively. The above data confirm the results of Senter and Tucker (*loc. cit.*, p. 694) and McKenzie and Walker (*loc. cit.*, p. 1693) that the value of the velocity coefficient in  $N/40$  solution is appreciably higher than in  $1.867 \times N/40$  solution (McKenzie and Walker state their results as  $k \times 10^{-3}$ , whereas they should be  $k \times 10^{-2} \times 2.3$ ). This difference is in accord with the different relative concentrations of phenylbromoacetate ions in the two solutions, for, in the reactions

25 hrs.	19.3		24 hrs.	36.0	
47	19.7		45½	37.0	
72	19.7		70½	37.0	

if  $a_1$  is the initial concentration of bromo-acid and  $\alpha_1$  the degree of dissociation, the initial concentration of phenylbromoacetate ion is  $a_1\alpha_1$  and therefore the initial rate of reaction is  $k\alpha_1a_1$ , whereas the rate in Table III is actually measured by  $k_1a_1$ , so that  $k = k_1/\alpha_1 = k_2/\alpha_2$  similarly. Now  $\alpha_1 = 0.3106$  for N/40-solution, since the dissociation constant for phenylbromoacetic acid is 0.0035 (Senter and Tucker, *loc. cit.*, p. 692) and  $k_1 = 0.00406$ , taking the mean value in Table III (since the initial values are irregular), so that  $k = 0.013$ . Similarly for 1.867N/40-solution,  $\alpha_2 = 0.2390$  and  $k_2 = 0.00284$ , giving  $k = 0.012$ .

The important point of difference, however, is that whereas McKenzie and Walker's titration experiment showed the displacement of halogen to be complete after 25½ hours, in the present experiments all the halogen was not displaced in this time, but was complete only after some 50 hours, for the initial rate of reaction falls off rapidly as the reaction proceeds, owing to the accumulation of hydrogen ions in the system.

*Reaction between Water and 1-Phenylbromoacetic Acid at 25°.*

The optical kinetic experiment of McKenzie and Walker (*loc. cit.*, p. 1693) was also repeated, but in this case a 4-dcm. tube was used and measurements were made both for the yellow and the green mercury lines. Accordingly 0.3011 g. of *l*-bromo-acid with  $[\alpha]_{589}^{17.7}$  — 177° in benzene was dissolved in 30 c.c. of water (= 1.867N/40) at 25°. Solution occupied 62 minutes, and this is shown as zero-time in Table IV. The values of  $k$  are calculated for a unimolecular reaction.

TABLE IV.

120	+0.11		+0.14	

The final change in the rotation of the solution is thus to be attributed to the completion of the displacement reaction, and stages (II) and (III) of McKenzie and Walker's scheme become unnecessary. For comparison, the various results in the two papers previously referred to, calculated on the basis of a uni-molecular reaction, are summarised in the following table, together with the present results.

Experiment.	$k$ (Titration).	$k$ (Optical).
(1) <i>l</i> -Acid, 25° .....	—	0.00373
<i>r</i> -Acid, 25° .....	0.00284	—
(2) <i>l</i> -Acid, 36.8° .....	0.0142	0.0161
(3) Sodium salt of <i>l</i> -acid, 24.8° .....	—	0.0166
"   "   of <i>r</i> -acid, 25° .....	0.0147	—
(4) Sodium salt of <i>l</i> -acid, sodium hydroxide, 24.1° .....	—	0.0179
"   "   of <i>r</i> -acid, sodium hydroxide, 25° .....	0.0181	—
	0.0175	

In cases (1), (2), and (3), the individual values of  $k$  fall off with time, so that the mean values above are calculated over corresponding time intervals. There is a general agreement throughout between the two series of coefficients, but those from the optical measurements are higher than those based on titrations; this difference would agree, as also in the case of the chloro-acid, with a catalytic racemisation of the phenylbromoacetate ion occurring simultaneously with the displacement racemisation. The catalytic racemisation of phenylbromoacetic acid in aqueous acetone solution was clearly demonstrated by McKenzie and Walker (*loc. cit.*, p. 1694). The mechanisms of the conversions of phenylbromoacetic acid and

its sodium salt to mandelic acid and sodium mandelate thus agree with the mechanism above suggested much better than with that advanced previously.

#### *Discussion of Results.*

The above results show that the reaction of water with *l*-phenylchloroacetate and *l*-phenylbromoacetate ions yields simultaneously both *l*-mandelate and *d*-mandelate ions by the same simple reaction from the kinetic point of view, the one reagent thus behaving both "normally" and "abnormally" at the same time in this reaction. The production of phenylaminoacetic acids of either sign from a given phenylchloroacetic acid (Senter and Drew, J., 1915, 105, 638; 1916, 107, 1091) or phenylbromoacetic acid (Senter and Tucker, J., 1918, 113, 140) by reaction with ammonia in various solvents is explicable on the above basis, for the relative values of the velocity coefficients will certainly depend on the solvent medium (compare Senter, Drew, and Martin, J., 1918, 113, 155). In the case of the other conversions similarly studied (Senter, Drew, and Martin, *loc. cit.*; Senter and Ward, J., 1924, 125, 2137; 1925, 127, 1847), it would appear probable that the relative values of the two velocity coefficients differ more widely, agreeing with the production of the same isomeride in excess for all solvents studied.

The author wishes to thank Dr. Senter for his interest in this work, and the Department of Scientific and Industrial Research for a maintenance grant during part of the time occupied in carrying it out.

BIRKBECK COLLEGE,

UNIVERSITY OF LONDON, E.C. 4. [Received, December 19th, 1925.]

## CLII.—*Substituted Cinnamic Amides and Acids.*

By HAROLD AINSWORTH HARRISON and HAROLD WOOD.

IN a previous paper (this vol., p. 577) the configuration of a 3 : 4'-dinitrochlorostilbene resulting from the elimination of one molecule of hydrogen chloride from the stilbene dichloride was determined by the fact that sulphuric acid converted it into 4-nitrophenyl 3-nitrobenzyl ketone. The constitution of this ketone was deduced from its non-identity with the isomeric 3-nitrophenyl 4-nitrobenzyl ketone obtained by oxidation of the intermediate aldol compound isolated during the condensation of *p*-nitrophenylacetic acid with *m*-nitrobenzaldehyde and therefore having the structure

Another synthesis of 4-nitrophenyl 3-nitrobenzyl ketone [from

3 : 4'-dinitro- $\alpha$ -phenyleinnamamide, utilising Weerman's modification of the Hofmann reaction (*Proc. K. Akad. Wetensch. Amsterdam*, 1907, **10**, 308; *Annalen*, 1913, **401**, 1; *Rec. trav. chim.*, 1917, **37**, 1)], which confirmed the foregoing conclusions, is now described.

When *p*-nitrophenylacetonitrile and *m*-nitrobenzaldehyde are combined, with sodium ethoxide or piperidine as condensing agent, according to the method of Remse (*Ber.*, 1890, **23**, 3135), 3 : 4'-dinitro- $\alpha$ -phenyleinnamitrile (I) and 3 : 4'-dinitro- $\beta$ -hydroxy- $\alpha$ -phenyldihydrocinnamitrile (II) are formed in about equal quantities. Neither Remse (*loc. cit.*) nor Freund (*Ber.*, 1901, **34**, 3107), both of whom carried out this same experiment, mentions the formation of (II), their sole product being (I).<sup>\*</sup> The aldol compound (II) may be converted into (I) by the action of sulphuric acid, pyridine or piperidine.

Two quite different stereoisomeric *amides* (III and IV) are produced when (I) and (II) are hydrolysed with sulphuric acid. Amide (IV) on further hydrolysis with sulphuric acid yields only one acid (VI), but amide (III) under the same conditions gives a mixture of

<sup>\*</sup> From *o*-nitrobenzaldehyde and *p*-nitrophenylacetonitrile, however, Freund (*loc. cit.*) did isolate two compounds analogous to (I) and (II) above.

(V) and (VI); the same mixture is also formed when the nitrile (I) is directly hydrolysed to the acid stage. When amide (III) is hydrolysed with nitrous acid, however, acid (V) is almost the sole product.

The two acids (V) and (VI) can be separated, by Stoërmer and Prigge's method (*Annalen*, 1915, 409, 20), by taking advantage of their widely differing strengths. Acid (VI) is the weaker, and from analogy with Stoërmer's results (see also Stoërmer and Voht, *ibid.*, 1915, 409, 36) it is provisionally called the "trans" modification; the term applies to the relative positions of the phenyl and carboxyl groups, and not to the two phenyl groups.

Acids (V) and (VI) can both be decarboxylated by heating with piperidine, and yield the same form of 3 : 4'-dinitrostilbene.

#### EXPERIMENTAL.

3 : 4'-Dinitro- $\beta$ -hydroxy- $\alpha$ -phenyldihydrocinnamonnitrile (II).—When the condensation of *p*-nitrophenylacetonitrile and *m*-nitrobenzaldehyde in presence of piperidine or sodium ethoxide was allowed to proceed for only a few hours the product contained not only 3 : 4'-dinitro- $\alpha$ -phenylcinnamonnitrile (I), m. p. 199—200° after recrystallisation from acetic acid (Remse and Freund give m. p. 195°), but also an equal amount of the intermediate *aldol* (II), which was isolated from the alcoholic mother-liquors, the total yield of the two nitriles being 85—90%. After many recrystallisations from acetic acid the aldol was obtained in yellow, crystalline aggregates, m. p. 135—136° (Found: C, 57.2; H, 3.6.  $C_{15}H_{11}O_5N_3$  requires C, 57.5; H, 3.5%). It is easily soluble in pyridine, nitrobenzene, acetone, or ethyl acetate, less soluble in alcohol or benzene, and somewhat sparingly soluble in chloroform, carbon tetrachloride, or light petroleum. (II) can be converted into (I) by dissolution in cold concentrated sulphuric acid, by dissolving it in hot pyridine and keeping the solution for several days, or by keeping the crude reaction mixture (in presence of alcoholic piperidine) for a week.

The Two Stereoisomeric Forms of 3 : 4'-Dinitro- $\alpha$ -phenylcinnamamide (III and IV).—Each of the nitriles (I) and (II) (20 g.) was carefully dissolved in warm concentrated sulphuric acid (340 c.c.), water (46 c.c.) added, and the mixture heated on the steam-bath for 6 hours. When cold, the solution was poured into 2 litres of water, and the precipitated amide washed with hot dilute ammonia and with water (yield 96—99%). The amide (III), obtained from (I), separated from acetic acid in almost colourless needles, m. p. 220° (Found: C, 57.4; H, 3.6.  $C_{15}H_{11}O_5N_3$  requires C, 57.5; H, 3.5%). It is sparingly soluble in the usual organic solvents, and is not hydrolysed to the acid by boiling with hydrochloric acid for 2 days. The higher-melting form of the amide (IV), obtained from

(II), is even less soluble than (III) in organic solvents. It separates from acetic acid in microscopic prisms and from nitrobenzene in thin plates, m. p. 272.5—273.5° (Found: C, 57.2; H, 3.9%).

*Conversion of the Amide (III) into 4-Nitrophenyl 3-Nitrobenzyl Ketone.*—A paste of the finely powdered amide (20 g.) and boiling methyl alcohol was cooled and added, with shaking, to a solution of sodium hypochlorite during 1 hour. The mixture was then heated at 80° for  $\frac{1}{2}$  hour, much unchanged amide filtered off, the warm liquor acidified with dilute sulphuric acid, and the dark brown precipitate repeatedly crystallised from alcohol (charcoal). The slightly brown needles thus obtained melted at 132°, alone or mixed with 4-nitrophenyl 3-nitrobenzyl ketone. The yield was exceedingly poor, but the constitution of the ketone was proved.

*cis and trans Forms of 3:4'-Dinitro- $\alpha$ -phenylcinnamic Acid (V and VI).*\*—Amide (III) (17 g.) was boiled with a mixture of strong sulphuric acid, acetic acid, and water (125 c.c. of each) for 2 days, the product poured into water, and the filtered solid digested with hot sodium carbonate solution; the addition at 95° of a slight excess of acetic acid precipitated, in 48% yield, the weaker "trans" acid (VI), which crystallised from ethyl acetate in large, pale yellow prisms, m. p. 221° (Found: C, 57.2; H, 3.2; equiv., 316.  $C_{15}H_{10}O_6N_2$  requires C, 57.3; H, 3.2%; equiv., 314). This isomeride is much less soluble than (V) in methyl alcohol or ethyl acetate.

From the hot filtrate after removal of acid (VI), most of the stronger "cis" acid (V) separated out, mixed with a little (VI), and addition of hydrochloric acid to the cold filtrate increased the yield to 36%. After two crystallisations from acetic acid (V) was obtained in rosettes of slightly brown needles, m. p. 205.5° (Found: C, 56.9; H, 3.3%; equiv., 312). It is readily soluble in hot methyl or ethyl alcohol, or acetic acid, and is moderately soluble in cold ethyl acetate.

From the nitrile (I), by hydrolysis under the above conditions, 32% of acid (VI) and 38% of acid (V) were obtained.

Hydrolysis of amide (IV) during 3 days led to the formation of acid (VI) in 77% yield. No acid (V) was discovered, the cold filtrate after removal of (VI) by acetic acid remaining quite clear on addition of hydrochloric acid.

*Hydrolysis of Amide (III) with Nitrous Acid.*—To a solution of amide (III) in cold concentrated sulphuric acid an excess of sodium nitrite was added, with water-cooling. After 2 days, the solution was diluted with water and kept for a week, a little more nitrite being added occasionally. The solid was removed, washed, and

\* For a description of the piperidine salts of these two acids, see this vol.,

thoroughly digested on the filter with hot sodium carbonate solution. Acetic acid was added to the boiling filtrate in slight excess, and the solution again filtered hot to remove a very small amount of precipitate (VI). On cooling, the filtrate deposited acid (V) in 80% yield.

*Decarboxylation of Acids (V) and (VI).*—The acid (3 g.) was dissolved in boiling acetone, piperidine ( $\frac{1}{2}$  c.c.) added, and the acetone distilled off. The intimate mixture thus obtained was heated at 225° for  $\frac{1}{2}$  hour, and, after cooling, the resinous product was washed several times with boiling acetone and finally recrystallised from acetic acid, when it melted at 216°, either alone or mixed with an authentic specimen of 3:4'-dinitrostilbene (for which see this vol., p. 580). The yields from acids (V) and (VI) were respectively 27% and 32%.

In conclusion, one of us (H. W.) desires to express his indebtedness to the Department of Scientific and Industrial Research for a maintenance grant, and the other (H. A. H.) to the Chemical Society Research Fund Committee for a grant for materials. We also thank Professor Lapworth for his continued interest and advice.

THE UNIVERSITY, MANCHESTER.

[Received, January 30th, 1926.]

### CLIII—*The Chemistry of the Glutaconic Acids. Part XIX. A Consequence of Mobility.*

By JOHN PACKER and JOCELYN FIELD THORPE.

THE mobility of the hydrogen atom in the three-carbon system

so far as it has yet been investigated, reaches its maximum in glutaconic acid, causing this substance to exist in only one form, the postulated "normal" form to which has been ascribed the tentative constitution  $\text{CO}_2\text{H}\cdot\text{CH}\cdot\text{CH}(\text{H})\cdot\text{CH}\cdot\text{CO}_2\text{H}$ .

If the corresponding unsaturated formulæ be set up on the models, drawings of which are shown in Fig. 1, it will be found that this mobility may or may not involve a change from the hypothetical *cis*- (I) to the *trans*- (II) form and *vice versa*, depending on the spatial relationship of the methylene hydrogen atoms to the double bond at the time of change.

While this fact is, in itself, no argument for or against the "normal" form, yet it supplies certain explanations and deductions which are of fundamental importance in connexion with the chemistry of these substances.

It is certainly paradoxical that, whilst the two hydrogen atoms

of the methylene group are of equal value owing to the occurrence of free rotation about the single bond, they should have different values when used in bringing about the three-carbon change. But it must be remembered that the positions of the constituent atoms in space are determined by the tendency for like groups to take up positions as remote as possible from one another, a tendency which the molecule can satisfy owing to its power of free rotation about the single bond.

FIG. 1.

In the case of glutaconic acid, where it is immaterial on which side of the central carbon atom the double bond is placed, the tautomeric change would be expected, in the case of the *trans*-form to take place mainly without alteration in stereochemical configuration, and in the case of the *cis*-form to result mainly in conversion into the *trans*-form. In those derivatives of glutaconic acid in which substituting groups are attached to the  $\alpha$ ,  $\beta$ , or  $\gamma$  carbon atom and which may in consequence exist theoretically in more forms, the necessary alterations in the stable positions of the atoms in space may lead to differences in the tendency of the *cis*- and *trans*-forms to be converted into one another by the tautomeric change.

Certain deductions given below render it probable that valuable evidence will be obtainable on these lines regarding the existence or non-existence of the postulated "normal" form. Experiments on this point are now in hand, but it is thought desirable to publish this new point of view at once, because it offers an explanation as to why both forms of, for example, the  $\beta$ -methylglutaconic acids readily yield anhydrides.

The argument has been used by us that the ready formation of the hydroxy-anhydride from both forms of  $\beta$ -methylglutaconic acid favours the assumption of the "normal" form rather than the *cis*- and *trans*-configuration, because in the analogous case of non-mobile systems, for example,  $\alpha\alpha$ -dimethylglutaconic acid,  $\text{CO}_2\text{H}\cdot\text{C}(\text{CH}_3)_2\cdot\text{CH}\cdot\text{CH}\cdot\text{CO}_2\text{H}$ , the *trans*-form gives no anhydride. It is evident, however, from a study of the models, which are similar

to those for glutaconic acid, that the formation of the hydroxy-anhydride may be preceded by a change of configuration and hence the relative ease of formation of the anhydride from the *trans*- and *cis*-forms is seen to depend on the mobility of the tautomeric system under the conditions of dehydration.

The authors do not wish to call into question the existence of the "normal" form, which is supported by a number of experimental facts, but they desire to point out that :

A. Assuming glutaconic acid to be the stable *trans*-form, it follows that the formation of the hydroxy-anhydride must take

FIG. 2.

place through the *cis*-modification, the inability to isolate the *cis*-form of the acid by hydration of the hydroxy-anhydride being due to the mobility of the system. The existence of two forms of  $\beta$ -methylglutaconic acid, each giving the same hydroxy-anhydride with equal readiness, is due to the same mechanism, but in this case the order of mobility is lower and hence the *cis*-modification can be isolated by hydrating the hydroxy-anhydride under special conditions.

B. In such cases as the  $\alpha\gamma$ -dimethyl- and  $\alpha\beta\gamma$ -trimethyl-glutaconic acids, the theoretically possible *cis*- and *trans*-forms should be capable of resolution into optically active forms, so that, for example, the four forms of the  $\alpha\beta\gamma$ -trimethylglutaconic acids depicted in Fig. 2 should be capable of existence as well as the "normal" form

$\text{CO}_2\text{H}\cdot\text{C}(\text{CH}_3)\cdot\text{C}(\text{CH}_3)(\text{H})\cdot\text{C}(\text{CH}_3)\cdot\text{CO}_2\text{H}$ . It will be seen that the tautomeric changes may result in the following transformations

but when the tendency of like groups to take up positions as far apart as possible is also considered the following deductions can be made :

(i) The two enantiomorphous *cis*-forms (III) and (V) will tend to pass into the correspondingly active *trans*-forms (IV) and (VI) rather than into each other, unless the change is arrested at the intermediate "normal" form.

(ii) The two enantiomorphous *trans*-forms (IV) and (VI) will show a greater tendency to interconversion (racemisation) than in the case of the *cis*-forms, and this change may take place to the practical exclusion of transformation into the *cis*-forms.

(iii) If the stable form of the acid is the *trans*-form, it will be capable of resolution into optically active forms which will be distinct from the active forms of the *cis*- (labile) acid ; inability to resolve the stable form would be evidence for the "normal" constitution.

C. In the case of  $\alpha$ - and  $\alpha\beta$ -substituted glutaconic acids the structural isomerides (VII) and (VIII) are theoretically possible, well as the "normal" form

(VII.)  $\text{CO}_2\text{H}\cdot\text{CR}^1\cdot\text{CR}^2\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$   $\text{CO}_2\text{H}\cdot\text{CR}^1\text{H}\cdot\text{CR}^2\cdot\text{CH}\cdot\text{CO}_2\text{H}$  (VIII) and each may exist in *cis*- and *trans*-forms. The two forms of (VII) will be incapable of resolution into optically active forms, whilst the two forms of (VIII) will be capable of such resolution under conditions not leading to tautomeric mobility. This should afford an experimental means of determining the position of the double bond in these unsaturated forms.

These isomeric forms are theoretically interconvertible by tautomeric change according to the scheme :

and a study of the models in these cases leads to the following conclusions :

(i) Where  $\text{R}^1$  and  $\text{R}^2$  are positive groups, the *trans*-forms will be more stable than the *cis*-forms.

(ii) Where  $R^2$  is a negative group (e.g.,  $C_6H_5$ ), the relative stability of the *cis*-forms will be increased.

D. The reduction in mobility of the glutaconic system brought about by the substitution of various groups for hydrogen atoms, and the consequent increase in stability of the labile unsaturated forms, can be explained by an application of Thorpe and Ingold's theory of the influence of attached groups on the carbon tetrahedral angle; for the effect of such groups is obviously to reduce the strain in the double bond or two-carbon ring.

The effect of a group in the  $\beta$ -position will be to stabilise both the  $\alpha\beta$ - and  $\beta\gamma$ -unsaturated forms, whilst the effect of a group in the  $\alpha$ -position will be greater in stabilising the  $\alpha\beta$ - than the  $\beta\gamma$ -unsaturated form, so that in general a group in the  $\beta$ -position will have a greater effect in retarding the mobility of the system than will the same group in the  $\alpha$ -position. Hence in the case of  $\alpha$ - and  $\alpha\beta$ -substituted acids, the  $\alpha\beta$ -unsaturated forms (VII) should be more stable than the  $\beta\gamma$ -unsaturated forms (VIII).

In the case of  $\beta$ -phenyl- $\alpha$ -methylglutaconic acid one stable and three labile forms are known. To the *cis*- and *trans*-labile forms of Thorpe and Wood have been assigned the  $\alpha\beta$ -, and to the labile form of Feist the  $\beta\gamma$ -unsaturated structure. If these constitutions are correct, the above considerations favour the "normal" structure for the stable form of the acid, since the only other possible structure is that of the  $\beta\gamma$ -unsaturated *trans*-form, which would be expected to be relatively unstable.

An examination of these acids from the above points of view has been commenced in the hope of thus throwing further light on their constitutions.

#### CLIV.—*Selective Solvent Action. Part V.* *Salting in.*

By ROBERT WRIGHT.

THE mutual lowering of solubility which takes place when an electrolyte and an organic substance are dissolved together in water has been the subject of many investigations (Rothmund, "Löslichkeit und Löslichkeitsbeeinflussung"), and is the basis of the process of "salting out" when an organic compound is driven out of aqueous solution by the addition of a salt. What may be termed "salting in" is the reverse phenomenon, that is, a mutual increase

in solubility of electrolyte and organic compound when added to the same solvent, which in this case is not pure water but aqueous alcohol.

In former papers (J., 1922, **121**, 2252; 1923, **123**, 2493; 1925, **127**, 2335) it was shown that the addition of a semi-solute to a mixed solvent raised both the vapour pressure and the freezing point of the constituent in which it was insoluble. Thus sodium chloride (or other salt) raised the alcohol vapour pressure of aqueous alcohol, whilst water raised the freezing-point of benzene in an alcohol-benzene mixture. It was pointed out that this might be explained on the solvate hypothesis: in the alcohol-benzene mixture, we have complexes formed between the two constituents; water, when added, competes with the benzene for the alcohol, forming water-alcohol solvates and decomposing some of the alcohol-benzene solvates, thus leaving the solution richer in free benzene and therefore with a higher freezing-point and benzene vapour pressure.

A corresponding effect might be expected in the case of solubility. The addition of salt to aqueous alcohol should form salt hydrates with a consequent increase in the free alcohol present and a corresponding increase in solvent power for benzene or other organic substances. Conversely, the presence of benzene should increase the solvent power of the mixed solvent for a water-soluble solute.

This effect can readily be demonstrated in a qualitative manner. To 100 c.c. of 50% alcohol, benzene is added 1 c.c. at a time until the solution turns turbid; if sodium chloride is now added to the turbid mixture, the liberated alcohol (due to the removal of water for the formation of salt hydrates) will dissolve the excess of benzene and cause the solution to become clear.

Quantitative determinations of this increase of solubility in 50% (by weight) aqueous alcohol have been made with benzene, carbon tetrachloride, and methyl salicylate as alcohol-soluble solutes, and with sodium chloride, sodium nitrate, potassium chloride, potassium bromide, and potassium nitrate as water-soluble salts. It will be noted that none of the salts crystallises with water of crystallisation.

In the method employed, about 12 g. of the aqueous alcohol were weighed in a stoppered tube and excess of salt was added. The benzene, or other organic compound, was weighed in a weight burette and added to the solution in the tube, in small quantities, until turbidity was produced, the quantity of benzene thus added being found by a second weighing. The turbid mixture was shaken in a thermostat at  $20^{\circ} \pm 0.1^{\circ}$  for 6 hours until the solution was saturated with both solutes. About 2 c.c. of the solution were then weighed in a stoppered bottle and the salt was estimated by evaporation to dryness and weighing. Since the proportion of benzene to

aqueous alcohol in the solution is known, the percentage of both salt and benzene dissolved in the aqueous alcohol can be calculated and compared with the percentage when only one solute—benzene or salt—is present. The results obtained are in Tables I and II, and it will be seen that the solubility of each semi-solute is increased by the presence of the other, the increase being considerable in the case of the organic compound.

TABLE I.

Solubilities of organic compounds in 100 g. of 50% aqueous alcohol saturated with different salts at 20°.

Salt present.	None.	NaCl.	NaNO <sub>3</sub> .	KCl.	KNO <sub>3</sub> .	KBr.
Benzene .....	5.8	9.6	9.5	6.7	6.4	7.8
Carbon tetrachloride...	6.4	13.4	8.2	9.9	7.1	9.9
Methyl salicylate .....	6.2	8.2	8.1	7.2	6.9	7.9

TABLE II.

Solubilities of salts in 100 g. of 50% aqueous alcohol saturated with organic compounds at 20°.

Organic compound.	None.	Benzene.	Carbon tetrachloride.	Methyl salicylate.
Sodium chloride .....	9.8	10.6	10.7	10.2
„ nitrate .....	19.4	21.2	20.8	20.4
Potassium chloride .....	6.0	6.5	6.8	6.2
„ nitrate .....	3.7	3.9	3.8	3.8
„ bromide .....	16.4	17.4	17.4	17.3

Four determinations of the solubility of the salt were made in each case, and the results seldom differed by more than one unit in the first decimal place. The solubility of the organic substance was less accurate and, since it was determined by the appearance of turbidity, was always too great, the error being about three units in the decimal place. This error is of less importance in that the increase in solubility of the organic substance is always much greater than that of the salt.

A somewhat more accurate investigation was carried out in the case of benzene and sodium chloride. The solubility of benzene in 50% alcohol was determined at a series of temperatures by adding a weighed quantity of benzene to a definite weight of the solvent and raising the temperature until the turbidity disappeared. A second series was also carried out after 5% of sodium chloride had been added to the aqueous alcohol. The results—which are in Table III—when plotted give two curves practically parallel to each other. The solubility of sodium chloride in 50% alcohol containing small quantities of benzene was also determined, the quantity of benzene being less than that which would produce turbidity. The results are in Table IV.

TABLE III.

Solubility of benzene in 50% aqueous alcohol.		Solubility of benzene in 50% alcohol with 5% NaCl.	
% Benzene.	Temp.	% Benzene.	Temp.
4.57	11.2°	5.80	9.1°

5.30	18.0	6.76	16.7
5.61	20.2	7.23	19.2
5.97	22.6	7.57	21.3

TABLE IV.

Solubility at 20° of sodium chloride in 100 g. of 50% aqueous alcohol containing a varying percentage of benzene.

% Benzene .....	0.00	1.91	4.10	5.34	7.95
% Sodium chloride .....	9.80	9.86	9.95	10.10	10.35

As is well known, the addition of potassium carbonate to aqueous alcohol causes the formation of two liquid phases, the greater concentration of the salt being found in the lower (aqueous) layer. The amount of carbonate required to produce turbidity increases with the amount of water present, hence a system which contains just sufficient carbonate to produce turbidity can be cleared by a slight addition of water. This small amount of water can be produced by the desolvation of aqueous alcohol caused by the addition of benzene. For example, if about 0.05 g. of potassium carbonate be dissolved in 2 c.c. of water and 10 c.c. of alcohol be added, a turbid mixture will result, which can be cleared by the addition of either a little water or a larger amount of benzene. A large excess of benzene will again produce turbidity, the benzene forming a layer on top of the aqueous alcohol. Also, if the system contains a larger proportion of carbonate, it is possible, by the addition of benzene, to produce a system of three liquid phases, the benzene and the aqueous salt solution being separated by a layer of aqueous alcohol. That potassium carbonate—like other salts—increases the solubility of benzene in aqueous alcohol is shown by the results given in Table V.

TABLE V.

Solubility at 20° of benzene in 100 g. of aqueous alcohol containing a varying percentage of potassium carbonate.

% Potassium carbonate .....	0.00	1.12	1.67	2.18	2.48	2.68*	2.86
% Benzene .....	5.8	6.4	6.5	7.1	7.3	7.6	8.0

\* Two phases separate.

It is evident from the results shown that with 50% aqueous alcohol there is a mutual increase in solubility of the two types of semi-

solute when they are present together. It has not been considered advisable to attempt to assign any definite degree of solvation to the semi-solutes, as the number of equilibria involved would render any such calculation of very doubtful value.

### CLV.—10-Chlorophenthiarsine, and its Rate of Formation from *o*-Phenylthiolphenyldichloroarsine.

By ELWYN ROBERTS and EUSTACE EBENEZER TURNER.

IN continuation of previous work (Roberts and Turner, J., 1925, 127, 2004), *o*-phenylthiolphenyldichloroarsine (I) has been prepared, and its rate of conversion into 10-chlorophenthiarsine (II) determined. Whereas *o*-phenoxyphenyldichloroarsine undergoes nearly 60% conversion into the ring compound, the sulphur analogue undergoes only about 20% conversion under the same conditions, i.e., when heated at 200° in a current of carbon dioxide.

A further comparison has been made between *o*-phenoxyphenyldichloroarsine and *o*-phenoxyphenylmethylchloroarsine (III) from the same point of view. The chloroarsine is even more stable towards heat than the above phenylthiol compound, undergoing in 6 hours at 200° only about 10% of the possible loss of hydrogen chloride. Moreover, side reactions appear to occur, and it has not been found possible to detect the presence of the expected 10-methylphenoxarsine in the product of decomposition. The latter, when treated with methyl iodide, afforded a little 10-iodophenoxarsine, but no 10 : 10-dimethylphenoxarsonium iodide. This substance has been prepared, for purposes of comparison, by treating with methyl iodide the product of interaction of magnesium methyl iodide and 10-chlorophenoxarsine.

It has been pointed out (Turner and Sheppard, J., 1925, 127, 544) that arsenic trichloride and diphenyl ether do not interact in absence of aluminium chloride. It seemed possible that this might be due to the low boiling point of the mixture, which is well below the temperature at which phenoxyphenyldichloroarsine undergoes conversion into the chlorophenoxarsine. It has, however, been

found that a mixture of phenyldichloroarsine and diphenyl ether boils unchanged at 250–260°, so that the ring closures in question are evidently determined more by collision effects than by those of activation due to increase of temperature.

#### EXPERIMENTAL.

*o*-Nitrodiphenyl Sulphide.—This substance, previously obtained by Mauthner (Ber., 1906, **39**, 3593), is more conveniently prepared by the following method: Potassium hydroxide (61 g.; 1 mol.) was dissolved in 5 c.c. of water, 120 g. (1 mol.) of thiophenol, and then 173 g. (1 mol.) of *o*-chloronitrobenzene and 8 g. of copper bronze were added. The mixture was heated at 170–185° for 2 hours after the initial vigorous reaction had subsided. The cooled product was extracted with carbon tetrachloride, the extract washed successively with alkali and water, and dried over calcium chloride. The solvent was removed, and the residue distilled under diminished pressure. In this manner, 138 g. of *o*-nitrodiphenyl sulphide were obtained, b. p. 210°/15 mm. Crystallisation from light petroleum removed traces of a disulphide, the pure nitro-compound having m. p. 79° (Mauthner gives 77°).

*o*-Aminodiphenyl Sulphide.—The foregoing nitro-compound was reduced with iron, water and ferric chloride (Roberts and Turner, *loc. cit.*). A little thiophenol is formed during the reduction, which proceeds less vigorously than in the case of *o*-nitrodiphenyl ether, but affords not less than an 85% yield of the amine hydrochloride.

*o*-Phenylthiolphenylarsinic Acid.—The pure acid was obtained in 12% yield by the method used for the preparation of phenoxyphenylarsinic acids, and crystallised from alcohol in irregular plates, m. p. 192–194° (Found: As, 24.0.  $C_{12}H_{11}O_3SAs$  requires As, 24.2%). The acid is sparingly soluble in water, and was not converted into the corresponding phenthiarsinic acid when heated with concentrated sulphuric acid, no doubt owing to sulphonation.

*o*-Phenylthiolphenyldichloroarsine.—The preceding arsinic acid, when reduced by the usual process, afforded the crude dichloroarsine as a dark oil, which was purified by conversion into the corresponding oxide (see below), the latter then being reconverted into the dichloroarsine. The latter was thus obtained as a pale yellowish-brown, viscous oil (Found: Cl, 21.3.  $C_{12}H_9Cl_2SAs$  requires Cl, 21.5%). (Traces of the carbon tetrachloride used for the extraction of the pure dichloroarsine were removed by gently heating the substance under diminished pressure for a few minutes.)

*o*-Phenylthiolphenylarsenious oxide separates from benzene in small, white, irregular rhombs, m. p. 187–189° (Found: As, 26.5.  $C_{12}H_9OSAs$  requires As, 27.2%).

*Conversion of o-Phenylthiolphenyldichloroarsine into 10-Chlorophenithiarsine.*—When heated at 200° under the conditions previously described in connexion with the conversion of the phenoxyphenyldichloroarsines into the corresponding chlorophenoxarsines, *o*-phenylthiolphenyldichloroarsine underwent the following course of decomposition :

Time (hours) .....	1	2	3	4	5	6
% decomposition .....	2.2	4.5	7.2	10.2	13.6	17.2

The heating was actually allowed to continue for 24 hours ; the product, almost solid when cold, then readily crystallised from light petroleum (b. p. 80—100°) in sulphur-yellow, rhombohedral masses, apparently consisting of rectangular plates, m. p. 129—130° (Found : Cl, 12.1.  $C_{12}H_8Cl_2SAs$  requires Cl, 12.1%).

*o-Phenoxyphenylmethylchloroarsine.*—*o*-Phenoxyphenyldichloroarsine (19 g.) was dissolved in alcohol containing a little acetone, and a solution of 12 g. of sodium hydroxide in 90 c.c. of water added. The mixture was cooled to 40°, and 8 c.c. of methyl iodide were added slowly. The initial reaction over, the whole was left over-night, when a pale yellow oil separated. The alcohol and acetone were distilled off and the residue was acidified with concentrated hydrochloric acid (25 c.c.); a gummy solid then separated. Potassium iodide (19 g.) was added, and the warmed mixture saturated with sulphur dioxide. The dark red, oily iodoarsine so obtained was converted into the corresponding oxide, and then, by the usual process, into the chloroarsine, which was obtained as a brownish-yellow, viscous oil; it contained a little dichloroarsine (Found : Cl, 13.8.  $C_{13}H_{12}OCl_2As$  requires Cl, 12.1%).

When this substance was heated at 200° in a current of dry carbon dioxide under the same conditions as before, the course of decomposition was as follows :

Time (hours) .....	1	2	3	4	5	6
% decomposition .....	2.5	3.9	5.0	6.4	7.8	9.9

Some methyl chloride was also evolved, and when the decomposition had proceeded for 24 hours, methyl iodide was added to the cooled residue. From the product so obtained, a very small quantity of 10-iodophenoxarsine, m. p. 144°, was isolated (Found : I, 33.8. Calc. : I, 34.3%).

*10:10-Dimethylphenoxarsonium Iodide.*—Finely-powdered 10-chlorophenoxarsine (4 g.) was added gradually to an ethereal solution of magnesium methyl iodide (twice the theoretical amount). It dissolved immediately with evolution of heat; and formation, locally, of a yellow coloration. As soon as it had all been added, the mixture was decomposed by addition of water and then dilute

hydrochloric acid, the ethereal layer separated, washed once with water, dried over sodium sulphate, filtered, and then treated with methyl iodide. After most of the ether had been evaporated, solid separated, which, after crystallisation from alcohol, formed colourless prisms, m. p.  $207^{\circ}$  (with effervescence) (Found: I, 31.1.  $C_{14}H_{14}OIAs$  requires I, 31.7%). The tedious method adopted by Lewis, Lowry, and Bergeim (*J. Amer. Chem. Soc.*, 1921, 43, 890) and by Aeschlimann (*J.*, 1925, 127, 811) does not appear to be necessary in the interaction between Grignard reagents and chlorophenoxarsine.

### CLVI.—Some Reactions of 1-*p*-Toluidinocyclopentane-1-carboxylic Acid. A New Carbazole Synthesis.

By STEPHEN HELLICAR OAKESHOTT and SYDNEY GLENN PRESTON  
PLANT.

THE reaction whereby 1-anilinocyclopentane-1-carboxylic acid, on fusion with a mixture of sodium ethoxide and potassium hydroxide, gives carbazole (Plant and Facer, *J.*, 1925, 127, 2037), may follow one of two courses: either the cyclopentane ring may open and form with the carboxyl group the second benzene nucleus of carbazole, or, alternatively, the carbazole may be produced entirely from the anilino-group. It is possible to decide this point by an investigation of 1-*p*-toluidinocyclopentane-1-carboxylic acid (I), which, if the former view is correct, ought to give 3-methylcarbazole as opposed to 3:6-dimethylcarbazole, in accordance with the latter view, on fusion under the same conditions.

We have now condensed *p*-toluidine with cyclopentanone cyanohydrin and have converted the 1-*p*-toluidino-1-cyanocyclopentane so obtained into the corresponding amide, which can be hydrolysed to 1-*p*-toluidinocyclopentane-1-carboxylic acid. On heating this acid with a mixture of sodium ethoxide and potassium hydroxide, 3-methylcarbazole was obtained. Its identity was established by careful comparison of the substance obtained and its picrate with 3-methylcarbazole and 3:6-dimethylcarbazole, which we find can be obtained most conveniently by oxidising the corresponding methyl derivatives of tetrahydrocarbazole with sulphur, and their respective picrates. It seems clear now that the production of carbazole from 1-anilinocyclopentane-1-carboxylic acid involves the enlargement of the carbocyclic system, probably by absorption of

the carboxyl group. A further investigation of this reaction has shown that it proceeds quite as well in the absence of sodium ethoxide and that the sodium or potassium salt of the acid can be used.

1-*p*-Toluidinocyclopentane-1-carboxylic acid is comparatively unstable and loses *p*-toluidine and water on heating above its melting point with the formation of the lactone of 1-1'-hydroxycyclopentane-1'-carboxylyl-*p*-toluidinocyclopentane-1-carboxylic acid (II), showing a behaviour similar to that of 1-anilino-cyclopentane-1-carboxylic acid in this respect.

#### EXPERIMENTAL.

1-*p*-Toluidino-1-cyanocyclopentane.—*cyclopentanone* cyanohydrin will condense with *p*-toluidine when a solution of these substances in benzene is boiled for 12 hours, but conditions similar to those used by Walther and Hübner (*J. pr. Chem.*, 1916, 93, 124) for the preparation of 1-anilino-1-cyanocyclohexane were found to be more convenient. To a solution of *cyclopentanone* (21 g.) and *p*-toluidine (27 g.) in glacial acetic acid (100 c.c.), cooled in ice, potassium cyanide (18 g.), dissolved in a little water, was added. 1-*p*-Toluidino-1-cyanocyclopentane separated in good yield and was washed with water. It crystallised from low-boiling petroleum in colourless needles, m. p. 55° (Found: N, 14.2.  $\text{C}_{13}\text{H}_{16}\text{N}_2$  requires N, 14.0%). The *nitrosoamine*, prepared from an alcoholic solution of the nitrile, dilute hydrochloric acid, and aqueous sodium nitrite, separated from methyl alcohol in yellow prisms, m. p. 58°.

A solution of 1-*p*-toluidino-1-cyanocyclopentane in cold sulphuric acid was kept for 2 days, poured on to ice and the mixture made alkaline with ammonia; the *amide* of 1-*p*-toluidinocyclopentane-1-carboxylic acid was then precipitated. It separated from aqueous methyl alcohol in colourless plates, m. p. 120°. Its *nitrosoamine*, prepared by adding sodium nitrite to the amide dissolved in alcoholic hydrochloric acid, separated from aqueous methyl alcohol in yellow needles, m. p. 132°.

1-*p*-Toluidinocyclopentane-1-carboxylic Acid.—A mixture of the crude amide and concentrated hydrochloric acid was boiled under reflux for 2 hours, evaporated to dryness, the residue treated with an excess of aqueous sodium hydroxide, and the solution boiled and filtered. The addition of glacial acetic acid to the cold filtrate precipitated 1-*p*-toluidinocyclopentane-1-carboxylic acid, which separated from benzene-petroleum in colourless leaves, m. p. 144°

(Found: N, 6.6.  $C_{13}H_{17}O_2N$  requires N, 6.4%). 1-*p*-Toluidinocyclopentane-1-carboxylic acid is soluble in dilute aqueous sodium hydroxide and in dilute hydrochloric acid and gives a *nitrosoamine*, which separates from aqueous methyl alcohol in pale yellow plates, m. p. 114° (decomp.).

On heating 1-*p*-toluidinocyclopentane-1-carboxylic acid in a small distillation flask, water and *p*-toluidine, which was identified by converting it into its acetyl derivative, were evolved. The remainder distilled at a higher temperature, leaving no residue, and, on recrystallisation from petroleum, the *lactone* of 1-1'-hydroxycyclopentane-1'-carboxyl-*p*-toluidinocyclopentane-1-carboxylic acid separated in colourless needles, m. p. 151° (Found: N, 4.7.  $C_{13}H_{23}O_3N$  requires N, 4.5%). This lactone dissolves slowly in cold aqueous sodium hydroxide and is reprecipitated unchanged by the addition of dilute hydrochloric acid. It is not soluble in dilute acids and is unchanged by heating with aniline at 170° or dry ammonia at 200°.

**3-Methylcarbazole.**—An intimate mixture of 1-*p*-toluidinocyclopentane-1-carboxylic acid (16 g.), potassium hydroxide (36 g.), and sodium ethoxide (40 g.) was heated at 350° for 30 minutes. The product was pulverised and added to water, when 3-methylcarbazole separated. It was purified by distillation and subsequent recrystallisation from glacial acetic acid and obtained in colourless, glistening plates, m. p. 207° (compare Ullmann, *Ber.*, 1898, 31, 1697). Its picrate separated from benzene in scarlet needles, m. p. 179° (compare Ullmann, *Annalen*, 1904, 332, 88). The 3-methylcarbazole prepared in this way dissolved in concentrated sulphuric acid to give a pale green solution, which became intensely green on addition of a few drops of nitric acid.

3-Methylcarbazole was also synthesised very conveniently by boiling a solution of 6-methyltetrahydrocarbazole (3 g.; prepared from *p*-tolylhydrazine and cyclohexanone; Borsche, Witte, and Bothe, *Annalen*, 1908, 359, 62) and sulphur (1.05 g.) in pure quinoline (10 c.c.) for 25 minutes and then pouring it into dilute hydrochloric acid-ice. The 3-methylcarbazole which separated, after distillation with a small quantity of iron powder and recrystallisation of the distillate from glacial acetic acid, was obtained in colourless plates, m. p. 207°. Mixed with the product derived from 1-*p*-toluidinocyclopentane-1-carboxylic acid, it showed no depression of m. p., and its colour reactions with concentrated sulphuric acid and nitric acid were as above (compare Ullmann, *loc. cit.*). The picrate of this specimen of 3-methylcarbazole, crystallised from benzene, melted at 180°.

**3:6-Dimethyltetrahydrocarbazole.**—A mixture of 4-methylcyclohexanone (5.5 g.), *p*-tolylhydrazine (6 g.), and alcohol (5 c.c.) was

gently warmed; on cooling, 4-methylcyclohexanone-p-tolylhydrazone separated. It was warmed to boiling with dilute sulphuric acid and heated on the steam-bath for an hour. The 3:6-dimethyltetrahydrocarbazole that separated crystallised from petroleum in small, colourless needles, m. p.  $112^{\circ}$  (Found: N, 7.0.  $C_{14}H_{17}N$  requires N, 7.0%). Its *picrate* separated from benzene in dark red prisms, m. p.  $147^{\circ}$ .

3:6-Dimethylcarbazole was prepared from 3:6-dimethyltetrahydrocarbazole (3.2 g.) and sulphur (1 g.) in quinoline (5 c.c.) as described above. The oily product, which gradually solidified, was distilled with iron powder and thereafter crystallised from benzene, dimethylcarbazole being thus obtained in colourless needles, m. p.  $219^{\circ}$  (compare Täuber and Loewenherz, *Ber.*, 1891, **24**, 1033). 3:6-Dimethylcarbazole gives a faintly brown solution in concentrated sulphuric acid, the colour being intensified on addition of nitric acid. The *picrate* of 3:6-dimethylcarbazole separated from benzene in red needles, m. p.  $192^{\circ}$  (compare Täuber and Loewenherz, *loc. cit.*). A mixture of this 3:6-dimethylcarbazole with the 3-methylcarbazole obtained from 1-p-toluidinocyclopentane-1-carboxylic acid melted completely below  $197^{\circ}$ .

One of us (S. G. P. P.) wishes gratefully to acknowledge the receipt of a grant from the Chemical Society Research Fund which has defrayed a part of the cost of this investigation.

## CLVII.—*The Hydrolysis of Guanidine.*

By JAMES BELL.

WHILE it is generally accepted that urea is the product of the direct hydrolysis of guanidine in accordance with the simple equation

the mechanism of this reaction has not hitherto been investigated. Ossikovszky (*Bull. Soc. chim.*, 1872, **18**, 161) obtained ammonia and carbon dioxide on boiling a solution of guanidine sulphate with excess of alkali and of acid, respectively: he therefore concluded that urea was formed as an intermediate product in this decomposition. The credit of being the first to obtain urea from guanidine is given to Baumann, whose only reference to this reaction consists of one sentence (*Ber.*, 1873, **6**, 1376), where he

states, without giving his experimental evidence, that urea can be obtained by boiling the solution of a guanidine salt with excess of barium hydroxide solution. Almost thirty years later, Fleming (*Chem.-Ztg.*, 1900, 24, 56) obtained impure urea in this way, but gave no quantitative results. Krall, however, in an attempt to investigate the mechanism of this reaction, was unable to obtain any urea on boiling a solution of the free guanidine base under a reflux condenser (*J.*, 1915, 107, 1396).

By means of the xanthhydrol test (Fosse, *Compt. rend.*, 1913, 157, 948) the author has been able to establish definitely the formation of urea, and to determine the extent of the reaction under various conditions. From the results obtained, information has been gained as to the mechanism of the reaction and of the accompanying secondary changes.

When a solution of free guanidine was boiled under a reflux condenser, ammonia gas was evolved and cyanate, carbonate, and urea were detected in the solution. In certain reactions, where urea, ammonium cyanate, and carbonate are produced, it has been shown that cyanic acid is first formed and is then hydrolysed on the one hand to ammonium carbonate, while on the other it combines in its *iso*-form with ammonia to form urea (Werner and Fearon, *J.*, 1920, 117, 1078). It has now been proved, however, that, in the case of guanidine, urea is the first product formed. When an aqueous solution of guanidine was allowed to remain at the ordinary temperature, the odour of ammonia developed and urea was found present, but no cyanate could be detected by the delicate copper-pyridine test (Werner, *J.*, 1923, 123, 2577). Barium nitrate also gave a negative test for carbonate, which was confirmed by the fact that the alkalinity of the solution remained constant. The first phase in the hydrolysis of guanidine is, therefore, represented by equation 1, the mechanism of which is discussed later.

It would thus appear that the production of ammonium cyanate and carbonate was due to the decomposition of urea, when boiled in the strongly alkaline solution of free guanidine (Werner, *J.*, 1918, 113, 84). This decomposition by guanidine was definitely proved by an experiment in which one equivalent of urea was added to a solution of guanidine, when an increase was obtained in the amount of cyanate and carbonate produced on boiling (Expt. 8). The next phases are therefore:

When a sufficiently dilute solution of guanidine was boiled under a reflux condenser, there was no escape of carbon dioxide, resulting

from the dissociation of ammonium carbonate, whereas the amount of ammonia evolved was greater than that required for equation 1. This could only arise from the further changes:

The amount of ammonia evolved was equal, within the limits of experimental error, to that required by these equations. It should be clearly understood that the latter changes (equations 4 and 5) took place under the special conditions stated above. With stronger solutions of guanidine, some carbon dioxide escaped through the reflux condenser and was not, therefore, all fixed as guanidine carbonate. Moreover, when a solution of guanidine was boiled without a reflux condenser, all the carbon dioxide escaped, urea and guanidine cyanate being left in the solution.

When investigating the rates of formation of these different products, it was noticed that, after a time, the proportion of guanidine cyanate present decreased as the reaction proceeded, showing that it also was undergoing change. Bamberger (*Ber.*, 1887, 20, 68) has brought forward evidence for the isomeric change of guanidine cyanate to dicyanodiamidine in accordance with the equation

The latter compound, however, could not be detected in the products formed during the hydrolysis of guanidine, and is therefore not formed under the conditions in question. Even after evaporation of some of the neutralised solution to dryness, no change of guanidine cyanate to dicyanodiamidine occurred. There can be no doubt that guanidine cyanate forms only urea or guanidine carbonate, or, in all probability, both these substances, a conclusion which is also the only one consistent with the quantitative data. More definite information as to the hydrolysis of guanidine cyanate would require separate investigation.

On boiling dilute solutions of guanidine (of approximately  $N/8$  strength), no evidence could be obtained of its dissociation into ammonia and cyanamide. However, when a normal solution was boiled, dissociation to a small extent was indicated by the formation of melamine,  $\text{C}_3\text{N}_6\text{H}_6$ , the tripolymeride of cyanamide. This dissociation is obviously a side reaction and not concerned in the formation of urea, since, in the first place, cyanamide does not produce urea under the conditions of these experiments, and in the second, a greater yield of melamine would have been obtained, in view of the ready polymerisation of cyanamide.

Krall (*loc. cit.*) has given reasons for doubting the usually accepted

formula for guanidine, *viz.*,  $\text{NH}\cdot\text{C}(\text{NH}_2)_2$ , and suggests that in solution, the free base exists probably as an equilibrium mixture of the two forms

Increase of alkali hydroxides would increase the proportion of B, and addition of acids that of A. In the course of the present work, additional evidence has been obtained in favour of this view. When a solution of free guanidine in presence of excess of alkali was kept at the laboratory temperature, the rate of formation of urea was greater than in the case of guanidine alone, whilst the alkali appeared to take no part in the reaction (Expts. 1 and 2). This fact is explained most easily on the above conception of the constitution of guanidine. As a rule, the  $\text{NH}\cdot$  radical is the more readily hydrolysed, and hydrolysis would therefore take place through the B form. The presence of additional alkali increases the proportion of B and therefore increases also the rate of hydrolysis. The mechanism of the reaction may be best explained thus:

This view of the constitution of guanidine has received support from Plimmer in his recent investigation of its behaviour towards nitrous acid (J., 1925, 127, 2658).

#### EXPERIMENTAL.

A solution of free guanidine was prepared by the precipitation of guanidine carbonate solution with one equivalent of barium hydroxide solution and filtering off the barium carbonate. The filtrate, which was an approximately *N*/8-solution, always contained some guanidine carbonate, owing to the absorption of carbon dioxide from the air by the strongly alkaline liquid during filtration. This carbonate was estimated at the outset and the necessary corrections were applied throughout.

In the experiments described, the urea formed was estimated by neutralising an aliquot part of the liquid, evaporating the solution to dryness, extracting the residue with glacial acetic acid, and adding excess of xanthhydrol, dissolved in methyl alcohol. After 12 hours, the precipitate of dioxanthylurea was collected on a weighed filter-paper, washed with alcohol, dried, and weighed. A small correction was applied for the slight solubility of dioxanthylurea in the mixture of acetic acid and methyl alcohol, the value of this

correction being determined in preliminary control experiments. The carbon dioxide in solution was estimated volumetrically, after precipitation as barium carbonate. Cyanates were estimated by precipitation and weighing as silver cyanate.

Dicyanodiamidine was tested for by adding copper sulphate and sodium hydroxide solutions, when the characteristic pink copper derivative of this substance was precipitated. Melamine was identified by its picrate.

In all the experiments, where a solution of guanidine was boiled, the burner was adjusted to secure quiet ebullition only.

*Expt. 1.* Changes produced in  $N/8$ -solution of guanidine at the ordinary temperature.  $a$  is the percentage of guanidine hydrolysed to urea.

Time (days) ...	5	10	20	31	60	70	156	189
$a$ .....	3.25	6.1	11.3	19.2	31.4	35.1	62.4	70.5

No cyanate or carbonate was formed.

*Expt. 2.* Changes produced at the ordinary temperature in  $N/8$ -solution of guanidine containing sodium hydroxide (1 mol.).

Time (days) .....	8	41	102	128
$a$ .....	9.5	34.5	64.9	70.4

Here the velocity of hydrolysis was greater than in the solution of guanidine alone. No cyanate or carbonate could be detected.

*Expt. 3.* Changes produced in  $N/8$ -solution of guanidine after  $1\frac{1}{2}$  hours' boiling under reflux.

100 C.c. of solution were used containing 0.702 g. of the free base. Urea, cyanate, and carbonate in the resulting liquid were estimated. Increase in alkalinity of liquid on boiling = 9.8 c.c. of  $N/10$ -acid (this included the ammonia evolved). This increase could only be due to the formation of ammonium carbonate as in equation 3. Increase in alkalinity, calculated from the carbonate found in solution, = 9.9 c.c. of  $N/10$ -acid. Hence no carbon dioxide escaped through the condenser. The ammonia evolved, calculated from equations 1, 4, and 5, = 8.05 c.c. of  $N$ -acid (Found:  $\text{NH}_3$  = 8.0 c.c. of  $N$ -acid). The following results represent the percentages of the different products, calculated in terms of the guanidine, from which each was originally derived, in accordance with equations 1—5: Urea, 36.5; ammonium cyanate, 9.05; ammonium carbonate, 4.15; guanidine cyanate, 9.07; guanidine carbonate, 8.30. Total, 67.05%.

*Expt. 4.* Changes produced in  $N/8$ -solution of guanidine after boiling under reflux for 3 hours.

Increase in alkalinity, calculated from the carbonate present, = 13.0 c.c. of  $N/10$ -acid. Increase found = 13.0 c.c. of  $N/10$ -acid.

Ammonia evolved = 4.45 c.c. of *N*-acid. Calc.:  $\text{NH}_3 = 11.25$  c.c. of *N*-acid. This was the only experiment in which the ammonia was not all driven out of solution. Found: Urea, 66.0; ammonium cyanate, 6.25; ammonium carbonate, 7.05; guanidine cyanate, 6.25; guanidine carbonate, 14.10. Total, 99.65%.

*Expt. 5.* Changes produced in *N*-solution of guanidine after  $1\frac{1}{2}$  hours' boiling under reflux.

A normal solution of guanidine was prepared by dissolving 4.13 g. of guanidine nitrate in 33.8 c.c. of *N*-sodium hydroxide solution. After boiling, urea, carbonate and cyanate were estimated as before. Increase in alkalinity = 6.4 c.c. of *N*-acid. Increase due to the carbonate found in solution = 3.0 c.c. of *N*-acid. Hence, ammonium carbonate formed = 6.4 c.c. of *N*-acid, and of this, a portion = 3.4 c.c. of *N*-acid, passed through the condenser, whilst the remainder = 3.0 c.c. of *N*-acid, reacted with free guanidine to form guanidine carbonate. Found: Urea, 59.5; ammonium cyanate, 6.45; ammonium carbonate, 9.4; guanidine cyanate, 6.45; guanidine carbonate, 8.9. Total, 90.7%.

Found for the ammonia evolved, 35.2 c.c. of *N*-acid. Calc., 34.2 c.c. The difference is due to ammonia involved in the formation of melamine, a small quantity of which was present. This difference would correspond to a 3% conversion into melamine.

*Expt. 6.* Changes produced in *N*/15-solution of guanidine containing one equivalent of barium hydroxide, after  $1\frac{1}{2}$  hours' boiling under reflux.

The results, in this case, were similar to those of the previous experiments, except that barium cyanate and carbonate were produced instead of the corresponding guanidine salts. The ammonia evolved was not estimated. Found: Urea, 80.0; barium cyanate, 13.4; barium carbonate, 2.9. Total, 96.3%.

*Expt. 7.* Changes produced in *N*/7-solution of guanidine, after 1 hour's boiling without reflux.

The solution was boiled in a distillation flask, connected with a condenser and flask for ammonia absorption. Water was added from a tap funnel at intervals to maintain the volume of the solution constant. No carbonate was found in the solution on boiling. Hence all the carbon dioxide escaped. The amount of ammonium carbonate formed was calculated from the increase in alkalinity.

Found for ammonia evolved, 14.3 c.c. of *N*-acid. Calc., 14.4 c.c. Found: Urea, 73.4; ammonium carbonate, 1.4; ammonium cyanate, 9.6; guanidine cyanate, 9.6%. Total, 94.0%.

*Expt. 8.* Action of guanidine on urea in solution on boiling.

A solution similar to that used in the previous experiment, containing one equivalent of urea (0.9 g.), was boiled for 1 hour under

the same conditions. It was assumed that the changes produced in the guanidine were the same as before. The increase in carbonate and cyanate was therefore due to the decomposition of the added urea. Found: Added urea converted into ammonium cyanate and carbonate = 13.3 and 3.7%, respectively. Therefore total urea decomposed = 17.0%.

From the determination of urea in the two experiments, the decomposition of added urea was calculated to be 21.9%. The difference in these results is due to the fact that, in this experiment, more guanidine was fixed as cyanate than in the previous one, and hence the amount of guanidine hydrolysed would be slightly less.

The author gratefully acknowledges his indebtedness to Professor E. A. Werner, Sc.D., for advice received in the course of this work and to Dr. W. R. Fearon, F.T.C.D., at whose suggestion this investigation was undertaken.

TRINITY COLLEGE, DUBLIN.

### CLVIII.—Nitrosylsulphuric Acid. Part I.

By GEORGE ALBERT ELLIOTT, LESLIE LEONARD KLEIST, FREDERICK JAMES WILKINS, and HARRY WILLIAM WEBB.

THE object of this investigation was to examine the constitution and properties of nitrosylsulphuric acid.

To the substance of the molecular formula  $\text{HSO}_5\text{N}$  have been ascribed two structural formulæ, viz., that of nitrosulphonic acid (I) (Michaelis, *Ber.*, 1874, 7, 1075; Raschig, *Z. angew. Chem.*, 1905, 18, 1032) and that of nitrosylsulphuric acid (II) (Tilden, *J.*, 1874, 27, 630; Lunge, *Ber.*, 1879, 12, 1058). The evidence for the existence of an acid of the structure (I) is unsatisfactory.

We first prepared the acid by several different methods and found that its melting point and crystalline form did not vary with the method used. Fractional crystallisation from sulphuric acid also failed to effect any change. Therefore, whilst the acid may be tautomeric, the existence of non-dynamic isomerides is improbable.

The action of hydrogen chloride on the crystalline acid at the ordinary temperature rapidly led to the formation of nitrosyl chloride and sulphuric acid, the reaction being reversible, as was

foreshadowed by the work of Tilden (*loc. cit.*). The presence of the nitroso-group thus indicated was more definitely suggested by the reaction between the acid and benzoyl chloride, which produced *dibenzoylsulphuric acid*,  $O_2S(O\cdot CO\cdot C_6H_5)_2$ , whose formation can be satisfactorily explained only on the assumption that nitrosylsulphuric acid contains both a nitroso- and a hydroxyl-group. The mechanism of the reaction would then be as follows. The first stage is the formation of *monobenzoylsulphuric acid* :

Nitrosyl chloride is actually formed as soon as the two substances are mixed and is rapidly liberated at 35–40° without appreciable heat evolution. The monobenzoylsulphuric acid then reacts additively with a further molecule of benzoyl chloride, probably at the carbonyl group of the latter, and a crystalline product is obtained which loses hydrogen chloride on standing, dibenzoylsulphuric acid being formed :

Confirmation of this mechanism was obtained by examining the reaction between benzoyl chloride and sulphuric acid. Oppenheim (*Ber.*, 1870, 3, 736) states that this reaction yields a benzoylsulphuric acid which rapidly changes to *m*-sulphobenzoic acid on standing, and that the latter is formed exclusively if the reaction is carried out at 150°. No mention of an additive product is made and the experimental data are very meagre. We have found that the substance produced at the ordinary temperature is a crystalline additive compound, to which the constitution  $PhCCl(OH)\cdot O\cdot SO_2\cdot OH$  may most readily be assigned. It loses hydrogen chloride on standing, forming monobenzoylsulphuric acid; this change, however, is inhibited by an atmosphere of hydrogen chloride. The additive compound showed no sign of transformation into sulphobenzoic acid on being kept for 6 months over a dry alkaline absorbent at the ordinary temperature, although during this time the hydrogen chloride was completely eliminated.

At 100°, the highest temperature used in our experiments, conversion of benzoylsulphuric acid into sulphobenzoic acid occurred, but so slowly that the amount formed during our experiments could be neglected in making deductions from the results obtained. The change was a unimolecular one and the product consisted mainly of *o*- and not *m*-sulphobenzoic acid. It is probable that the meta-acid, stated by Oppenheim to be the sole product, is produced by direct sulphonation, and the ortho-acid by intramolecular transformation. The production of the ortho-acid in this way can

be satisfactorily explained by assuming intermediate anhydride formation and subsequent rehydration :

We were unable to obtain pure dibenzoylsulphuric acid by the interaction of benzoyl chloride and sulphuric acid.

The action of acetyl chloride on nitrosylsulphuric acid yielded similar evidence of the presence of the nitroso-group. The first product of the reaction appears to be acetylsulphuric acid, but this changes with great rapidity into the isomeric sulphoacetic acid. The evidence for this change lies in the rapid decrease in the amount of free sulphuric acid produced by the decomposition of the product with water, whilst the total sulphur content of the substance remains constant. The change is very much more rapid than that of benzoylsulphuric acid, but we did not investigate it further as it had already been examined by Van Peski (*Rec. trav. chim.*, 1921, 40, 103) and others.

The action of acetic anhydride on nitrosylsulphuric acid also yielded acetylsulphuric acid. Equimolecular quantities of the two substances without any diluent reacted so violently at the ordinary temperature that the sudden evolution of heat was usually sufficient to shatter the glass container. If the acetic anhydride was in great excess and was kept below 15° during the addition of the nitrosylsulphuric acid, the latter dissolved, and by shaking the solution with silver oxide a substance was obtained to which the constitution  $\text{CH}_3\text{CO}\cdot\text{O}\cdot\text{SO}_2\cdot\text{O}\cdot\text{NO}\cdot\text{CH}_3\cdot\text{CO}_2\text{Ag}$  is assigned.

By the action of ether on nitrosylsulphuric acid, ethyl nitrite and ethyl hydrogen sulphate were produced :

Ethyl hydrogen sulphate and solutions of nitrosylsulphuric acid in sulphuric acid gave no nitroethane, which one would expect to be produced if the acid had the nitrosulphonic structure.

The most important evidence for the nitrosulphonic structure and possible tautomerism of the acid is the work of Biehringer and Borsum (*Ber.*, 1916, 49, 1402). By treating a sulphuric acid solution of dimethylaniline with solid sodium nitrite they obtained mixtures of *p*-nitro- and *p*-nitroso-dimethylaniline. We decided to repeat their work, for three reasons: (1) The setting up of equilibria involving the two forms of nitrous acid and sulphuric acid was not excluded by their method of experiment. (2) Since

they poured a reaction mixture containing an excess of nitrite on ice, direct nitration of unchanged dimethylaniline and secondary oxidation of the nitroso-derivative would be expected. (3) They do not mention the production of sulphur dioxide which would be expected as a by-product from the nitrosulphonic form.

Using a solution of crystalline nitrosylsulphuric acid in sulphuric acid, of concentration equivalent to that used by them, we confirmed the result that both *p*-nitro- and *p*-nitroso-dimethylaniline are produced. We also established the following facts: (1) The percentage yield of the *p*-nitro-derivative increases with the excess of nitrosylsulphuric acid used in the reaction mixture. (2) If an excess of dimethylaniline is used, no oxides of nitrogen are produced by pouring the mixture on ice and no *p*-nitro-derivative is obtained. (3) When an excess of nitrosylsulphuric acid is present and the mixture is poured into absolute alcohol or dry ether, no *p*-nitro-derivative is obtained. Both these solvents rapidly decompose nitrosylsulphuric acid, forming ethyl nitrite and ethyl hydrogen sulphate. (4) When crystalline nitrosylsulphuric acid is added to a solution of dimethylaniline in dilute sulphuric acid (2*N*), in which the former acid is immediately decomposed, both the *p*-nitro- and the *p*-nitroso-derivative are obtained. (5) If a solution of dimethylaniline in concentrated sulphuric acid is added to a dilute solution of nitric acid (10%) or of potassium nitrite (5%), the *p*-nitro-derivative is formed. (6) No sulphur dioxide could be detected in any of the experiments.

All these facts are in accord with the view that the *p*-nitrodimethylaniline is not produced by the action of a presumed nitrosulphonic acid, but is a secondary product obtained by pouring the reaction mixture on ice and is produced either by secondary oxidation of the nitroso-compound or by direct nitration of the dimethylaniline. The results of Biehringer and Borsum do not establish, therefore, in our opinion, the existence of nitrosulphonic acid or the possibility of tautomerism.

#### *Conversion of Nitrosylsulphuric Acid into the Anhydride.*

The anhydride of nitrosylsulphuric acid is assumed to have the structure  $\text{ON}\cdot\text{O}\cdot\text{SO}_2\cdot\text{O}\cdot\text{SO}_2\cdot\text{O}\cdot\text{NO}$  and is stated to be formed by the action of nitric oxide on sulphur trioxide, or of sulphur dioxide on well-cooled nitrogen pentoxide (Berl. *Z. angew. Chem.*, 1910, 23, 2250).

There appears to be no definite experimental evidence for the direct conversion of nitrosylsulphuric acid into the anhydride, a change which would yield important evidence as to structure.

We have examined the change by three methods:

- (1) By the action of heat alone.
- (2) By heating in the presence of dehydrating agents.
- (3) By the determination of the solubility of the acid in sulphuric acid.

*Action of Heat on Nitrosylsulphuric Acid.*—Michaelis and Schumann (*Ber.*, 1874, 7, 1075) carried out a preliminary investigation on this point and suggested that the decomposition took place according to the scheme :

Their experimental methods, however, were very rough, and no experimental evidence was offered that the final product was the anhydride. They ascribe the nitrosulphonic structure to the acid, but it is improbable that an acid of either the nitro- or the nitroso-structure would undergo a decomposition of the type suggested, in view of the great instability of these groups in the molecule.

Theoretically there is another mode of decomposition :

The nitrous acid would then decompose to form nitrogen trioxide and water, which would decompose more nitrosylsulphuric acid. The net result is represented by the equation  $3\text{HSO}_5\text{N} = \text{HS}_2\text{O}_8\text{N} + \text{H}_2\text{SO}_4 + \text{N}_2\text{O}_3$ . When decomposition is complete, the resulting liquid should yield 15.4% of nitrous acid by decomposition with water. If the reaction proceeds according to the suggestion of Michaelis, however, the percentage of nitrous acid so obtained should be 21.8. (By "percentage of nitrous acid" should be understood the amount of nitrous acid obtained by the complete decomposition of the residue with water, calculated as a percentage of the anhydrous substance.)

By following the change in the nitrous acid content we found that the decomposition by heat appears to follow the course suggested by Michaelis.

*The Action of Dehydrating Agents.*—The results obtained by heating the acid in the presence of dehydrating agents (phosphorus pentoxide in particular) were unsatisfactory. We were unable to detect the anhydride in the distillate: nitrosylsulphuric acid, the main product obtained, was probably formed by the recombination of sulphur trioxide, water, and nitrogen peroxide in the receiver. Dehydration of nitrosylsulphuric acid was also attempted by making a saturated solution in 98% sulphuric acid at 50°. The solution, after being heated for several hours at 100°, was cooled to 16° and found to be supersaturated. A crystal of nitrosylsulphuric acid induced crystallisation, the product being the un-

changed acid. Further experiments showed that nitrosylsulphuric acid appears to be capable of existence in saturated solution in sulphuric acid even at 300°. This is remarkable in view of the ease with which water is lost on heating the acid alone.

*The Solubility of Nitrosylsulphuric Acid in Sulphuric Acid.*—The method previously described for the attempted isolation of the anhydride would yield positive results only if the anhydride (if formed) were relatively less soluble in sulphuric acid than nitrosylsulphuric acid. We therefore examined the solubility of nitrosylsulphuric acid at 0°, 20.9°, 37.3°, and 49.6° in various concentrations of sulphuric acid. The curves expressing the relationship between the solubility of nitrosylsulphuric acid and the concentration of sulphuric acid all showed a marked increase in the solubility coefficient when the concentration of sulphuric acid reached 73%. Schlesinger and Salathe (*J. Amer. Chem. Soc.*, 1923, 45, 1863) have investigated the absorption spectra of a series of 0.1*N*-solutions of nitrosylsulphuric acid in sulphuric acid of different concentrations. If the concentration of sulphuric acid is plotted against the frequency for a given value of the logarithm of the thickness in their results, the curves so obtained are similar to ours and show a change of slope at a concentration of 78% H<sub>2</sub>SO<sub>4</sub>.

The shape of our curves is not incompatible with the conclusion that anhydride formation takes place.

From some points of view, an alternative structure O<sub>2</sub>S<O>N·OH seems to merit consideration. (1) An acid of this type would lose water on heating to give an anhydride of the structure (III), a change which is parallel to the conversion of nitric acid into nitrogen pentoxide. (2) It offers an explanation of the great difficulty of replacing both the hydroxyl groups of sulphuric acid by the nitroso-group. (3) The structure is in accord with the methods of synthesis of the acid. (4) The behaviour of the acid on reduction is more in accord with this structure than with the nitroso-structure. (5) The synthesis of the anhydride from sulphur dioxide and nitrogen pentoxide (Berl, *loc. cit.*) is readily explicable in terms of the above formula :

and so is the production of the anhydride from nitrogen tetroxide and sulphur dioxide (Provostaye, *Ann. Chim. Phys.*, 1840, 73, 362), in which reaction nitrogen trioxide is a by-product :

It is possible that nitrosylsulphuric acid exists in two tautomeric forms,  $O_2S \begin{smallmatrix} \text{O} \cdot \text{NO} \\ \text{OH} \end{smallmatrix} \rightleftharpoons O_2S \begin{smallmatrix} \text{O} \\ \text{O} \end{smallmatrix} \text{N} \cdot \text{OH}$ , which are in equilibrium in sulphuric acid solution and in the molten state.

### EXPERIMENTAL.

*Preparation of Nitrosylsulphuric Acid.*—(1) By the addition of dry liquid nitrogen tetroxide to concentrated sulphuric acid at 15–18°. The separation of crystals and the removal of excess of tetroxide were facilitated by blowing dry air through the mass. (2) As above, but using gaseous nitrogen tetroxide. (3) By passing sulphur dioxide, dried by sulphuric acid, into pure nitric acid (94.5%  $HNO_3$ ) at 25°. (4) By leading nitrosyl chloride, generated by heating aqua regia, into concentrated sulphuric acid.

The crystals in each case were rapidly drained by a pump and dried on a porous plate over sulphuric acid. All the products consisted of rhombic prisms (m. p. 73.5°). Tilden (*loc. cit.*) obtained by the last method of preparation a product of m. p. 85–87°, but we have not been able to repeat his work.

*The Action of Benzoyl Chloride.*—A mixture of 1 g.-mol. of nitrosylsulphuric acid with 2.4 g.-mols. of benzoyl chloride was heated for 30 minutes on the water-bath, moisture being excluded. After 12 hours, yellowish-brown, rhombic crystals separated. These were filtered off rapidly on asbestos, washed with dry carbon tetrachloride, and dried on a porous plate over phosphorus pentoxide. The product was very hygroscopic. It had no odour of benzoyl chloride, and on treatment with water it was completely decomposed into sulphuric, benzoic, and hydrochloric acids. Ethyl alcohol was readily converted by it into ethyl benzoate. It was insoluble in all common organic solvents and reacted readily with substances containing a hydroxyl group and with ether and acetone. No evidence of the presence of an acid with a sulphonic group could be obtained. The product was analysed as follows: A weighed sample was warmed with excess of water until completely dissolved. The total acidity was then determined by sodium hydroxide and phenolphthalein, and the sulphuric acid as barium sulphate. Hydrochloric acid was estimated by silver nitrate and ammonium thiocyanate. As an approximate check on the results the benzoic acid was estimated in several samples by removing the sulphuric acid with baryta, slightly acidifying the solution with hydrochloric acid, extracting with ether, and weighing the dried product. The hydrochloric acid content of the samples varied with the time which elapsed before analysis and, in order to make apparent the composition of the acidic residue, the analyses are

expressed in terms of hydrochloric acid-free substance. For convenience of expression also, the acidities obtained after aqueous decomposition are expressed as percentages of the anhydrous substance. The same device is used also for the theoretical values, which are those calculated for  $(\text{PhCO}\cdot\text{O})_2\text{SO}_2\cdot\text{HCl}$ .

The hydrochloric acid content does not exceed one molecule, and sample 1, dried in hydrochloric acid vapour, approximates closely to the theoretical value. It might be expected that a substance of the nitrosulphonic structure under the conditions of our experiments would yield sulphur dioxide as a decomposition product. 2.4 G.-mols. of benzoyl chloride were heated on the water-bath with 1 g.-mol. of nitrosylsulphuric acid, and the evolved gases drawn through potassium dichromate solution. The amount of sulphur thus found as sulphur dioxide is shown as a percentage of the total sulphur.

Time (hours) .....	2	4	6	8	10	12
% S as $\text{SO}_2$ .....	0.49	0.44	0.26	0.19	0.10	0.02

The results indicate that about 1.5% of the total sulphur is evolved as sulphur dioxide on continued heating at  $100^\circ$ . Although the rate of evolution decreases with time, it is considered that the sulphur dioxide is formed by reduction of sulphuric acid and is not due to the presence of the nitrosulphonic form of the acid, since benzoyl chloride and sulphuric acid yield a similar result (*q.v.*).

*Action of Sulphuric Acid on Benzoyl Chloride.*—The first method used was to mix benzoyl chloride (1 or 2 mols.) with concentrated sulphuric acid. The manner of mixing made a great difference to the purity of the product and to the hydrogen chloride content. If the sulphuric acid was added to the benzoyl chloride, the solution became deep green and most of the chlorine was evolved as hydrogen chloride. If the reverse process was adopted, the coloration was much less and the evolution of hydrogen chloride was very small at the ordinary temperature. Preparations were made in this way,

using sulphuric acid varying in concentration from 96 to 100% at temperatures from 0–40°. The products were treated and analysed as previously described for nitrosylsulphuric acid.

\* After 48 hours over lime.

† After keeping 48 hours.

The last two preparations, when calculated to hydrochloric acid-free product, gave total acidity = 72.24, 72.06% H<sub>2</sub>SO<sub>4</sub>, and sulphuric acid = 47.82, 48.48%, respectively, whereas the values theoretically required are 72.77 and 48.51%.

The repetition of the exact experimental conditions used in the case of nitrosylsulphuric acid yielded products which appeared to be mixtures of mono- and di-benzoylsulphuric acids or of the mono-acid and sulphobenzoic acid. Preparations carried out at 16° and 30° gave similar products. At 0°, however, the products were very near in composition to the mono-acid.

In view of the difficulty of purifying the products, the method of preparation was further improved by dissolving the benzoyl chloride in excess of dry carbon tetrachloride, adding the 98% sulphuric acid gradually with continuous shaking, and keeping the mixture for 30 minutes, with exclusion of moisture. In this way, it is immaterial whether 1, 2, or 3 molecular proportions of benzoyl chloride are used and the temperature can also be varied between 0–35° without affecting the purity of the product: the yield is theoretical. Analyses of typical products were as follows:

	% Total acidity as H <sub>2</sub> SO <sub>4</sub> .	% H <sub>2</sub> SO <sub>4</sub> .	% HCl.
1	78.40	44.02	9.20
2	78.88	43.64	10.00
3	78.78	43.31	10.04

The total sulphur content of the products was determined by fusion, and the fact that the figure so obtained was identical with that for the percentage of sulphuric acid obtained by decomposing the substance with water was taken to indicate the absence of

sulphobenzoic acid from the products. This estimation was carried out as follows. To 1 g. of the substance contained in a platinum dish about 5 g. of moistened sodium peroxide were added and the mixture was stirred with a platinum rod. The product was intimately mixed with 30—40 g. of a mixture of 1 part of potassium nitrate and 2 parts of fusion mixture. The top of the mass was then covered with 15—20 g. of fusion mixture, and the whole heated gently until fusion was complete. If signs of charring appeared, the determination was repeated. The method was much quicker than a Carius estimation and better than the Eshka method for the substances under analysis. The method is given in detail, as duplicates showed it to be quite satisfactory.

*Transformation of Benzoylsulphuric Acid into Sulphobenzoic Acid.*—Determinations were made of the total sulphur content of a number of products by fusion, and of the sulphuric acid produced by decomposition with water. The samples were prepared using equimolecular proportions of sulphuric acid and benzoyl chloride at 0°, 16°, and 120°. The results were as follows :

	1.	2.	3.
Sulphuric acid by water treatment ( $\text{H}_2\text{SO}_4$ %)	42.31	43.30	37.40
Total sulphur (by fusion) as $\text{H}_2\text{SO}_4$ % .....	42.16	43.16	37.43

This evidence for the absence of sulphobenzoic acid is conclusive unless the latter is completely decomposed by treatment with warm water. No satisfactory information could be found in the literature on this point and therefore we determined the velocity of transformation of benzoylsulphuric acid into sulphobenzoic acid at 100°, the highest temperature used in our experiments. 70 G. of monobenzoylsulphuric acid were heated, in a constant-temperature bath at 100°, in a flask fitted with a moisture trap. The gases were drawn off continuously through potassium dichromate and the sulphur dioxide content was estimated. Samples of the residue in the flask were drawn off at intervals and the sulphuric acid produced by decomposition with water was estimated. At the conclusion of the heating the total sulphur content of the residue was determined by the fusion method previously described.

Time (hours).	% $\text{H}_2\text{SO}_4$ obtained.	k.	% Total S lost as $\text{SO}_2$ .
0	43.20	—	—
10	36.67	0.01639	0.26
15	33.83	0.01630	0.25
20	31.14	0.01637	0.23
25	28.75	0.01628	0.22

Total sulphur content of the residue after 25 hours = 42.10% as  $\text{H}_2\text{SO}_4$ .  $k$  is calculated on the basis of a unimolecular reaction.

*Isolation of Sulphobenzoic Acid* [With R. PEPPERELL].—The above

material which had been heated for 25 hours at  $100^{\circ}$  was warmed with 500 c.c. of water and concentrated to 250 c.c. The precipitated benzoic acid was filtered off and the sulphuric acid precipitated with baryta and filtered off. This filtrate was concentrated to 100 c.c., and the excess of barium exactly precipitated with sulphuric acid. The barium sulphate and any further benzoic acid were removed and the filtrate was evaporated to small bulk and extracted with ether until no further benzoic acid could be obtained. The residue on final concentration on the water-bath solidified to an amorphous hygroscopic mass which was dried by heating to  $105^{\circ}$  (Found: S, 16.1. Theory for  $\text{CO}_2\text{H}\cdot\text{C}_6\text{H}_4\cdot\text{SO}_3\text{H}$ : S, 15.8%). The substance did not melt sharply, but was completely molten at  $135^{\circ}$ . The anhydride (m. p.  $129\text{--}130^{\circ}$ ) was prepared by refluxing with acetyl chloride for 2 hours and extraction with benzene. The acid also condensed readily with resorcinol in presence of zinc chloride to give a phthalein. The product was hence *o*-sulphobenzoic acid, but the original substance contained some meta-acid also.

*Action of Acetyl Chloride.*—25 G. of nitrosylsulphuric acid were added slowly to 35 g. of acetyl chloride dissolved in 100 c.c. of carbon tetrachloride, and the mixture was warmed to  $30\text{--}35^{\circ}$  to start the reaction. A vigorous evolution of nitrosyl chloride occurred, the temperature rising to  $60\text{--}70^{\circ}$ , and a yellow, viscous, non-crystallisable oil separated. This was washed repeatedly with carbon tetrachloride and ligroin and analysed as rapidly as possible by methods similar to those used in the case of the corresponding benzoyl derivative (Total acidity, as  $\text{H}_2\text{SO}_4$ , 101.9;  $\text{H}_2\text{SO}_4$ , 68.4.  $\text{CH}_3\cdot\text{CO}\cdot\text{O}\cdot\text{SO}_3\text{H}$  requires 105.0 and 70.0%, respectively). The substance was completely decomposed by water into acetic and sulphuric acids.

The product was heated under reflux in carbon tetrachloride for 30 minutes and the percentage of sulphuric acid obtained by decomposition with water was reduced to 54.32% from 68.40%. After another hour's refluxing, it was further reduced to 27.58%, the total sulphur content remaining constant.

*Action of Acetic Anhydride.*—(1) 10 G. of acetic anhydride were dissolved in 200 c.c. of carbon tetrachloride and 12 g. of nitrosylsulphuric acid were added. On refluxing for 30 minutes a yellow oil separated, from which the last traces of solvent were removed in a vacuum. (2) 5 G. of nitrosylsulphuric acid were dissolved in 200 c.c. of acetic anhydride, the mixture being kept cool, and the solution was shaken with 5 g. of dry silver oxide. The silver oxide was rapidly converted into a gelatinous suspension, which was filtered off in a vacuum, washed with acetic anhydride, and dried over sulphuric acid. The product was amorphous and

hygroscopic and on treatment with water gave no oxides of nitrogen. The resulting solution gave no precipitate with barium nitrate. Liebermann's reaction showed the presence of nitrite or a nitroso-group in the substance. The salt contained sulphur, nitrogen, and silver, in addition to carbon, hydrogen, and oxygen (Ag, by heating, 31.5; by conversion to  $\text{AgCl}$ , 32.0. S, estimated as  $\text{BaSO}_4$ , 9.4.  $\text{CH}_3\cdot\text{CO}\cdot\text{O}\cdot\text{SO}_2\cdot\text{O}\cdot\text{NO}$ ,  $\text{CH}_3\cdot\text{CO}_2\text{Ag}$  requires Ag, 32.1; S, 9.5%).

*Action of Nitrosylsulphuric Acid on Dimethylaniline.*—(1) To a solution of 35 g. of dimethylaniline in 40 c.c. of concentrated sulphuric acid a solution of 70 g. of nitrosylsulphuric acid in 30 c.c. of sulphuric acid was added, at 10–15°. By following the experimental procedure of Biehringer and Borsum (*loc. cit.*) there were obtained: *p*-nitrodimehtylaniline, 63%; *p*-nitrosodimehtylaniline, 37%. (2) The above experiment was repeated using half the amount of nitrosylsulphuric acid (*i.e.*, an excess of dimethylaniline). No nitro-derivative was obtained but only the nitroso-derivative. (3) Quantities as in Expt. (1) were used and the mixture was dropped slowly into absolute alcohol at 0°. No nitro-derivative was obtained. By pouring the product into 300 c.c. of dry ether a mixture of the sulphates of dimethylaniline and *p*-nitrosodimehtylaniline was obtained. Some nitric oxide was evolved on first mixing the reactants, but no sulphur dioxide could be detected at any stage of the reaction.

*Action of Heat on Nitrosylsulphuric Acid.*—(1) 30 G. of the crystalline acid were heated for 30 minutes at 350° in a wide glass tube fitted with a moisture trap; nitrogen trioxide was rapidly evolved during the first 15 minutes. A pale yellow, very viscous oil remained (Found:  $\text{HNO}_2$ , 19.3%).

(2) 50 G. of nitrosylsulphuric acid were heated under similar conditions at 300° for 9 hours. The residual oil was analysed as before (Found:  $\text{HNO}_2$ , 20.2%).

At both these temperatures sulphur trioxide was evolved owing to the decomposition of the product, and this fact may explain the poor agreement with the value required by the suggestion of Michaelis. On attempting to carry out the decomposition at temperatures low enough to ensure that no sulphur trioxide was produced, it was found that the rate of decomposition was so slow that several weeks would be required for complete decomposition.

(3) 50 G. of the acid were heated in a constant-temperature bath at 150°. Samples were withdrawn at intervals and analysed as before.

Time (hrs.)	...	0	0.75	11.3	16.5	26.3	39.0	46.8	59.3	137.0
% $\text{HNO}_2$	.....	35.9	32.8	30.7	30.2	29.7	29.0	28.1	27.5	25.8

(Theoretical value for anhydride, 21.8%  $\text{HNO}_2$ .)

Similar determinations were carried out at 115° and 130° and in each case the early rapid evolution of nitrogen trioxide was observed. The slowness of decomposition of nitrosylsulphuric acid at the lower temperatures is undoubtedly due to the stabilising influence of sulphuric acid, which is a secondary product of the reaction. The decomposition of the acid begins at 73°, when it begins to melt.

The general conclusion to be drawn from the results is that the mode of decomposition suggested by Michaelis is in accord with the experimental facts. It must be pointed out, however, that (1) sulphuric acid is produced by the decomposition and tends to prevent further loss of nitrogen trioxide on heating, and (2) water escapes from the reaction zone in the early part of the heating; consequently the nitrous acid content of the residue would be expected to exceed the theoretical value.

*Solubility of Nitrosylsulphuric Acid in Sulphuric Acid.*—The general method of solubility determinations was adopted, the nitrosylsulphuric acid in excess being agitated with sulphuric acid of known concentration contained in thin glass tubes in a thermostat. Each tube was protected against the ingress of moisture by running the stirrer through a glass tube sealed with petroleum jelly. The sulphuric acid used was of concentrations 56.7, 62.1, 73.1, 74.9, 84.1, 90.4, and 99.8%.

After 3 hours, a sample was filtered through glass wool into a weighing bottle containing sulphuric acid and, after weighing, the contents were made up to 100 c.c. with sulphuric acid, the nitrous acid then being estimated by a method specially devised for this work. At the higher temperatures and with the lower concentrations of sulphuric acid, some of the solutions contained free nitrous acid (*i.e.*, not combined as nitrosylsulphuric acid). In order to determine the amount of the latter acid actually present, this

FIG. 1.

free nitrous acid was removed by rapid blowing with air followed by immersion in the thermostat for 15 minutes. The sample was then taken in the usual way. The results here given are also shown graphically in the figure.

### CLIX.—*Unsymmetrically Substituted Dinitro- and Diamino-derivatives in the Stilbene and Tolane Series. Part II. The Mode of Addition of Water to 3:4'-Dinitro- and Diamino-tolanes.*

By HAROLD AINSWORTH HARRISON.

IN a former communication (this vol., p. 577) it was shown that two nitro-groups unsymmetrically situated in the two benzene nuclei of stilbene exert a definite influence on the reactivity of chlorine atoms attached to the carbon atoms in the side chain. The experiments now described indicate that similar influences are discernible in the unsymmetrically substituted dinitro- and diamino-tolanes, as exemplified by the mode of addition of the elements of water to the triple bond. Polarity considerations again appear to furnish a guide in determining the seat of reactivity.

3:4'-Dinitrotolane (I) was obtained from the dichloride or dibromide of 3:4'-dinitrostilbene, or from  $\alpha$ -chloro-4:3'-dinitrostilbene, by the action of alcoholic potassium hydroxide. In the preparation from the dibromide, although traces of the stilbene were undoubtedly produced by loss of bromine (compare Pfeiffer and Kramer, *Ber.*, 1913, 46, 3655), no difficulty was experienced in obtaining the pure tolane.

3:4'-Dinitrotolane assumed the elements of water only with great reluctance.\* With the nitro-groups in these positions it was to be expected from the alternating polarity rule that harmonious combination of directing influences would exist, tending to make such a configuration exceedingly reactive and prone to attack at

\* All the ortho-substituted nitrotolanes prepared by Reinhardt (*Ber.*, 1913, 46, 3598), by Pfeiffer and Kramer (*ibid.*, 1913, 46, 3655), and by Pfeiffer (*Annalen*, 1916, 411, 72) take up the elements of water with remarkable ease. It is significant, however, that neither Reinhardt nor Pfeiffer mentions the addition of water to 4:4'-dinitrotolane.

the carbon atoms in the side chain. But no such enhanced reactivity was manifested and the yield of 3-nitrophenyl 4-nitrobenzyl ketone (II) was small. Robinson, Allan, Oxford, and Smith (this vol., p. 401) recognise the existence of two quite distinct effects when a nitro-group is attached to the benzene ring: the one arising from the conjugation of the nitroxyl with the nucleus and resulting in positive charges on the ortho- and para-carbon atoms, and the other a general electrical effect over the nucleus and the side chain. Applying these conceptions to 3:4'-dinitrotolane, one deduces respectively that a smaller density of electrons exists in the region of the two carbon atoms marked + than in the region of their immediate neighbours, and that the acetylenic carbon atoms  $\alpha\alpha'$  are under the influence of a strong positive field, which inhibits reactivity towards positive ions at both centres. Since, however, the positive charge in the *p*-nitrophenyl group is nearer the acetylenic bond than is that in the *m*-nitrophenyl group, the electrons of the acetylenic bond will be displaced in the direction of the arrow, that is, from  $\alpha \rightarrow \alpha'$ .<sup>\*</sup> Addition of water, therefore, though difficult, takes place as follows:

It is also possible that the *p*-nitrophenylacetylene group is a conjugated system, but the existence of such conjugation could only be disclosed by experiments with anionoid reagents.

An attempt to investigate the influence of the amino-groups on the elimination of hydrogen chloride from 3:4'-diaminostilbene dichloride was unsuccessful, owing to the impossibility of retaining the chlorine atoms in the molecule during the reduction; 3:4'-*di*-aminostilbene was the sole product.<sup>†</sup>

3:4'-*Diaminotolane*, like the nitrotolane, was very reluctant to assume the elements of water; this inertness is at first sight the more surprising in view of the peculiar ease with which 4:4'-diaminotolane passes into the deoxybenzoin, warm dilute hydrochloric acid

<sup>\*</sup> Similar cases have been considered by Lucas and his colleagues (*J. Amer. Chem. Soc.*, 1924, **46**, 2475; 1925, **47**, 1459, 1462).

<sup>†</sup> Replacement of the chlorine atoms by hydrogen does not occur, since 3:4'-*di*-aminodibenzyl (prepared for purposes of comparison) coincided with none of the products obtained during the whole investigation.

effecting its quantitative conversion (Reinhardt, *Ber.*, 1913, 46, 3598). Under no conditions\* did sulphuric acid bring about the corresponding reaction in the case of 3:4'-diaminotolane; during one reduction experiment only, in which zinc and hydrochloric acid were employed, was a small amount of 4-aminophenyl 3-aminobenzyl ketone produced. From the *diacetyl* derivative of the aminotolane (III), however, the action of concentrated sulphuric acid resulted in the formation of the *diacetyl* derivative of this ketone (IV) in good yield, its constitution being inferred from its non-identity with 3-acetylaminophenyl 4-acetylaminobenzyl ketone, prepared from the corresponding nitrophenyl nitrobenzyl ketone (this vol., p. 579).

The conception of combined general and alternating polar effects again proves valuable here. Electronic repulsion from the two acetyl-amino-groups, resulting from their conjugation with the respective benzene nuclei, produces a strongly negative field in the region of the acetylenic carbon atoms, which are consequently in a highly reactive state. Addition of water thus takes place with great ease.

The mechanism of reaction of the free aminotolane, on the other hand, is obscured by salt formation, but to account for the great difference in reactivity between 4:4'- and 4:3'-diaminotolane it is only necessary to suppose that the former exists in hydrochloric acid as its mono-acid salt, and the latter as its di-acid salt. In fact, the author ventures to suggest that the diquaternary ammonium base derived from 4:4'-diaminotolane would assume the elements of water with great difficulty.

#### EXPERIMENTAL.

**3:4'-Dinitrostilbene Dibromide.**—Finely-divided 3:4'-dinitrostilbene (21.6 g.) (this vol., p. 580) was suspended in chloroform (1 litre), bromine (12 c.c.) added, and the whole kept during 2—4 days. The stilbene gradually dissolved and later the dibromide partly crystallised. The solvent and excess of bromine were then distilled off, and the solid residue† was recrystallised from boiling glacial acetic acid (about 925 c.c.). The yield was 90%. As with the dichloride, two forms could be obtained by fractional crystallisation. The pure  $\alpha$ -form is sparingly soluble in acetic acid,

\* The concentration and temperature were varied over a wide range.

† This, unlike the dichloride (this vol., p. 581), did not char during removal of the last few c.c. of solvent.

crystallising in almost white, thick prisms, m. p.  $234^{\circ}$  (Found: Br, 36.9.  $C_{14}H_{10}O_4N_2Br_2$  requires Br, 37.2%). Its production seems to be favoured by longer exposure of the chloroform solution to daylight. The pure  $\beta$ -form is more soluble in acetic acid or chloroform, crystallising from the former solvent in pale brown, minute plates, m. p.  $214^{\circ}$  (Found: Br, 36.95%). Both forms are sparingly soluble in most organic solvents; they separate from boiling nitrobenzene in small prisms. Even the  $\beta$ -form, which in substances of this type usually reacts differently from the  $\alpha$ -form (compare Pfeiffer, *Ber.*, 1912, 45, 1810), on being heated with pyridine at  $90^{\circ}$  for 2 hours loses both bromine atoms, reverting to the stilbene.\*

3:4'-Dinitrotolane (I).—The mixture of dibromides (22.8 g.) was suspended in boiling alcohol (220 c.c.), and a solution of potassium hydroxide (6.6 g.) in water (15 c.c.) added. After being boiled under reflux for 1 hour, the mixture was allowed to cool to  $50^{\circ}$  and the brown solid filtered off. After being well washed with cold alcohol and then with water, the product was crystallised twice from glacial acetic acid, and then from a large volume of alcohol to free it from traces of stilbene (see p. 1232). The pure tolane melted at  $173$ – $174^{\circ}$ ; the yield was 70% (Found: C, 62.3; H, 3.2.  $C_{14}H_8O_4N_2$  requires C, 62.7; H, 3.0%). It is easily soluble in hot benzene, nitrobenzene, acetone, or ethyl acetate, less readily in acetic acid or chloroform, somewhat sparingly soluble in ethyl alcohol, and very sparingly soluble in carbon tetrachloride, carbon disulphide, ether, or light petroleum. It produces a deep red solution in strong sulphuric acid.†

*Addition of water.* The nitrotolane (1 g.), obtained in a fine state of division by pouring an alcoholic solution into water, was dissolved in cold concentrated sulphuric acid. After being maintained at  $15^{\circ}$  for 30 minutes,‡ the solution was slowly poured on to ice, and the slightly resinous deposit filtered off and dissolved in acetone. Slow evaporation of the solvent left behind dark glistening plates, which after three crystallisations from alcohol (charcoal) melted at  $101^{\circ}$ , alone or mixed with an authentic specimen of 3-nitrophenyl 4-nitrobenzyl ketone (this vol., p. 582). Although the yield was only fair, no other product was isolated.

\* Unlike the dibromide of the parent substance (Limpricht, *Annalen*, 1868, 145, 338), 3:4'-dinitrostilbene dibromide does not yield the corresponding benzil when heated with water under pressure, even at  $215^{\circ}$  for 60 hours.

† Compare the bluish-violet colour given under similar conditions by 2:4-dinitrotolane (Pfeiffer, *loc. cit.*).

‡ Any other conditions, such as alteration of temperature, use of solvents, change in concentration or duration, resulted in a charred product or recovery of the unchanged nitrotolane.

**3 : 4'-Diaminostilbene.**—A solution of the dinitrostilbene (2 g.) in boiling acetic acid (15 c.c.) was cooled to 70° and zinc dust (10 g.) and hydrochloric acid (40 c.c.) were gradually added with stirring; the reaction was complete in  $\frac{3}{4}$  hour. The boiling solution was filtered, and, on cooling, the *hydrochloride* separated in yellow, pearly plates or needles.\* The free amine after recrystallisation from alcohol formed small, yellow plates or needles, m. p. 156° (Found : C, 80.0; H, 6.9.  $C_{14}H_{14}N_2$  requires C, 80.0; H, 6.7%). It is very soluble in ethyl acetate or acetone, less readily in alcohol, ether or benzene, and sparingly soluble in chloroform, carbon tetrachloride, carbon disulphide or light petroleum. The *diacetyl* derivative crystallises from methyl alcohol in clumps of needles, m. p. 226—227° (Found : C, 73.3; H, 6.3.  $C_{18}H_{18}O_2N_2$  requires C, 73.5; H, 6.1%). This derivative is very soluble in ethyl acetate, soluble in acetone or alcohol, and sparingly soluble in benzene or chloroform. It gives no colour with cold concentrated sulphuric acid.

**3 : 4'-Diaminodibenzyl.**—The diaminostilbene (1.2 g.) was reduced with sodium (2 g.) in boiling ethyl alcohol (30 c.c.), the reaction being complete in  $\frac{1}{2}$  hour. When cold, the opaque solution was acidified with dilute hydrochloric acid and a small amount of tar removed by extraction with ether. The free base crystallised from the warm solution on addition of dilute sodium hydroxide (weight of crude product = 0.95 g.), and when recrystallised from aqueous alcohol formed small, white plates, m. p. 73—75°. It is easily soluble in acetone, alcohol, ether or benzene; the *hydrochloride* is readily soluble in water, from which it crystallises in needles. The *diacetyl* derivative crystallises from aqueous alcohol in small clusters of thick needles, m. p. 177° (Found : C, 72.7; H, 6.9.  $C_{18}H_{20}O_2N_2$  requires C, 73.0; H, 6.8%). It is readily soluble in alcohol, acetone, or ethyl acetate, moderately easily soluble in hot chloroform, and almost insoluble in benzene. It gives no colour with cold sulphuric acid.

**Reduction of 3 : 4'-Dinitrostilbene Dichloride.**—3 : 4'-Diaminostilbene was also obtained, though with difficulty, from 3 : 4'-dinitrostilbene dichloride by reduction in alcoholic solution with zinc and hydrochloric acid at 15°.† The reduction was incomplete, and the light brown *substance* which remained after filtration of the normal reaction product, when crystallised from alcohol melted

\* It is essential to isolate this amine as its hydrochloride, otherwise the melting point varies over a range of 50°.

† No reduction took place with iron powder and calcium chloride, whilst stannous chloride and acetic acid yielded a mixture of products exceedingly difficult to purify.

at 202—205° (Found: C, 65.2; H, 3.0%). It contained chlorine, but gave an immediate intense purple colour with cold concentrated sulphuric acid, and was therefore not the unchanged dichloride (see this vol., p. 582). On the other hand, it could not be diazotised. Its constitution was not further investigated.

*Reduction of  $\alpha$ -Chloro-4:3'-dinitrostilbene.*—Facile reduction occurred when crystalline stannous chloride (25 g.) in 80% acetic acid (25 c.c.) was added to the chlorostilbene (5 g.) dissolved in boiling glacial acetic acid (50 c.c.). The solution was almost neutralised with sodium hydroxide,\* and the tin precipitated by hydrogen sulphide. The filtrate was boiled and neutralised, and the free ketonic base recrystallised several times from alcohol (charcoal); after purification, it formed rosettes of almost colourless needles, m. p. 153°, which were not identical with 3:4'-diaminostilbene, m. p. 156°, obtained from the dichloride (see above), since an intimate mixture melted about 15° below this temperature.

A better yield of the diacetyl derivative of this base was obtained by shaking the crude reduction liquor, while still warm, with acetic anhydride in presence of sodium acetate. After standing over-night, the solution was poured into water and the suspended solid extracted with methyl ethyl ketone. The ketone layer, which separated after the addition of a large quantity of calcium chloride, was dried over potassium carbonate, the solvent removed, and the diacetyl compound recrystallised three times from methyl alcohol with the addition of ether; it then melted at 204°. (The properties of these two compounds are described below.)

*3:4'-Diaminotolane.*—The nitrotolane (3 g.) was boiled with alcohol (25 c.c.), and the suspension quickly cooled to 10°. Zinc dust (5 g.) was added, and then, very slowly, hydrochloric acid (17 c.c.) † during 1 hour, the temperature being maintained at 10—15°. The solution of the hydrochloride was filtered from much (2 g.) unreduced nitrotolane and the precipitated amine was extracted with ether and recrystallised from aqueous alcohol, when it formed light brown needles, m. p. 124—125° (Found: C, 80.6; H, 6.1.  $C_{14}H_{12}N_2$  requires C, 80.8; H, 5.8%). It dissolves easily in alcohol, ether, ethyl acetate or acetone, rather less readily in hot benzene or chloroform, and is sparingly soluble in carbon disulphide or light petroleum. It is not converted into the deoxybenzoin by boiling with hydrochloric acid. Its *diacetyl* derivative crystallises from methyl alcohol in thick needles, m. p. 226° (Found: C, 73.8;

\* The free amine appears to be somewhat unstable to hydrogen sulphide in presence of alkali; possibly a sulphur atom is incorporated in the molecule (compare Jones and Robinson, J., 1917, **111**, 911).

† Zinc and acetic acid give coloured by-products.

H, 5.55.  $C_{18}H_{16}O_2N_2$  requires C, 74.0; H, 5.5%). This diacetyl derivative, unlike those of diaminostilbene (m. p. 226—227°) and diaminodibenzyl (m. p. 177°), gives an immediate red colour with cold concentrated sulphuric acid.

**4-Acetylaminophenyl 3-Acetylaminobenzyl Ketone (IV).**—Pure 3:4'-diacetyldiaminotolane (III) (0.3 g.) was dissolved in cold concentrated sulphuric acid (3.0 c.c.), and the temperature maintained at 15° for  $\frac{1}{2}$  hour. No hydrolysis took place under these conditions. The deep red solution was then poured on to ice, and the mauve-coloured solid at once filtered off. It slowly changed to a grey non-crystalline mass, which by purification from alcohol was transformed into almost white needles, m. p. 204° (Found: C, 69.3; H, 6.1.  $C_{18}H_{18}O_2N_2$  requires C, 69.7; H, 5.8%). The yield was good, and no other product was detected. This diacetyl compound was identical with that obtained from the reduction of  $\alpha$ -chloro-4:3'-dinitrostilbene (see above). It is soluble in alcohol, dilute acetic acid, or ethyl acetate, but sparingly soluble in ether. It no longer gives a red colour with cold concentrated sulphuric acid.

**4-Aminophenyl 3-Aminobenzyl Ketone.**—During the course of one experiment on the reduction of 3:4'-dinitrotolane with zinc and hydrochloric acid at 70—80°, after separation of the hydrochloride of the normal reduction product, precipitation of the mother-liquors with alkali yielded a brown solid which, after being twice crystallised from aqueous alcohol, melted at 156°. Its melting point was depressed 20° by admixture of an authentic specimen of 3:4'-diaminostilbene (m. p. 156°),\* but not at all by addition of the amine (m. p. 153°) formed on reduction of  $\alpha$ -chloro-4:3'-dinitrostilbene; its diacetyl derivative, m. p. 204°, was identical with that obtained by the action of sulphuric acid on 3:4'-diacetyldiaminotolane. Without doubt it was a deoxybenzoin produced by addition of water to the triple bond of the tolane, probably under the influence of the metal, since boiling hydrochloric acid alone effected no change (Found: C, 74.0; H, 6.4.  $C_{14}H_{14}ON_2$  requires C, 74.3; H, 6.2%). This amine is soluble in all the usual organic solvents, and crystallises in clusters of slightly brown, flat needles from alcohol.

**3-Acetylaminophenyl 4-acetylaminobenzyl ketone** was obtained when the corresponding dinitro-ketone (1.3 g.) was reduced at 10° with zinc and hydrochloric acid, as in previous experiments. The crude amine isolated from the hydrochloride was at once acetylated, and the product recrystallised from alcohol, when it melted at 184—186° (Found: C, 69.35; H, 6.0.  $C_{18}H_{18}O_2N_2$  requires C, 69.7; H, 5.8%). The solubilities of this diacetyl derivative were similar to those of

\* Which even under these conditions, therefore, is not produced (compare Reinhardt, *loc. cit.*).

the isomeric ketone, m. p.  $204^{\circ}$ , but a mixture of the two melted at  $170$ — $179^{\circ}$ . This dissimilarity definitely establishes the constitution of 4-acetylaminophenyl 3-acetylaminobenzyl ketone, and consequently the mode of addition of water to 3 : 4'-diaminotolane and to its diacetyl derivative.

In conclusion, the author wishes to thank Professor Lapworth for suggesting the research, and the Research Fund Committee of the Chemical Society for a grant which has defrayed part of the expenses.

THE UNIVERSITY, MANCHESTER.

## CLX.—*Investigations in the Diphenyl Series. Part I.* *Migration Reactions.*

By FRANK BELL, JOSEPH KENYON, and PERCY HARRY ROBINSON.

In view of the appearance of a paper by Vorländer (*Ber.*, 1925, 58, 1913), in which 4-hydroxylaminodiphenyl is described, and of another by Scarborough and Waters on the chlorination and bromination of 4-aminodiphenyl (this vol., p. 557), it has been thought advisable to communicate some of the results already obtained by the authors in the same field.

The literature shows that numerous attempts have been made to elucidate the spatial relations of the two nuclei in diphenyl compounds, and there is considerable evidence in favour of the view of the closeness of the 4, 4'-positions in some derivatives. If the 4, 4'-positions in diphenyl are close together, there is a reasonable probability that those types of reactions which involve the para-migration of certain groups in simple benzene compounds might also be exhibited, under appropriate conditions, by certain derivatives of diphenyl, the migrating group passing from position 4 to position 4'. Migration reactions in the diphenyl series analogous to the following have been looked for, but have not been found :

In the corresponding diphenyl compounds decomposition occurs in case (II), whilst in cases (I) and (III) migration does take place, not, however, to the 4'-position but most probably to the adjacent 3-position.

There is an extensive literature on the preparation of diphenyl by the thermal decomposition of benzene, the most recent account being that of Lowe and James (*J. Amer. Chem. Soc.*, 1923, **45**, 2666), who, however, used an apparatus which is outside the resources of an ordinary laboratory. A simpler device is described in the experimental part; chlorobenzene, under similar treatment in the apparatus described, underwent extensive carbonisation, and no 4:4'-dichlorodiphenyl was obtained. The nitration of diphenyl was carried out by a modification of the methods due to Hübner (*Annalen*, 1881, **209**, 339) and Van Hove (*Bull. Soc. chim. Belg.*, 1923, **32**, 52).

By the reduction of 4-nitrodiphenyl with aluminium amalgam and moist ether, there is obtained a complex mixture of 4-azodiphenyl, 4-azoxydiphenyl, 4-aminodiphenyl, and 4-hydroxylaminodiphenyl, together with unchanged nitrodiphenyl. By crystallisation of this mixture from benzene, a 30% yield of 4-hydroxylaminodiphenyl is obtained. Vorländer (*loc. cit.*), who gives no experimental details whatever, states that the compound was prepared "nach bekanntem Verfahren" and melted at 132—134°.

The insolubility of 4-hydroxylaminodiphenyl militates seriously against migration experiments under favourable conditions. Sulphuric acid of various concentrations was employed at first, but as the minimum concentration of this acid necessary for solution of the hydroxylamino-compound at the ordinary temperature is above 50%, deep-seated decomposition occurs, and no crystalline material other than 4-azoxydiphenyl can be isolated from the products of the reaction. By the action of 10% sulphuric acid at 100°, a very small proportion of a new compound was formed. This substance has not yet been thoroughly investigated, but it is believed to be 4-diphenyl(4-amino-3-diphenyl)amine,

When hydrogen chloride is passed into a dry ethereal solution of 4-hydroxylaminodiphenyl, or when this compound is left for some time in contact with strong hydrochloric acid, 4-hydroxylaminodiphenyl hydrochloride is formed, which, on heating, decomposes to give principally 4-azoxydiphenyl.

An alcoholic solution of hydrogen chloride converts 4-hydroxylaminodiphenyl almost completely into 4-azoxydiphenyl, but at the same time there is produced a very small proportion of a compound which melts at 69° and contains chlorine.

Acetyl chloride reacts readily with 4-hydroxylaminodiphenyl to yield a diacetyl derivative believed to be diacetyl-4-hydroxylaminodiphenyl. This compound can be prepared in almost theoretical yield by dissolving 4-hydroxylaminodiphenyl in warm acetic

anhydride, and when warmed with strong hydrochloric acid it undergoes hydrolysis and simultaneous conversion into a chloro-base (m. p. 69°), the hydrochloride of which hydrolyses very readily, and in consequence has not been prepared in a sufficiently pure state for analysis. The chloro-base yields a monoacetyl derivative of m. p. 146° which is identical with that obtained by the action of acetic acid on diphenyl-4-acetylchloroamine (*vide* below), so that the course of this reaction is probably expressed by the following scheme :

4-Methylaminodiphenyl was prepared by treating 4-acetylaminodiphenyl with sodium and methyl iodide with subsequent elimination of the acetyl group, and was purified by conversion into its nitroso-derivative.

4-Nitrosomethylaminodiphenyl, both alone and when suspended in ether (in which it is only sparingly soluble), was mixed with an alcoholic solution of hydrogen chloride, when slow reaction ensued with evolution of gas. No nitroso-4-methylaminodiphenyl was found in the reaction mixture, which consisted mainly of 4-methylaminodiphenyl together with a little of the unchanged substance.

4-Diazomethylaminodiphenyl is a by-product in the preparation of 4-nitrosomethylaminodiphenyl from the crude secondary amine, which probably contains a little 4-aminodiphenyl.

Diphenyl-4-acetylchloroamine. It is clear from the literature that the preparation of aryl acyl chloroamines is susceptible to slight variations in experimental conditions (compare Armstrong, J., 1900, 77, 1047; Chattaway and Orton, J., 1901, 79, 275).

A similar susceptibility has been found in the case of 4-acetylaminodiphenyl, which, however, reacts rapidly and quantitatively at 70—80°. One sample yielded 67% of diphenyl-4-acetylchloroamine after only 10 minutes' heating. Further, the state of subdivision is very important, and may account for the difficulties met with by Armstrong and his students in the case of acetanilide (*loc. cit.*). When the 4-acetylaminodiphenyl was powdered mechanically, the yields were poor.

When diphenyl-4-acetylchloroamine is warmed with glacial acetic acid it is transformed into a chloro-4-acetylaminodiphenyl believed to be 3-chloro-4-acetylaminodiphenyl (compare above).

No trace of 4'-chloro-4-acetylaminodiphenyl was detected, although its presence was specially sought.

3-Chloro-4-acetylaminodiphenyl results directly if the sodium hypochlorite solution used is above normal in strength.

A quantitative yield of 3-chloro-4-acetylaminodiphenyl results also from the direct chlorination of 4-acetylaminodiphenyl in acetic acid. Again no trace of 4'-chloro-4-acetylaminodiphenyl was detected. This is in marked contrast with the bromination of 4-acetylaminodiphenyl in acetic acid, which yields 30% of the theoretical quantity of 4'-bromo-4-acetylaminodiphenyl together with 65% of a bromo-base (m. p. 65°) not yet fully examined.

#### EXPERIMENTAL.

*Diphenyl.*—The heating coil, which consists of about 1 yard of 32 gauge nichrome wire, is loosely threaded through a strip of mica 5"  $\times$  1 $\frac{1}{4}$ " and suspended in the neck and body of a 5-litre flask fitted with an upright condenser. Benzene (1 $\frac{1}{2}$  litres) is placed in the flask and boiled. When benzene is dripping freely from the condenser, the current is switched on, and by means of a sliding resistance is gradually raised to the value (about 3 amps.) at which the flask begins to fill with fumes. Little attention is required, and at the end of about 30 hours the liquid is transferred to a flask and distilled. Benzene comes over first, and then the temperature rises rapidly. The fraction b. p. 245–260° is collected and crystallised from alcohol. The yield of pure diphenyl averages 9 g. per hour.

*Nitration of Diphenyl.*—To a solution of diphenyl in acetic acid (2 parts) at 70–90°, nitric acid (*d* 1.51; 2 $\frac{1}{2}$ –3 mols.) is added in small quantities. The solution darkens, and when about one-third of the acid has been added a visible and steady reaction sets in. The remaining acid is added more carefully, the experiment taking 1 $\frac{1}{2}$  to 1 $\frac{1}{2}$  hours from the first addition of acid. After cooling, the crystalline crop of 4-nitrodiphenyl is filtered off, and the filtrate diluted with water. The oily layer thus precipitated is separated roughly from the aqueous layer and filtered from a further amount of 4-nitrodiphenyl. The oil is heated in a current of steam to free it from residual acid and unchanged diphenyl, and then distilled in a vacuum. Moisture and a trace of diphenyl come over first, and the main bulk distils at 188–193°/20 mm. The distillate is dissolved in alcohol at 40° and the crystals of 4-nitrodiphenyl which separate on cooling are filtered off. After evaporation of the alcohol, 2-nitrodiphenyl crystallises in characteristic large plates or prisms. 100 G. of diphenyl give 60–70 g. of 4-nitrodiphenyl, m. p. 114°, and 35–39 g. of 2-nitrodiphenyl, m. p. 35–37°.

*4-Hydroxylaminodiphenyl.*—A solution of 4-nitrodiphenyl (50 g.) in ether (1300 c.c., previously distilled from sodium hydroxide) is cooled in a freezing mixture and to it is added aluminium amalgam (10 g.), in very thin sheets, at such a rate that the reaction does not become too vigorous; the reaction vessel is shaken from time to time. Very little hydrogen is evolved if the mixture is kept cold, and the amalgam takes about 2 hours for complete reaction. The mixture is then filtered, the bulky aluminium hydroxide washed several times with dry ether, and the filtrate and washings are evaporated to dryness. The residue is dissolved in the minimum amount (about 250 c.c.) of boiling benzene, and the yellow solution allowed to cool. 4-Hydroxylaminodiphenyl separates in almost colourless, glistening leaflets which appear to fill the whole bulk of the liquid. These are filtered off and dried (yield, 10–14 g.). The compound melts at 152–154° to a red liquid which sets, and in turn melts at 188–190° (Found: C, 77·8; H, 6·0; N, 7·7.  $C_{12}H_{11}ON$  requires C, 77·8; H, 5·9; N, 7·6%).

The formation of a deep damson colour with concentrated sulphuric acid is a sensitive reaction for this compound.

4-Hydroxylaminodiphenyl (2 g.) was maintained in the molten state for 30 minutes, and the cooled residue (1·86 g.) dissolved in boiling benzene. The solution on cooling deposited crystals of 4-azodiphenyl, and after evaporation of the benzene, the residue consisted of a mixture of 4-azoxydiphenyl (m. p. 211–212°) and 4-aminodiphenyl (m. p. 52°).

On treatment of an ethereal solution of 4-hydroxylaminodiphenyl with hydrogen chloride or by leaving a suspension in concentrated hydrochloric acid for some time, the *hydrochloride* is obtained as a white powder (Found: HCl, 16·6.  $C_{12}H_{11}ON, HCl$  requires HCl, 16·5%). The principal product obtained on heating the hydrochloride is 4-azoxydiphenyl.

*Action of 10% sulphuric acid.* 4-Hydroxylaminodiphenyl (5 g.) is triturated with sulphuric acid (600 c.c. of 10%), and the mixture heated on a steam-bath until the whole assumes a deep chocolate colour. It is then filtered hot, and the insoluble residue extracted with 2 litres of boiling water. The filtrates deposit amine sulphates, which are filtered off and suspended in sodium carbonate solution. The mixture is boiled and, after addition of some alcohol, filtered from a trace of impurity. On cooling, the liquid fills with fine, silky crystals, which are filtered off and crystallised from aqueous alcohol; m. p. 156°. It is difficult to make certain that the product is quite free from 4-aminodiphenyl, since the sulphate of this compound must be present in the filtrate. As the compound is insoluble in sodium hydroxide, it is tentatively suggested that it

may be produced by the *o*-semidine change of an intermediate reactive 4-hydrazodiphenyl (Found : C, 85.0; H, 6.1.  $C_{24}H_{20}N_2$  requires C, 85.6; H, 6.0%).

By the action of an alcoholic solution of hydrogen chloride on the hydroxylamine there was obtained a small quantity of a chloro-base, m. p. 69° (see below).

*Diacetyl-4-hydroxylaminodiphenyl* was prepared by dissolving 4-hydroxylaminodiphenyl in acetic anhydride and pouring the solution, filtered from a little 4-azoxydiphenyl, into excess of water. The well-washed precipitate crystallised from alcohol in clusters of short, thick needles, m. p. 119° (Found : C, 71.2; H, 5.8; N, 5.2.  $C_{16}H_{15}O_3N$  requires C, 71.4; H, 5.6; N, 5.2%).

This compound gives a deep damson colour with concentrated sulphuric acid. This diacetyl derivative (24 g.) was dissolved in 90 c.c. of concentrated hydrochloric acid by warming on a water-bath, 500 c.c. of water were added, and the whole was filtered while boiling. The hydrochloride which separated on cooling was difficult to purify by crystallisation, as it was so readily hydrolysed. It was decomposed by sodium carbonate, and the oil obtained was filtered off after solidification. By repeated crystallisation from aqueous alcohol, it was obtained as a constant-melting chloro-base, m. p. 69° (Found : N, 6.9.  $C_{12}H_{10}NCl$  requires N, 6.9%).

It gives an acetyl derivative which crystallises from alcohol in glistening needles, m. p. 146° (Found : C, 68.4; H, 5.0; N, 6.0.  $C_{14}H_{12}ONCl$  requires C, 68.4; H, 4.9; N, 5.7%).

*4-Aminodiphenyl*.—This compound is formed during the preparation of 4-hydroxylaminodiphenyl, but its separation from the accompanying azoxy-, azo-, and nitro-compounds is difficult. The benzene filtrate from 4-hydroxylaminodiphenyl was therefore evaporated to dryness, the residue finely powdered and suspended in ether, aluminium amalgam added until the ethereal solution became colourless, the filtered solution evaporated to dryness, and the residue dissolved in boiling alcohol; on cooling, 4-hydrazodiphenyl separated in colourless, glistening needles, m. p. 167—169°. This was filtered off, and by dilution of the mother-liquor 4-aminodiphenyl (m. p. 52—53°) was obtained.

4-Nitrodiphenyl is converted directly into 4-aminodiphenyl by the same process when excess of aluminium amalgam is added. This appears to be the cleanest method of preparation, and the yield is good.

*4-Hydrazodiphenyl* was heated with hydrochloric acid and sulphuric acid of various strengths, but only 4-azodiphenyl and 4-amino-diphenyl could be isolated from the products, thus confirming the observation of Rassow (*J. pr. Chem.*, 1901, 63, 449).

4-Azoxydiphenyl was isolated from the product obtained by partial reduction of 4-nitrodiphenyl, by means of its ready solubility in benzene and insolubility in alcohol. It melts at  $212^{\circ}$  whether prepared by this method or by Zimmermann's (*Ber.*, 1880, 13, 1960), who, however, gives the m. p. as  $206^{\circ}$  (Found: C, 81.8; H, 5.2; N, 8.1. Calc.: C, 82.3; H, 5.1; N, 8.0%).

4-Azodiphenyl (m. p.  $249^{\circ}$ ) was obtained by distilling a mixture of 4-azoxydiphenyl and iron filings under reduced pressure.

4-Methylaminodiphenyl.—A mixture of 4-acetylaminodiphenyl (31.5 g.; m. p.  $171^{\circ}$ ), dry xylene (200 c.c.), and sodium (5 g.) was heated at  $130^{\circ}$  for 2–3 hours and cooled, methyl iodide (25 g.) was added, and the reaction completed by warming for a short period. The xylene was distilled off and the residue heated under reflux with alcoholic potash for 15 hours. Alcohol and xylene were removed in a current of steam, and the residue was extracted with ether. The ethereal extract was dried with sodium sulphate and after evaporation of the ether the residue distilled almost wholly at  $198$ – $202^{\circ}/20$  mm., the distillate setting to a semi-solid mass. This was best purified by conversion into the nitroso-derivative, and subsequent decomposition of this by boiling with concentrated hydrochloric acid according to the following procedure. The semi-solid mass was dissolved in glacial acetic acid, and the calculated amount of sodium nitrite added. The precipitate was filtered off, dried on porous plate, and boiled with alcohol, which extracted the nitrosoamine from an insoluble yellow product (A). On cooling the filtrate, the nitrosoamine crystallised, and was obtained as an almost colourless, microcrystalline powder, m. p.  $116^{\circ}$ , by recrystallisation from alcohol (Found: C, 73.6; H, 5.7.  $C_{13}H_{12}ON_2$  requires C, 73.6; H, 5.7%).

The nitrosoamine gave brilliant colours at the various stages of the Liebermann reaction. To obtain the secondary base, the nitroso-compound was boiled with concentrated hydrochloric acid. The hydrochloride thus obtained crystallised from dilute hydrochloric acid as a white powder (Found: HCl, 16.6.  $C_{13}H_{13}N.HCl$  requires HCl, 16.6%). On decomposition with sodium carbonate, 4-methylaminodiphenyl was obtained as an oil which rapidly solidified and had m. p.  $38^{\circ}$ . It was readily soluble in almost all organic solvents, gave an acetyl derivative, m. p.  $118$ – $119^{\circ}$ , which was very soluble in alcohol and separated from aqueous alcohol in a gelatinous condition.

This base is much better characterised as its *p*-toluenesulphonyl derivative, which was readily prepared by the action of *p*-toluenesulphonyl chloride in pyridine solution, and crystallised from alcohol in lustrous, white needles, m. p.  $128^{\circ}$  (Found: N, 4.2.  $C_{20}H_{19}O_2NS$  requires N, 4.2%).

Its constitution is easily checked, since it may also be prepared by shaking the *p*-toluenesulphonate of 4-aminodiphenyl with methyl sulphate and sodium hydroxide. The *p*-toluenesulphonate of 4-aminodiphenyl, prepared by the usual method, crystallises from alcohol in colourless needles, m. p. 160° (Found: N, 4.5.  $C_{19}H_{17}O_2NS$  requires N, 4.3%).

The yellow product (A) obtained in the preparation of 4-nitrosomethylaminodiphenyl crystallised readily from benzene in splendid, lustrous, yellow plates which decomposed violently at 187°. On boiling with dilute sulphuric acid, there was vigorous evolution of nitrogen. When this had ceased, water was added and the whole filtered boiling hot. 4-Methylaminodiphenyl sulphate crystallised from the filtrate; the residue, after solution in sodium hydroxide and precipitation, melted at 164° and was identical with 4-hydroxydiphenyl prepared directly from 4-aminodiphenyl. The compound (A) must therefore be 4-diazomethylaminodiphenyl (Found: C, 81.8; H, 5.7; N, 11.1.  $C_{25}H_{21}N_3$  requires C, 82.6; H, 5.8; N, 11.6%).

4-Diazoaminodiphenyl is formed by treating an acetic acid solution of 4-aminodiphenyl with sodium nitrite and forms yellow plates, m. p. 147° (*Ber.*, 1925, 58, 1913).

4-Nitrosomethylaminodiphenyl both alone and when suspended in ether was treated with an alcoholic solution of hydrogen chloride. After 24 hours, the white solid was filtered off and decomposed with sodium hydroxide. The solid thus obtained was dissolved in alcohol, and on cooling, a small crop, m. p. 96°, was obtained. Although crystallisation does not alter this melting point, the product appears to be a mixture of unchanged 4-nitrosomethylaminodiphenyl and 4-methylaminodiphenyl, for, on treatment with acetic anhydride and subsequent crystallisation from alcohol, pure 4-nitrosomethylaminodiphenyl was obtained. After separation of the crop of m. p. 96°, the mother-liquor began to deposit an oil which, after purification, yielded 4-methylaminodiphenyl (m. p. 38°).

*Diphenyl-4-acetylchloroamine*.—4-Acetylaminodiphenyl (31.5 g.) was dissolved in the minimum quantity of boiling alcohol, and the solution stirred rapidly into 3 litres of cold water, a paste of the consistency of whipped cream resulting. This paste was filtered off with the aid of the pump but not pressed out; it was washed with water to remove all alcohol, and then suspended in water (600 c.c.) containing potassium bicarbonate (60 g.). A considerable excess of sodium hypochlorite solution was added [equivalent to 11.6 g. of hypochlorous acid instead of 7.9 g. (calc.)], the strength of the whole mixture being 0.16*N* in respect of hypochlorous acid.

The mixture was maintained at about 70° with constant shaking for  $\frac{1}{2}$  hour, and then allowed to cool. The solid was filtered off and a sample extracted with chloroform. The solvent was removed by a current of air and finally by evacuation. A weighed quantity of this product was dissolved in chloroform and shaken with acetic acid and potassium iodide solution and the liberated iodine was estimated (Found: Cl, 13.9.  $C_{14}H_{12}ONCl$  requires Cl, 14.4%).

This compound crystallises from chloroform-light petroleum in square plates melting at 127° if heated rapidly, and at 160° undergoes a vigorous change, presumably to 3-chloro-4-acetylaminodiphenyl.

*Transformation of Diphenyl-4-acetylchloroamine.*—The main bulk of this substance was filtered off, well washed with water, dissolved in glacial acetic acid, and the solution kept at 80° for 10 minutes and cooled; the vessel then became filled with masses of colourless needles, m. p. 145°, and 147° after recrystallisation from aqueous alcohol. The final mother-liquors contained a little unchanged 4-acetylaminodiphenyl and a trace of a brown oil.

Fractional crystallisation of this substance and of the residues in the acetic acid mother-liquors failed to detect the presence of any trace of 4'-chloro-4-acetylaminodiphenyl. The compound, hydrolysed by boiling 50% sulphuric acid, gave a base which, after crystallisation from aqueous methyl alcohol, melted at 69°. 4'-Chloro-4-aminodiphenyl has m. p. 134°, so that it is highly probable that the above compound is 3-chloro-4-aminodiphenyl, and this view of its constitution is supported by its preparation by direct chlorination.

Chlorine (6.65 g.) (5% excess) was slowly bubbled through a solution of 4-acetylaminodiphenyl (21 g.) in glacial acetic acid (300 c.c.) in a tall vessel. A copious precipitate began to form at once, and after completion of the experiment 50 c.c. of water were added and the pale yellow product was filtered off. It melted at 144° and after recrystallisation from alcohol was obtained in fine, colourless needles, m. p. 146°. This substance on hydrolysis gave a base, m. p. 69°, identical with that obtained above. Exhaustive fractional crystallisation showed that the chlorination was practically quantitative, only 4% of unchanged 4-acetylaminodiphenyl being recovered and no trace of 4'-chloro-4-acetylaminodiphenyl was detected.

CLXI.—*The Labile Nature of the Halogen Atom in Organic Compounds. Part XII. Halogen Compounds of Barbituric Acids.*By ALEXANDER KILLEN MACBETH, THOMAS HENRY NUNAN,  
and DAVID TRAILL.

PREVIOUS work on the halogen derivatives of certain diketones has now been extended to compounds of the barbituric acid series. Baeyer (*Annalen*, 1864, **130**, 133) pointed out that there is a difference in the reactivity of the two halogen atoms in dibromobarbituric acid, one being more readily replaced than the other by hydrogen. Whiteley (J., 1921, **119**, 377) extended this observation and found that the reduction of dibromobarbituric acid is effected to the extent of one-half of the total bromine when an aqueous solution of the compound is added to a neutral solution of potassium iodide.

Hydrazine hydrate has now been found to act in a similar way, nitrogen being liberated in a volume agreeing with the reduction of one bromine atom. Similarly the chlorine atom is removed by this reagent from dichlorobarbituric acid. The corresponding halogen compounds of 1-phenylbarbituric acid and 1:3-diphenylbarbituric acid, as anticipated, gave results in agreement with the above observations, the reduction occurring readily in all cases.

The stability of the monohalogen derivatives of the barbituric acids may be connected with the enolic constitution of these compounds, in accordance with the explanation advanced (J., 1922, **121**, 1117, 2173) in the case of the derivatives of 1:1-dimethyl-*cyclohexane*-3:5-dione and *cyclohexanespirocyclohexane*-3:5-dione (I;  $R_2 = \text{Me}_2$  and  $\text{C}_3\text{H}_{10}$ ), respectively).

The difference in behaviour of the dichloro-derivatives of barbituric acids and those of the other diketones previously examined (J., 1922, **121**, 1120, 2176; 1923, **123**, 1129) is of interest. In the former case one of the halogen atoms is eliminated by hydrazine hydrate, whereas in  $\gamma\gamma$ -dichloroacetylacetone,  $\gamma\gamma$ -dichlorobenzoylacetone, 4:4-dichloro*cyclohexane*-3:5-dione, and *cyclohexanespiro*-4:4-dichloro*cyclohexane*-3:5-dione no reduction occurs. A ready explanation of this difference is obtained on the polarity basis by

considering the alternate effects of the other atoms in the barbituric acid ring, all of which act together to increase the induced electro-positive character of the halogen atoms.

The stability of the halogen atom in the monohalogenobarbituric acids may, as has been indicated above, be explained by assuming an enolic structure for these compounds. In order to throw further light on this assumption the absorption spectra of characteristic

compounds of this class were examined. The results are shown in Figs. 1—4. The absorption of barbituric acid was examined by Hartley (J., 1905, 87, 1796), who found that the acid transmitted a continuous spectrum very freely through thicknesses of  $M/1000$ -solution varying from 1—20 mm. In view of the results obtained in the past few years in absorption work, we were not surprised to find, on further examination of barbituric acid, that it showed selective absorption, its spectrum being characterised by deep complex bands extending over  $1/\lambda$  2950—3400, 3700—4200, 4450—

Its constitution is easily checked, since it may also be prepared by shaking the *p*-toluenesulphonate of 4-aminodiphenyl with methyl sulphate and sodium hydroxide. The *p*-toluenesulphonate of 4-aminodiphenyl, prepared by the usual method, crystallises from alcohol in colourless needles, m. p. 160° (Found: N, 4.5.  $C_{19}H_{17}O_2NS$  requires N, 4.3%).

The yellow product (A) obtained in the preparation of 4-nitrosomethylaminodiphenyl crystallised readily from benzene in splendid, lustrous, yellow plates which decomposed violently at 187°. On boiling with dilute sulphuric acid, there was vigorous evolution of nitrogen. When this had ceased, water was added and the whole filtered boiling hot. 4-Methylaminodiphenyl sulphate crystallised from the filtrate; the residue, after solution in sodium hydroxide and precipitation, melted at 164° and was identical with 4-hydroxydiphenyl prepared directly from 4-aminodiphenyl. The compound (A) must therefore be 4-diazomethylaminodiphenyl (Found: C, 81.8; H, 5.7; N, 11.1.  $C_{25}H_{21}N_3$  requires C, 82.6; H, 5.8; N, 11.6%).

4-Diazoaminodiphenyl is formed by treating an acetic acid solution of 4-aminodiphenyl with sodium nitrite and forms yellow plates, m. p. 147° (*Ber.*, 1925, 58, 1913).

4-Nitrosomethylaminodiphenyl both alone and when suspended in ether was treated with an alcoholic solution of hydrogen chloride. After 24 hours, the white solid was filtered off and decomposed with sodium hydroxide. The solid thus obtained was dissolved in alcohol, and on cooling, a small crop, m. p. 96°, was obtained. Although crystallisation does not alter this melting point, the product appears to be a mixture of unchanged 4-nitrosomethylaminodiphenyl and 4-methylaminodiphenyl, for, on treatment with acetic anhydride and subsequent crystallisation from alcohol, pure 4-nitrosomethylaminodiphenyl was obtained. After separation of the crop of m. p. 96°, the mother-liquor began to deposit an oil which, after purification, yielded 4-methylaminodiphenyl (m. p. 38°).

*Diphenyl-4-acetylchloroamine*.—4-Acetylaminodiphenyl (31.5 g.) was dissolved in the minimum quantity of boiling alcohol, and the solution stirred rapidly into 3 litres of cold water, a paste of the consistency of whipped cream resulting. This paste was filtered off with the aid of the pump but not pressed out; it was washed with water to remove all alcohol, and then suspended in water (600 c.c.) containing potassium bicarbonate (60 g.). A considerable excess of sodium hypochlorite solution was added [equivalent to 11.6 g. of hypochlorous acid instead of 7.9 g. (calc.)], the strength of the whole mixture being 0.16*N* in respect of hypochlorous acid.

The mixture was maintained at about 70° with constant shaking for  $\frac{1}{2}$  hour, and then allowed to cool. The solid was filtered off and a sample extracted with chloroform. The solvent was removed by a current of air and finally by evacuation. A weighed quantity of this product was dissolved in chloroform and shaken with acetic acid and potassium iodide solution and the liberated iodine was estimated (Found: Cl, 13.9.  $C_{14}H_{12}ONCl$  requires Cl, 14.4%).

This compound crystallises from chloroform–light petroleum in square plates melting at 127° if heated rapidly, and at 160° undergoes a vigorous change, presumably to 3-chloro-4-acetylaminodiphenyl.

*Transformation of Diphenyl-4-acetylchloroamine.*—The main bulk of this substance was filtered off, well washed with water, dissolved in glacial acetic acid, and the solution kept at 80° for 10 minutes and cooled; the vessel then became filled with masses of colourless needles, m. p. 145°, and 147° after recrystallisation from aqueous alcohol. The final mother-liquors contained a little unchanged 4-acetylaminodiphenyl and a trace of a brown oil.

Fractional crystallisation of this substance and of the residues in the acetic acid mother-liquors failed to detect the presence of any trace of 4'-chloro-4-acetylaminodiphenyl. The compound, hydrolysed by boiling 50% sulphuric acid, gave a base which, after crystallisation from aqueous methyl alcohol, melted at 69°. 4'-Chloro-4-aminodiphenyl has m. p. 134°, so that it is highly probable that the above compound is 3-chloro-4-aminodiphenyl, and this view of its constitution is supported by its preparation by direct chlorination.

Chlorine (6.65 g.) (5% excess) was slowly bubbled through a solution of 4-acetylaminodiphenyl (21 g.) in glacial acetic acid (300 c.c.) in a tall vessel. A copious precipitate began to form at once, and after completion of the experiment 50 c.c. of water were added and the pale yellow product was filtered off. It melted at 144° and after recrystallisation from alcohol was obtained in fine, colourless needles, m. p. 146°. This substance on hydrolysis gave a base, m. p. 69°, identical with that obtained above. Exhaustive fractional crystallisation showed that the chlorination was practically quantitative, only 4% of unchanged 4-acetylaminodiphenyl being recovered and no trace of 4'-chloro-4-acetylaminodiphenyl was detected.

One of the authors (F. B.) gratefully acknowledges receipt of a grant from the Advisory Council of the Department of Scientific and Industrial Research.

CLXI.—*The Labile Nature of the Halogen Atom in Organic Compounds. Part XII. Halogen Compounds of Barbituric Acids.*By ALEXANDER KILLEN MACBETH, THOMAS HENRY NUNAN,  
and DAVID TRAILL.

PREVIOUS work on the halogen derivatives of certain diketones has now been extended to compounds of the barbituric acid series. Baeyer (*Annalen*, 1864, **130**, 133) pointed out that there is a difference in the reactivity of the two halogen atoms in dibromobarbituric acid, one being more readily replaced than the other by hydrogen. Whiteley (J., 1921, **119**, 377) extended this observation and found that the reduction of dibromobarbituric acid is effected to the extent of one-half of the total bromine when an aqueous solution of the compound is added to a neutral solution of potassium iodide.

Hydrazine hydrate has now been found to act in a similar way, nitrogen being liberated in a volume agreeing with the reduction of one bromine atom. Similarly the chlorine atom is removed by this reagent from dichlorobarbituric acid. The corresponding halogen compounds of 1-phenylbarbituric acid and 1:3-diphenylbarbituric acid, as anticipated, gave results in agreement with the above observations, the reduction occurring readily in all cases.

The stability of the monohalogen derivatives of the barbituric acids may be connected with the enolic constitution of these compounds, in accordance with the explanation advanced (J., 1922, **121**, 1117, 2173) in the case of the derivatives of 1:1-dimethyl-*cyclohexane-3:5-dione* and *cyclohexanespirocyclohexane-3:5-dione* (I;  $R_2 = \text{Me}_2$  and  $\text{C}_3\text{H}_{10}$ ), respectively).

The difference in behaviour of the dichloro-derivatives of barbituric acids and those of the other diketones previously examined (J., 1922, **121**, 1120, 2176; 1923, **123**, 1129) is of interest. In the former case one of the halogen atoms is eliminated by hydrazine hydrate, whereas in  $\gamma\gamma$ -dichloroacetylacetone,  $\gamma\gamma$ -dichlorobenzoylacetone, 4:4-dichloro*cyclohexane-3:5-dione*, and *cyclohexanespiro-4:4-dichlorocyclohexane-3:5-dione* no reduction occurs. A ready explanation of this difference is obtained on the polarity basis by

considering the alternate effects of the other atoms in the barbituric acid ring, all of which act together to increase the induced electro-positive character of the halogen atoms.

The stability of the halogen atom in the monohalogenobarbituric acids may, as has been indicated above, be explained by assuming an enolic structure for these compounds. In order to throw further light on this assumption the absorption spectra of characteristic

compounds of this class were examined. The results are shown in Figs. 1—4. The absorption of barbituric acid was examined by Hartley (J., 1905, 87, 1796), who found that the acid transmitted a continuous spectrum very freely through thicknesses of  $M/1000$ -solution varying from 1—20 mm. In view of the results obtained in the past few years in absorption work, we were not surprised to find, on further examination of barbituric acid, that it showed selective absorption, its spectrum being characterised by deep complex bands extending over  $1/\lambda$  2950—3400, 3700—4200, 4450—

4530 and with heads at  $1/\lambda$  3000, 3170, 3760, 3880, 4490 approximately. The sodium salt (barbituric acid in the presence of  $N/10$ -sodium hydroxide) shows an absorption practically identical with that of the acid itself and therefore it is evident that in aqueous solution the acid exists in the enolised form (II). As was expected, in the presence of a strong acid the keto-enol change is induced: the absorption curve of barbituric acid in the presence of hydro-

chloric acid does not show to the same extent the marked selective effect characteristic of the enolic structure, the acid being present mainly in the ketonic form (III).

It was considered of interest to examine the absorption of barbitone, as the constitution of this compound is definitely fixed and it may be taken as characteristic of the *C*-dialkyl type. Its spectrum, like that of barbituric acid in the presence of hydrochloric acid, shows no selective effect characteristic of the enolic

form. In the presence of alkali, barbitone further develops the small absorption band at about  $1/\lambda$  3760, and this is probably due to enolisation involving a hydrogen atom of one of the imino-groups.

The absorption spectra of dichloro- and dibromo-barbituric acids are shown in Figs. 3 and 4. The curves are of the same type as those of barbitone, the selective effect connected with the enolic structure being absent. It has been pointed out that hydrazine hydrate reacts with the dihalogen compounds, eliminating one of the halogen atoms and forming the hydrazine salt of the resulting monohalogen derivative. No marked band development is observed in the spectra of the dihalogen compounds on the addition of sodium hydroxide, and therefore it must be inferred that, at the dilutions employed, this reagent does not react greatly with the labile halogen atoms.

The evidence of the absorption spectra of barbituric acid and its derivatives therefore clearly shows (a) that the parent acid exists in the enolic form in aqueous solution, whilst in acid solution the compound is present mainly as the ketonic modification; and, further, (b) that the dihalogen derivatives are compounds of the *C*-dihalogen type, which leaves no grounds for attributing the reactivity of the halogen atom to an oxygen-halogen linking (compare Graham and Macbeth, J., 1922, **121**, 1109, 2601). The bands found in the regions  $1/\lambda$  3000 and 3760 are probably connected with enolisation involving an imino-group, as these are found in barbitone and dibromobarbituric acid in the presence of alkali.

#### EXPERIMENTAL.

The absorption spectra recorded were all obtained with a Hilger spectroscope fitted with a camera attachment. The reductions described were carried out in a Van Slyke nitrometer, hydrazine hydrate (50% solution) being employed throughout.

*Dichlorobarbituric acid.* Barbituric acid, prepared by Gabriel and Coleman's method (*Ber.*, 1904, **37**, 3657), was chlorinated in aqueous suspension at 30–40°, leaflets, m. p. 219–220°, being obtained. The reaction with hydrazine hydrate is vigorous and is complete in a few seconds. 5 C.c. of a solution of 0.980 g. in 25 c.c. of alcohol liberated 11.9 c.c. of nitrogen at 10.5° and 732 mm. One g.-mol. therefore liberates 13.93 g. of nitrogen, corresponding with the removal of one chlorine atom.

The *hydrazide* of monochlorobarbituric acid is precipitated from the above reaction mixture and may also be prepared by the addition of hydrazine hydrate to an alcoholic solution of monochlorobarbituric acid. It does not melt below 300° (Found:

Cl, 18.2;  $N_2H_4$ , 16.7.\*  $C_4H_7O_3N_4Cl$  requires Cl, 18.4;  $N_2H_4$ , 16.6%).

*Dibromobarbituric acid* was prepared by Biltz and Hamburger's method (*Ber.*, 1916, 49, 635). Recrystallised from 2*N*-nitric acid, it had only a faint rose tinge and melted at 234°. A very vigorous reaction takes place with hydrazine hydrate, and white crystals of the hydrazide of monobromobarbituric acid separate. 5 C.c. of a solution of 1.124 g. of the dibromo-compound in alcohol liberate 12.1 c.c. of nitrogen at 15° and 729.1 mm. One g.-mol. therefore liberates 14.07 g. of nitrogen, which corresponds with the reduction of one bromine atom.

The *hydrazide* of monobromobarbituric acid, isolated above, may also be prepared directly from monobromobarbituric acid. It does not melt below 300° (Found: Br, 33.8;  $N_2H_4$ , 13.3.  $C_4H_7O_3N_4Br$  requires Br, 34.0;  $N_2H_4$ , 13.5%).

*Monobromobarbituric acid*, prepared by Biltz and Hamburger's method (*loc. cit.*), showed no reduction with hydrazine hydrate at the laboratory temperature.

5 : 5-Dibromo-1 : 3-diphenylbarbituric acid, prepared by Whiteley's method (*J.*, 1907, 91, 1367), reacts vigorously with hydrazine hydrate with the elimination of one bromine atom. 0.438 G. of the dibromo-compound liberated 12.6 c.c. of nitrogen at 13° and 719.8 mm. on treatment with hydrazine hydrate. One g.-mol. liberates 14.2 g. of nitrogen, which is in fair agreement with the removal of one halogen atom.

The *hydrazide* of 5-bromo-1 : 3-diphenylbarbituric acid separates during the above reaction as a creamy solid which recrystallises from alcohol in small needle-shaped laths; these appear as arborescent aggregates under the microscope; m. p. 220° (Found: Br, 21.6;  $N_2H_4$ , 8.3.  $C_{16}H_{15}O_3N_4Br$  requires Br, 21.8;  $N_2H_4$ , 8.5%).

5-Bromo-1 : 3-diphenylbarbituric acid, prepared by Whiteley's method (*J.*, 1921, 119, 378), was not reduced by hydrazine hydrate, but formed the above hydrazide.

1-Phenylbarbituric acid was prepared on lines parallel to those followed in the preparation of the diphenyl acid. Phosphoryl chloride (60 g.), malonic acid (20 g.), and phenylcarbamide (25 g.) were heated under reflux for 6 hours with dry chloroform (200 c.c.) at a temperature just below the boiling point. After removal of the chloroform in a current of air, the residual syrup was left in alcohol to decompose the phosphoryl chloride and then poured on ice. The solution of the creamy solid in sodium carbonate was filtered, and acidified with hydrochloric acid. The resulting solid

\* Estimated by a modification of Rimini's method (see *J.*, 1925, 127, 897).

was gently heated with a little alcohol to remove the soluble acetylated products, and after crystallisation from alcohol had m. p.  $262^{\circ}$  (Found: N, 13.7.  $C_{10}H_8O_3N_2$  requires N, 13.7%).

**3:3-Dibromo-1-phenylbarbituric Acid.**—Phenylbarbituric acid (5 g.) was heated on a water-bath with glacial acetic acid (50 c.c.) \* and dissolved on the gradual addition of the theoretical amount of bromine. The solution, after further heating (30 minutes), was poured on ice. Repeated crystallisation of the precipitated yellow solid gave almost white, lath-shaped crystals of the dibromo-acid, m. p.  $204^{\circ}$  (Found: Br, 44.0.  $C_{10}H_6O_3N_2Br_2$  requires Br, 44.2%).

The dibromo-acid reacts readily in alcoholic solution with hydrazine hydrate, liberating nitrogen and precipitating the hydrazide of the monohalogen acid. 0.2980 G. liberated 9.8 c.c. of nitrogen at  $16^{\circ}$  and 748 mm. One g.-mol. therefore liberates 13.9 g. of nitrogen, which corresponds with the reduction of one bromine atom.

The *hydrazide* of 3-bromo-1-phenylbarbituric acid, isolated above, forms rectangular needles, m. p.  $146^{\circ}$  (Found: Br, 25.4;  $N_2H_4$ , 10.5.  $C_{10}H_{11}O_3N_4Br$  requires Br, 25.6;  $N_2H_4$ , 10.2%).

**5-Bromo-1-phenylbarbituric Acid.**—The calculated quantity of bromine was added to the parent acid (5 g.), suspended in chloroform (50 c.c.) and warmed on the water-bath. After  $\frac{1}{2}$  hour, the solution was filtered, and the solid crystallised several times from spirit, being thus obtained in faintly pink, crystalline warts, m. p.  $213^{\circ}$  (Found: Br, 28.2.  $C_{10}H_7O_3N_2Br$  requires Br, 28.2%). No reduction took place on treatment with hydrazine hydrate, the above hydrazide being formed.

We (T. H. N. and D. T.) wish to acknowledge a grant from the Department of Scientific and Industrial Research which enabled us to participate in the work.

DURHAM COLLEGES,

[Received, February 24th, 1926.]

\* It is inadvisable to use more acetic acid, as the dibromide is then not precipitated when the solution is subsequently poured on ice.

CLXII.—*The Velocities of the Reactions between Ethyl Iodide and the Sodium Salts of Various Substituted Phenols in Ethyl-alcoholic Solution.*

By LEONARD JAMES GOLDSWORTHY.

ALTHOUGH much work has been done on the relation between the constitutions of different alkyl halides and their activities towards the sodium salts of phenol and of  $\alpha$ - and  $\beta$ -naphthol (Segaller, J., 1913, **103**, 1154, 1421; 1914, **105**, 106, 112; Cox, J., 1918, **113**, 666, 821; 1920, **117**, 493; Shroder and Acree, J., 1914, **105**, 2583), the effects of the substituents in the phenolic substances on the velocities have not hitherto been studied. The object of the present investigation was to ascertain the effect of introducing methyl and chlorine in different positions in the molecule of sodium phenoxide, on the rate of reaction of this substance with ethyl iodide. It was hoped that the results might be of some value in reference to the general and induced polarity effects accompanying substitution in the benzene ring.

As Segaller and others have shown, the reactions between alkyl halides and sodium phenoxides are bimolecular but of a special type, the velocity coefficients being smaller the greater the initial concentrations of the reacting substances, in accordance with the equation  $k_v = k_1 + a \log v$ , where  $v$  is the volume containing 1 g.-mol. of the alkyl halide and sodium phenoxide. All the reactions studied in this investigation were therefore carried out in solutions of the same strength, *viz.*, seminormal, with a view to obtain comparable results.

The following are the mean values ( $k \times 10^5$ ) of the observed velocity coefficients for the sodium salts of the cresols and chlorophenols: Concentrations of sodium salts and of ethyl iodide,  $N/2$ . Temp. 42.5°.

(Phenol .....	702)	<i>p</i> -Chlorophenol .....	393
<i>p</i> -Cresol .....	918	<i>o</i> - " .....	334
<i>m</i> - " .....	810	<i>m</i> - " .....	278
<i>o</i> - " .....	726	2:4-Dichlorophenol .....	196

The results resemble those obtained by Boyd and Marle (J., 1914, **105**, 2117) in their investigation on the reactivities of substituted sodium phenoxides towards ethylene and propylene oxides, the order of the reactivities of the cresols and chlorophenols towards ethyl iodide and ethylene oxide being identical.

A possible explanation of the order of the reactivities towards ethyl iodide is suggested by the results obtained by Shroder and Acree in the study of the reactions between sodium phenoxide and

alkyl halides (J., 1914, 105, 2582). They have shown that in a mixture of sodium phenoxide and ethyl iodide in alcoholic solution, the "ionic" and "molecular" reactions

and

occur simultaneously, the former being about five times as fast as the latter. The "ionic" reaction involves the transfer of an electron from the phenoxide ion to the iodine atom, a process which will be the more easily effected the weaker the tendency of the phenoxide ion to hold its electron—in other words, the smaller the ionisation constant of the phenol in question. We should expect, therefore, that the order of the reactivities of the phenoxides would be the inverse of the order of the ionisation constants of the corresponding phenols. The results, except in the case of sodium *o*-tolyl oxide, accord with this expectation, the ionisation constants increasing in the order *o*-, *p*-, and *m*-cresol, phenol, *p*-, *o*-, and *m*-chlorophenol, 2:4-dichlorophenol.\* In the case of sodium *o*-tolyl oxide the retarding steric effect of the methyl group in the ortho-position may account for the unexpectedly low reactivity.

#### EXPERIMENTAL.

The ethyl alcohol used in these experiments was commercial absolute alcohol, carefully dried by digestion with lime and calcium. The ethyl iodide was purified by successive washings with dilute caustic soda solution and water, drying over calcium chloride, and distillation from silver powder. The cresols and chlorophenols, supplied by Kahlbaum, were purified by fractional distillation a few hours before use. All the instruments used were standardised against instruments carrying the certificate of the National Physical Laboratory.

The experiments were carried out at  $42.5^\circ \pm 0.1^\circ$  in a thermostat provided with an Ostwald toluene regulator and an efficient stirrer.

To a weighed quantity of the phenol was added a measured volume of an alcoholic solution containing an equivalent quantity of sodium ethoxide. The solution was then diluted to normal concentration by adding the calculated volume of alcohol. 50 C.c. of this solution

\* The ionisation constants of phenol and the cresols have been determined by Dawson and Mountford (J., 1918, 113, 937). The order of the constants for *p*- and *o*-chlorophenols may be deduced from the measurements of the hydrolysis of their salts by Hantzsch and Farmer (Ber., 1899, 32, 3066, 3089). It is assumed from a consideration of the induced polarity effects that the ionisation constant of *m*-chlorophenol, for which data are not available, is greater than those of *o*- and *p*-chlorophenol.

were mixed quickly with an equal volume of a normal solution of ethyl iodide, and 10 c.c. of the mixture were introduced into each of eight small test-tubes, which had been steamed out previously. The test-tubes, provided with well-fitting rubber stoppers, were then placed in the thermostat. After 10 minutes, the contents of one of the tubes were transferred quickly to a beaker containing ice and an amount of standard acid nearly sufficient to neutralise the unchanged phenoxide. The titration was completed as quickly as possible, with lacmoid as indicator. Further titrations were carried out in a similar way at suitable intervals of time. The results were calculated from the equation  $k = xy/ta(a - x)$ , in which  $y$ ,  $a$ , and  $a - x$  represent the volume (in c.c.) of acid required to neutralise the phenoxide in 10 c.c. of the mixture before the commencement of the experiment, in the first titration (zero-time), and after  $t$  minutes, respectively.

In order to economise space the detailed results of only one experiment are shown, *viz.*, that in which the salt was sodium *m*-tolyl oxide, and *N*/5-hydrochloric acid was used for titration.

$t$ .	$a-x$ .	$x$ .	$k \times 10^5$ .	$t$ .	$a-x$ .	$x$ .	$k \times 10^5$ .

### CLXIII.—Carboxylated $\beta$ -Diketones.

By GILBERT T. MORGAN and CHARLES RAYMOND PORTER.

IN this communication we describe the synthesis of new  $\beta$ -diketones containing auxiliary carboxyl groups, these substances having been prepared with the object of facilitating the resolution of metallo- $\beta$ -diketones into optically active enantiomerides.

Hitherto this separation has been effected only with such salts as  $[\text{CoAc}_2\text{en}]\text{Cl}_2$  and  $[\text{CoPr}_2\text{en}]\text{Cl}_2$ , where Ac and Pr represent the univalent radicals of acetylacetone and propionylacetone respectively (Werner, Schwyzer, and Karrer, *Helv. Chim. Acta*, 1921, 4, 113), but not with metallo- $\beta$ -diketones such as  $[\text{BePr}_2]$  and  $[\text{CuPr}_2]$  or  $[\text{FeAc}_3]$  and  $[\text{CoAc}_3]$ , where the metal is wholly combined with the organic

radical. Even if the two foregoing pairs of metallo- $\beta$ -diketones exist respectively in tetrahedral and octahedral forms, an experimental difficulty arises from the fact that these substances, being non-ionised inner metallic complexes, do not combine either with optically active acids or with alkaloids. Moreover, the examination of selected crystals has not in this series led to positive results.

An auxiliary acidic group has been conferred on acetylacetone by condensing the sodium salt of this  $\beta$ -diketone with *ethyl  $\omega$ -chloro-m-toluate* (*m-carbethoxybenzyl chloride*),  $\text{CH}_2\text{Cl}\cdot\text{C}_6\text{H}_4\cdot\text{CO}_2\text{Et}$ , when 3-*m-carbethoxybenzylacetylacetone* (I;  $\text{R} = \text{CH}_3$ ) was produced which by hydrolysis in concentrated sulphuric acid furnished 3-*m-carboxybenzylacetylacetone* (II;  $\text{R} = \text{CH}_3$ ), a  $\beta$ -diketone containing two acidic functions, a chelate radical and the carboxyl substituent.

Cobaltic and chromic derivatives of the free carboxy-diketone were prepared but found to be unsuitable for resolutions with optically active alkaloids.

Homologues of the foregoing diketones with unsymmetrical chelate groups were prepared by a similar series of operations carried out on sodium butyrylacetone, when 3-*m-carbethoxybenzylbutyrylacetone* (I;  $\text{R} = \text{C}_3\text{H}_7$ ) resulted, and this ester on hydrolysis yielded 3-*m-carboxybenzylbutyrylacetone* (II;  $\text{R} = \text{C}_3\text{H}_7$ ).

The free carboxy-diketone (II;  $\text{R} = \text{C}_3\text{H}_7$ ) gave a green dicupric salt convertible into a grey monocupric derivative the colour of which suggested (Morgan, Drew, and Porter, *Ber.*, 1925, 58, 333) that the metal was held in the chelate group, but, although soluble in organic media, the monocupric compound rapidly decomposed in warm solutions into dicupric salt and carboxy-diketone.

A similar pair of beryllium derivatives was prepared, the monoberyllium compound being soluble in organic media, but crystallisation of this substance was impossible because of its rapid decomposition into ill-defined, insoluble products. Moreover, the alkaloidal salts of this monoberyllium derivative were also unsatisfactory and afforded no indication of any resolution.

Both carboxy- $\beta$ -diketones exhibit keto-enol isomerism: specimens crystallised from non-hydroxylic solvents such as benzene or petroleum were more fusible and gave immediately with ferric chloride purple colorations, thus indicating the enolic variety, whereas preparations crystallised from alcohol were less fusible

and developed the coloration only gradually, thereby suggesting a diketonic modification.

#### EXPERIMENTAL.

*Ethyl  $\omega$ -chloro-*m*-toluate* (*m*-carbethoxybenzyl chloride) was prepared by a modification of the patented method (E.P. 29720/1910; D.R.-P. 234913; Friedländer's "Fortschritte," X, p. 117). *m*-Toluic acid (100 g.) was gradually warmed to 120° with 75 c.c. of thionyl chloride and thereby converted into *m*-toluoyl chloride, b. p. 105°/20 mm. Chlorine was passed into 112.5 g. of this chloride at 160—180° until its weight increased to 138 g. The resulting  $\omega$ -chloro-*m*-toluoyl chloride was warmed gently with 50 c.c. of alcohol; a vigorous reaction set in with evolution of hydrogen chloride, the flask being finally heated to 140°. The ester was washed rapidly with dilute aqueous sodium carbonate and water, dried, and distilled under reduced pressure; 130 g. (= 89%) were obtained boiling at 140—150°/12 mm. (Found: Cl, 18.4.  $C_{10}H_{11}O_2Cl$  requires Cl, 17.9%).

I. 3-*m*-Carbethoxybenzylacetylacetone (I; R =  $CH_3$ ).—Eighty g. of sodium acetylacetone and 130 g. of the foregoing ester were heated together under reflux at 135—145° for 3 hours and finally at 160°. The cooled product was extracted with water and ether; the dried ethereal layer was distilled, yielding acetylacetone and 84 g. of a higher fraction, b. p. 175—215°/11 mm. The less volatile fraction dissolved in alcohol and was added to aqueous copper acetate containing an equivalent proportion of ammonia. After 2 or 3 days the copper derivative was collected, and washed with dilute acetic acid to dissolve copper hydroxide and with ether to remove liquid impurities. The ethereal washings were worked up again with further distillations of crude diketone.

*Copper 3-m-carbethoxybenzylacetylacetone*, a light grey, micro-crystalline powder, was insoluble in water but soluble in organic solvents; it crystallised from benzene and melted at 173—176° (Found: C, 61.3; H, 5.6.  $C_{30}H_{34}O_8Cu$  requires C, 61.6; H, 5.8%).

On extraction with dilute sulphuric acid and ether 67 g. of this copper salt yielded 42 g. (= 70%) of the liquid diketone, b. p. 209—215°/12 mm., which developed a reddish-purple coloration with alcoholic ferric chloride.

*Acidic Hydrolysis of 3-m-Carbethoxybenzylacetylacetone*.—The ester was not affected by boiling with 5*N*-sulphuric acid, 40% sulphuric acid, concentrated hydrochloric acid, or glacial acetic acid. Heating with syrupy phosphoric acid led to products giving no coloration with ferric chloride.

A solution of 1 or 2 g. of the ester in 3 or 4 volumes of concentrated

sulphuric acid was heated on the water-bath; hydrolysis occurred and the cooled red liquid yielded a white solid when poured on to crushed ice. This product was crystallised from benzene or benzene-petroleum. The first mother-liquors contained unchanged carboethoxy- $\beta$ -diketone, which was recovered and worked up in subsequent batches.

3-*m*-Carboxybenzylacetylacetone (II;  $R = CH_3$ ), obtained by this hydrolysis in 50% yield, crystallised from alcohol in colourless needles, m. p.  $130^\circ$ , and from benzene in white needles, m. p.  $115^\circ$ . The change in melting point is reversible and is probably due to keto-enolic isomerism. A specimen crystallised from benzene gave with ferric chloride a purple coloration, whereas the preparation from alcohol developed this colour only after a time (Found: C, 67.1; H, 5.8.  $C_{13}H_{14}O_4$  requires C, 66.7; H, 6.0%).

3-*m*-Carboxybenzylacetylacetone was fairly stable in acid solution but readily hydrolysed by alkalis (p. 1261). It was soluble in ordinary organic solvents except light petroleum and dissolved sparingly in water.

*Copper Derivatives of 3-m-Carboxybenzylacetylacetone.*—A bluish-green precipitate separated on adding excess of aqueous copper acetate to an acetone solution of 3-*m*-carboxybenzylacetylacetone. This dicupric salt containing copper attached both to carboxyl and chelate groups (Cu, 21.7.  $C_{26}H_{24}O_8Cu_2$  requires Cu, 21.5%) was insoluble in the ordinary organic solvents excepting pyridine, in which it dissolved extremely readily. On concentrating the pyridine solution, a precipitate was formed which lost pyridine on drying and reverted to the original dicupric salt. This substance developed slowly a red ferric chloride coloration, decomposed to a brown paste at  $250^\circ$ , and lost half its copper on trituration with an equivalent proportion of *N*/10-sulphuric acid, yielding a light grey monocupric derivative (Cu, 11.9.  $C_{26}H_{26}O_8Cu$  requires Cu, 12.0%), which decomposed at  $235$ – $240^\circ$  to a brown paste. It was insoluble in all ordinary solvents, and with ferric chloride it developed a red coloration only after a few minutes. This slowness of reaction and the grey colour suggest that the copper of the monocupric salt is attached to the chelate group.

*Other Metallic Derivatives.*—Normal beryllium acetate added to an acetone solution of the 3-*m*-carboxybenzylacetylacetone produced a white precipitate of beryllium derivative insoluble in organic solvents. A portion of the beryllium could be removed by trituration with dilute sulphuric acid (one equivalent) and the residue was then soluble in organic media, but it could not be purified by crystallisation because it reverted to a mixture of free diketone-carboxylic acid and the diberyllium derivative of this acid.

The dark green chromium derivative, although soluble in chloroform, was transformed in the warm solution into an insoluble green vitreous mass.

II. 3-*m*-Carbethoxybenzylbutyrylacetone (I;  $R = C_3H_7$ ).—Butyrylacetone prepared from methyl propyl ketone and ethyl acetate (Morgan and Drew, J., 1924, 125, 737) was dissolved in 10 volumes of dry cold ether and converted into its sodium salt by the addition of sodium in thin slices. After collecting the separated sodium derivative, the mother-liquors were concentrated, the total yield being practically quantitative. A mixture of 110 g. of sodium butyrylacetone and 145 g. of 3-*m*-carbethoxybenzyl chloride was heated under reflux in an oil-bath. At 140–150°, the sodium salt dissolved to a clear liquid and sodium chloride separated. After an hour at 160°, the cooled product was extracted with ether and water. The ethereal layer was washed with dilute acetic acid and distilled under reduced pressure. Butyrylacetone passed over first, yielding 25 g. of its copper derivative, and a higher fraction was obtained boiling above 180°/10 mm. The less volatile portion, dissolved in alcohol, was treated with excess of aqueous copper acetate containing one equivalent proportion of ammonia. After a few days, the mixture was slightly acidified and the copper derivative collected and washed successively with light petroleum and ether. The grey copper derivative, when extracted with dilute sulphuric acid and ether, regenerated the diketone, b. p. 200–201°/6 mm. (yield 47 g. or 22%).

Copper 3-*m*-carbethoxybenzylbutyrylacetone was soluble in chloroform or benzene and crystallised from the latter as a light grey, microcrystalline powder, m. p. 168–170° (Found: C, 63.6; H, 6.6.  $C_{34}H_{42}O_8Cu$  requires C, 63.6; H, 6.5%).

3-*m*-Carboxybenzylbutyrylacetone (II;  $R = C_3H_7$ ).—The foregoing ester was hydrolysed in 1 to 2 g. lots by mixing with 3 or 4 volumes of concentrated sulphuric acid, the solution being stirred for 2 to 3 minutes on the water-bath. The cooled yellow solution was then poured on to crushed ice and the white solid crystallised as quickly as possible from carbon tetrachloride (yield 50%).

This diketonic acid was more soluble and less stable than its lower homologue from acetylacetone, the crude material being decomposed completely on boiling for more than a few minutes with solvents. It was readily soluble in these organic media and dissolved sparingly in water. When crystallised from aqueous alcohol, the diketo-acid separated in small plates sintering at 80° and melting indefinitely at 100–112°. The purple ferric coloration developed only slowly with this specimen. But a preparation crystallised from benzene-petroleum melted at 78–90° and gave

the ferric coloration immediately (Found : C, 69.1; H, 6.9.  $C_{15}H_{18}O_4$  requires C, 68.7; H, 6.8%).

*Copper Derivatives of 3-m-Carboxybenzylbutyrylacetone.*—Dicupric 3-m-carboxybenzylbutyrylacetone was obtained as a bluish-green precipitate by adding copper acetate to an acetone solution of the diketo-acid. On washing with acetone, a portion dissolved and monocupric derivative was recovered from this extract. The insoluble dicupric salt decomposed to a brown paste when heated above  $225^\circ$  (Found : Cu, 19.4, 19.8.  $C_{30}H_{32}O_8Cu_2$  requires Cu, 19.6%).

*Monocupric 3-m-carboxybenzylbutyrylacetone*, prepared as a grey powder by triturating the foregoing copper compound with *N*/10-sulphuric acid, was soluble in alcohol or acetone, but crystallisation had to be effected as rapidly as possible because the substance decomposed on boiling the solution, with formation of the free diketo-acid and dicupric compound. The monocupric compound sintered at  $173^\circ$  and melted to a green liquid at  $176$ – $178^\circ$  (Found : Cu, 11.1.  $C_{30}H_{34}O_8Cu$  requires Cu, 10.9%).

*Beryllium Derivatives of 3-m-Carboxybenzylbutyrylacetone.*—On mixing an acetone solution of 3-m-carboxybenzylbutyrylacetone with aqueous normal beryllium acetate a copious white precipitate was obtained insoluble in water and the ordinary organic solvents, thus corresponding in properties with the foregoing dicupric salt. This insoluble beryllium compound was triturated with a very slight excess of 2*N*-sulphuric acid, and the mixture filtered. The filtrate contained beryllium; the precipitate was now soluble in organic media. This soluble beryllium derivative could not, however, be crystallised, as its solutions in benzene or other organic solvents rapidly underwent chemical change with the formation of a gelatinous white precipitate.

Numerous attempts were made to prepare the morphine, cinchonidine, brucine, and strychnine salts of the foregoing soluble beryllium derivative, but the products were ill-defined, uncrystallisable, vitreous, or oily substances from which no definite evidence as to resolution could be deduced.

III. *m*-Carboxybenzylacetone or  $\omega$ -Acetonyl-*m*-toluic Acid,  $CH_3 \cdot CO \cdot CH_2 \cdot CH_2 \cdot C_6H_4 \cdot CO_2H$ .—On warming with dilute aqueous sodium hydroxide, *m*-carbethoxybenzylacetylacetone or *m*-carbethoxybenzylbutyrylacetone dissolved to a colourless solution from which acids precipitated a white solid soluble in ether. This product, which was also obtained by alkaline hydrolysis of *m*-carb-oxybenzylacetylacetone and *m*-carboxybenzylbutyrylacetone, was identified as *m*-carboxybenzylacetone. It was slightly soluble in water, but dissolved readily in organic media, crystallising therefrom on addition of light petroleum; it also separated from the latter

solvent in lustrous plates, m. p.  $77^{\circ}$  (Found: C, 68.5; H, 6.4.  $C_{11}H_{12}O_3$  requires C, 68.7; H, 6.2%). The equivalent weight by alkalimetry was 194; theory requires 192.

IV. 3-*o*-Carbethoxybenzylacetylacetone,

—*o*-Toluoyl chloride, obtained in practically quantitative yield from *o*-toluic acid and phosphorus trichloride at  $120$ – $170^{\circ}$ , was subjected to a stream of chlorine at  $160$ – $180^{\circ}$  without a catalyst until the calculated increase in weight had been attained. The resulting  $\omega$ -chloro-*o*-toluoyl chloride boiled at  $129$ – $133^{\circ}/12$  mm.

When treated with a slight excess of warm alcohol, this chloride was esterified with loss of hydrogen chloride. The ethyl  $\omega$ -chloro-*o*-toluate was washed with dilute aqueous sodium carbonate, dried, and distilled in small quantities, when the ester boiled at  $139$ – $143^{\circ}/12$  mm.

When larger quantities were distilled, after a portion of the ester had passed over, a solid product collected in the condenser which was identified as phthalide, m. p.  $73^{\circ}$  (Found: C, 71.9; H, 4.6. Calc.: C, 71.6; H, 4.5%).

Ethyl  $\omega$ -chloro-*o*-toluate was condensed with sodium acetylacetone as in the case of the  $\omega$ -chloro-*m*-toluate (p. 1258).

3-*o*-Carbethoxybenzylacetylacetone was obtained by acidifying its grey copper derivative (m. p.  $168$ – $170^{\circ}$ ); it boiled at  $196^{\circ}/14$  mm. and gave a reddish-purple coloration with ferric chloride (Found: C, 68.6; H, 7.1.  $C_{15}H_{18}O_4$  requires C, 68.7; H, 6.9%).

In the distillation of the foregoing diketone, a solid (Found: C, 73.75; H, 5.15%) of higher boiling point came over after the diketone. This product was obtained crystalline by adding petroleum to its benzene solution.

The authors desire to express their thanks to the Birmingham University Research Committee for grants which have helped to defray the expense of this research.

EDGBASTON.

[Received, February 14th, 1926.]

## CLXIV.—A Comparison of the Atomic Weights of Silicon from Different Sources.

By PERCY LUCOCK ROBINSON and HAROLD CECIL SMITH.

RESULTS obtained in a recent redetermination of the atomic weight of boron (Briscoe and Robinson, J., 1925, 127, 696) indicated that the value varies slightly with the source of supply. The values

10.818, 10.825, and 10.841 found for Asiatic, Tuscan, and Californian material respectively were tentatively explained as due to variation in the isotope ratio. This paper reviewed the evidence and stated the conclusion that, despite excellent work supporting the opposite contention, there was no inherent improbability in this suggestion. It is to be deplored that much of the earlier work on atomic weights has been on material of unspecified origin, as this makes the discrepancies valueless for statistical investigation. The necessity for further work on boron being obvious, the problem was attacked by comparing the densities of boric oxide from these and other sources. The results of this investigation supported the original conclusion (Briscoe, Robinson, and Stephenson, this vol., p. 70).

Late in 1924, Jaeger and Dijkstra (*Proc. K. Akad. Wetensch. Amsterdam*, 1924, 27, 290; *Z. anorg. Chem.*, 1925, 143, 233) showed that the densities of tetraethylsilane indicated no difference in the atomic weight of silicon exceeding 0.019 unit, which corresponds to a density difference of 0.00010 unit—a remarkable degree of accuracy for the pycnometer method employed. The inconclusive character of these results (see Briscoe and Robinson, *Nature*, 1926, 117, 377) led us to proceed with the redetermination of the atomic weight of silicon projected early in 1924 for the reasons given below.

A brief comparison of the geological occurrence of boron and silicon is appropriate here. Boron is widely distributed and forms about 0.001% of the earth's crust (Clarke and Washington, *Proc. Nat. Acad. Sci.*, 1922, 8, 108). It is found primarily in tourmaline and datolite, from which it is liberated and subsequently concentrated, principally as calcium salts, by the drying up of lakes as in the Asiatic and American deposits, or artificially separated from the steam of fumaroles as at Volterra. Clearly, in each case the boron has been associated for a considerable period with the area in which it is found. Silicon, next to oxygen the most abundant element, occurs terrestrially to the extent of 25.80% (Clarke, "Data of Geochemistry," 1920, 30). The transportation of siliceous material is almost entirely by mechanical means and then only over short distances, which makes it probable that silicon has remained associated with the continental mass on which it is found for considerable geological periods. This would appear to be the case even if Wegener's displacement theory should eventually be substantiated. Thus boron and silicon, for different reasons, have probably retained for great periods of time their general relationship to that area of the earth's surface on which they are found.

Silicon presents certain well-known general chemical similarities

to boron, and, occurring as it does in three isotopic forms, Si = 28, 29, 30 (Aston, *Phil. Mag.*, 1920, 40, 628: Si = 30; confirmed, *Nature*, 1924, 114, 273), appears to be a suitable element for the further investigation of the constancy of atomic weight.

Determinations of the atomic weight of silicon previous to 1920, fully discussed by Clarke (*Mem. Nat. Acad. Sci.*, 1920, 16, 22), are tabulated below (Table I) together with more recent work, under the three heads: halide: silver ratio, halide: oxide ratio, and vapour density.

TABLE I.

*Halide: Silver Ratios.*

Pelouze, <i>Compt. rend.</i> , 1845, 20, 1047 .....	28.370
Dumas, <i>Annales</i> , 1860, 113, 31 .....	28.077
Schiel, <i>ibid.</i> , 1861, 120, 94 .....	27.945
Baxter, Weatherill, and Holmes (preliminary paper), <i>J. Amer. Chem. Soc.</i> , 1920, 42, 1194 .....	28.111
Baxter, Weatherill, and Scripture, <i>Proc. Amer. Acad. Arts Sci.</i> , 1923, 58, 245 .....	28.063, 28.061
Hönigschmid and Steinheil, <i>Z. anorg. Chem.</i> , 1924, 141, 101...	28.105

*Halide: Oxide Ratios.*

Thorpe and Young, <i>J.</i> , 1877, 51, 576 .....	28.381
Becker and Meyer, <i>Z. anorg. Chem.</i> , 1905, 43, 251 .....	28.231
Meyer, <i>ibid.</i> , 1905, 46, 45 .....	28.231

*Vapour Density.*

Jaquerod and Tourpaian, <i>J. Chim. phys.</i> , 1913, 11, 269 .....	28.496
Germann and Booth, <i>ibid.</i> , 1917, 21, 81 .....	28.306

The only values in this table which merit serious consideration from the point of view of high accuracy, as distinct from mere novelty of method, are the more recent halide: silver results. The hope that the comparatively simple and direct halide: oxide ratio might produce results of high accuracy is evidently not realised, probably on account of the difficulty of dehydrating the oxide. Reinvestigation of the method with the facilities now available might more nearly fulfil anticipations. The vapour density determinations are open to criticism on the lines suggested by Clarke (*loc. cit.*). The halide: silver ratios exhibit considerable variation, 27.945—28.370, although the four more recent values are in agreement to 1 part in 560 parts. They lie—though probably by that chemist's happy accident—on either side of Dumas's figure. There is a considerable discrepancy between Baxter's (*loc. cit.*) 1920 preliminary and 1923 final figures, *viz.*, 1 part in 550 parts. The International Committee (*J. Amer. Chem. Soc.*, 1925, 47, 597) have given 28.06 as the rounded mean in spite of Hönigschmid's (*loc. cit.*) 28.105. Clearly, further investigation is required if the atomic

weight of silicon is to be known to a greater accuracy than about 1 part in 700 parts.

*Outline of the Present Investigation.*

With the element silicon the choice of a suitable compound for equivalent determination is limited to the halides, and of these the tetrachloride is certainly the most convenient. The silicates are indefinite in composition; the organic compounds, while occasionally of suitable stability and constancy of composition, are difficult to analyse with the required precision; and the oxide, into which a number of compounds may readily be converted, presents difficulties which have already been commented upon. Furthermore, the tetrachloride readily lends itself to a comparison of the atomic weights of material from different sources, provided a suitable method can be devised for the determination of its density with sufficient accuracy.

Silicon tetrachloride was prepared by chlorinating ferrosilicon, manufactured from silica, in one case from an unknown source, and in four others from known localities in Canada, the United States of America, Sweden, and France. As no British ferrosilicon of known origin was available, silicon was prepared from a Scottish pegmatite, and this was chlorinated. The sample of unknown origin was used in a purely preliminary manner to establish methods employed in the preparation, handling, and purification of the compound. About equal amounts of the five samples of known origin were prepared and they were individually subjected to a rigorous, but strictly uniform, process of purification. When pure, the density of each was determined by the use of glass floats calibrated as to density with extreme accuracy. The constancy of the molecular volume of the chlorides of the various isotopes being assumed, the apparent atomic weights were thus compared.

*The Preparation of Silicon Tetrachloride.*

*Sources of Material.*—Of the methods available for preparing silicon tetrachloride, the most convenient for producing it in quantity without using elementary silicon is that involving the chlorination of ferrosilicon, originally described by Warren (*Chem. News*, 1892, 66, 112). Inquiries were therefore instituted into the production of ferrosilicon in various countries. The materials used were selected from samples from Europe and America, the final choice depending on the geographical locality and the geological age of the silica used in the manufacture (Table II). A British sample was thought desirable, and the pegmatite mentioned below was used as a source of elementary silicon.

TABLE II.

*Europe.*

- (a) 91.2% Ferrosilicon, smelted by the Gullspangs Elektrokemiska Aktiebolag, at Gullspang, Sweden, from quartzite obtained at Anenaset, W. of Lake Animmen, Sweden.
- (b) 75% Ferrosilicon, smelted by Keller and Leleux, at Usine de Livet, Isère, from quartzite obtained at Bourg St. Maurice, Haute Savoie, France.
- (c) Pegmatite from a vein 4.5 miles W. of Strontian, Scotland.

*America.*

- (a) 50% Ferrosilicon, smelted by the Southern Ferro Alloys Company, Chattanooga, Tenn., from silica obtained from the sandstone cap of Lookout Mountain, Alabama, U.S.A.
- (b) 90% Ferrosilicon, smelted by the Union Carbide and Carbon Products Company, Niagara Falls, from quartzite obtained at Killarney, Ontario, Canada.

The authors wish to record their grateful thanks to these and other firms and individuals in various parts of the world who have made this investigation possible by so courteously placing material and information at their disposal.

*Preparation of Silicon Tetrachloride from Ferrosilicon.*—Warren's method (*loc. cit.*) was subsequently elaborated by Martin (J., 1914, 105, 2836), but preliminary experiments showed that these complications were largely unnecessary in the present case. Chlorination of the ferrosilicon was carried out in iron tubes 3 ft. by 1.5 in. which were dried by twice heating to redness in a combustion furnace and cooling with dry air passing through them. After a run they were thoroughly washed and redried, but the majority of the tubes were perforated after two, and none lasted beyond three, chlorinations. Ferrosilicon as a coarse powder retained on a 40-mesh sieve was found to be most suitable. This was obtained by crushing the material in a Weatherhead mill; it was then dried, at 110°, in charges of 200—300 g. immediately before being put into the tubes. The iron tube was heated by a silica-tube resistance furnace. Chlorine from a cylinder was led through two sulphuric acid wash-bottles, past a T-piece manometer dipping 8 inches into frequently renewed sulphuric acid, to the reaction tube. The products were led through an adapter into a clean dry receiving bottle, cooled in a freezing mixture and fitted with an exit tube leading to a ventilator shaft. A rapid stream of chlorine was passed through the heated tube, and after 25 minutes the production of silicon tetrachloride began, and when the rate of production diminished fresh ferrosilicon was exposed to the action of the gas by rotating the tubes slightly and tapping them. Occasional slight back-pressure, due to ferric chloride, was relieved in this way, but after 2.5—3.5 hours the tubes choked up completely and thus ended the run. About 700 c.c. of crude product were obtained from each source and

hermetically sealed by closing the bottle with a tied-in waxed cork.

*Preparation of Silicon Tetrachloride from Pegmatite.*—The pegmatite was rich enough in silicon to be treated as an impure specimen of the oxide, and was reduced with aluminium in the presence of sulphur (Holleman, *Proc. K. Akad. Wetensch. Amsterdam*, 1904, 1, 189; Kuhne, D.R.-P. 147871). 200 G. of finely ground mineral were very thoroughly mixed with aluminium powder (200 g.) and flowers of sulphur (250 g.), charged into a No. 6 Battersea crucible, covered with a layer of sulphur, and fired by means of magnesium ribbon set in a primer of magnesium powder and barium peroxide. Immediately following the reaction, the hot crucible was plunged into water, the aluminium sulphide being thus decomposed, leaving nodules of crystalline silicon. These were washed, dried, crushed, and finely ground in a Weatherhead mill, and this powder was treated with concentrated hydrochloric acid, when there was a marked evolution of gas and a smell suggestive of a silicide. The wash-acid was heated to boiling, cooled, diluted with water and filtered through a Buchner funnel with the aid of a pump. The resulting moist mass was digested with 1 : 2 hydrochloric acid for some time, again filtered, well washed in the funnel, and dried at 110°. 300 G. of silicon as a fine, dark grey powder were obtained from nine reductions.

About 30 g. of this material were placed in a clean dry Jena glass tube of 0.75 in. bore and chlorinated as described for ferro-silicon. The silicon glowed during the chlorination and a small quantity of white residue remained. About 700 c.c. of product were obtained and bottled as before.

*Rough Fractionation of Crude Silicon Tetrachloride.*—This step was introduced to rid the crude product of most of its chlorine and all its solid impurities. The cork of the bottle containing the crude material was replaced by a waxed cork, provided with a short wide delivery tube, which was already connected by means of rubber to a specially constructed fractionating column, 2 ft. long, filled with glass beads. The bottle was carefully heated by a water-bath, and a small head fraction carrying most of the chlorine was allowed to go entirely to waste. A head fraction of about 70 c.c. was now collected in a small bottle cooled in a freezing mixture and, as the last third of this fraction ran colourless, it was concluded that the bulk of the chlorine had been removed. A main fraction of about 600 c.c. was then collected in a dry litre bottle, containing 40 c.c. of pure mercury: it was stoppered as previously described. A slight flouring of the mercury in the case of each main fraction indicated that a trace of chlorine was still

present. The tail fractions subsequently yielded specimens of the hexachloride (b. p.  $141.5^{\circ}$ ), and a fraction of higher boiling point that could not be driven up the column, which was, presumably, the octachloride. The amounts of higher chlorides found were less than those obtained by Martin (*loc. cit.*) in his carefully regulated chlorinations.

#### *Purification of Silicon Tetrachloride.*

The importance of a rigorous purification need hardly be stressed. The crude material possibly contained :

Chlorine .....	b.p. $-34^{\circ}$	Disilicon hexachloride .....	b.p. $145^{\circ}$
Hydrochloric acid .....	$-83$	Trisilicon octachloride .....	212
Phosphorus trichloride .....	76	Antimony trichloride .....	226
Arsenic trichloride .....	130		

Silicon dioxide and its hydrates are probably only very slightly volatile in the vapour of silicon tetrachloride.

Of these compounds, only phosphorus trichloride was likely to persist, but it has a boiling point  $16.5^{\circ}$  above that of silicon tetrachloride. The methods available for purifying the liquid were fractional crystallisation and distillation, and contact with mercury and sodium. Fractional crystallisation was originally part of the scheme, but, unfortunately, became impossible by reason of the increased difficulties experienced in obtaining supplies of liquid air. The means available were thus fractional distillation and prolonged contact with liquid sodium amalgam. They were conducted in the following stages (see Fig. 1, where T, H, and M represent tail, head, and main fractions respectively) :

1. Rough fractionation through a single-column still.
2. Standing for 6 months over mercury, with frequent shakings.
3. Systematic fractional distillation in four stages, conducted in dry air at about atmospheric pressure in an all-glass four-column still.
4. Standing with frequent shakings for upwards of 2 months over sodium amalgam.
5. Fractional distillation into five fractions in a vacuum.
6. Fractional distillation into five fractions in a vacuum.

*Main Fractionation of Silicon Tetrachloride at Atmospheric Pressure.*—This was conducted in a 4-column still (Fig. 2) of Durosil glass similar in principle to that used in the purification of boron trichloride by Briscoe and Robinson (*loc. cit.*). Each piece of the apparatus\* was cleaned with chromic-nitric acid, washed with water, rinsed with pure alcohol, and allowed to drain. The parts

\* Our thanks are due to Mr. G. Ellison of this department for making the individual pieces of glass-ware used in this investigation.

were then assembled and dried by passing dry air in at M and out through  $T_1$  for 3 days, the mercury in the valves sealing the apparatus from outside air. The capillary of the special joint was then sealed, and freshly-made sodium amalgam was filtered into M by means of a long-stemmed funnel. All exit tubes were bent to point downwards, so that any liquid condensing in the phosphorus pentoxide guard-tubes was unable to return to the apparatus.

About 600 c.c. of the roughly-fractionated crude product, after standing over mercury with repeated shaking for 5–6 months, were distilled into  $B_1$ , which was cooled in ice-cold water, leaving

FIG. 2.

behind a tail fraction of 20 c.c. A paper jacket containing solid carbon dioxide kept the base of  $C_1$  cool, while extra mercury which had been poured into  $V_1$  cut off connexion between  $B_1$  and  $B_2$ .  $T_1$  was then sealed off.  $B_1$  was gently warmed with a soft flame, as this method of heating gave steady boiling, and a head fraction of about 50 c.c. was distilled into  $H_1$  which was cooled in solid carbon dioxide. This head fraction was sealed off, mercury was run from  $V_1$  to establish connexion with  $B_2$ , and a main fraction of about 500 c.c. was distilled forward into  $B_2$ , which was cooled in iced water, the base of  $C_2$  being jacketed with solid carbon dioxide. More mercury was poured into  $V_1$  and the tip of  $T_1$  was broken under rubber to connect with a phosphorus pentoxide tube, thus establishing equal pressures at both sides of the valve. A tail of

about 50 c.c. remained in  $B_1$ . Similar head and tail fractions were rejected in distillations from  $B_2$  and  $B_3$ , resulting in 300 c.c. of material in  $B_4$ . The liquid in  $B_4$  was then distilled forward past the thermometer into M (cooled in solid carbon dioxide) where it was sealed up. About 25 c.c. of liquid returned to  $B_4$  on account of column capacity.

To prepare the apparatus for the next distillation the tails and drainings from the columns were distilled from the various boilers by opening the side-tubes  $T_1$ ,  $T_2$ ,  $T_3$ , and  $T_4$ , after which these side-tubes were sealed up and dry air was passed completely through the apparatus for 3 or 4 days with occasional warmings, thus removing the last traces of silicon tetrachloride: the new head-bulbs were then fused on, and the apparatus carefully dried for the next sample.

*The Boiling Point of Silicon Tetrachloride.*—This is a useful criterion of purity, and it was measured with all the accuracy possible under the conditions of the experiment. The thermometer used (range  $10-60^\circ$ ) was subsequently compared with the N. P. L. thermometer mentioned below, and was usually less than  $0.02^\circ$  in error. Temperatures, which remained fairly steady, were taken at short intervals, any fluctuations being traceable to variations in the rate of distillation which caused slight pressure changes in the system. There was absolutely no tendency towards a rise of temperature during the last stages of each distillation. Table III gives the mean boiling point and atmospheric pressure for each sample.

TABLE III.

Sweden .....	$57.10^\circ$	761.6 mm.	France.....	$56.83^\circ$	753.9 mm.
Scotland .....	$56.95$	758.0 mm.	Canada .....	$56.91$	756.0 mm.
U.S.A. ....	$57.12$	763.3 mm.			

This indicates a boiling point between  $57.02^\circ$  and  $57.05^\circ$  at 760 mm., a figure in fair agreement with the  $56.9^\circ$  of Becker and Meyer (*loc. cit.*) and the  $56.8^\circ$  of Stock, Somieski, and Wintgen (*Ber.*, 1917, 50, 1754).

[*Special Note on the French Fraction.*—A few days after distillation the vessel containing the main fraction of the French material from the 4-column still developed an extensive series of cracks round the upper portion near the special joint. Since there was no apparent entry of air into the container, it was painted over with thick collodion varnish, bound with pure rubber tape and finally painted with a viscous solution of pure rubber. After standing for some days, it was joined to a new, clean, dry special-joint container provided with fresh sodium amalgam, the strains between the two vessels being relieved by a number of right-angle

bends in the thin-walled connecting tube. The special joint was then broken, and, with the exception of about 10 c.c., the liquid was poured into the new vessel, the exit tube of which carried a phosphorus pentoxide guard-tube.]

*First Vacuum Distillation of Main Fractions.*—The containers, holding the five main fractions from the 4-column still, were severally sealed to trains (Fig. 3) consisting of a small head-bulb A and

FIG. 3.

FIG. 4.

FIG. 5.

containers, B for the head fraction proper, C provided with a special joint for the main fraction, and D for the tail fraction. The train was evacuated five times while at about  $120^{\circ}$ , being each time slowly filled with dry air, and finally allowed to cool under atmospheric pressure. The silicon tetrachloride was cooled with liquid air to near its freezing point, and the capillary of the special joint was broken with the train at atmospheric pressure though still protected from moisture by the drying train. It was evacuated

and sealed off at E when the manometer registered less than 2 mm. pressure. (In the course of these distillations it was observed that solid silicon tetrachloride at very low pressures retained permanent gas which was disengaged when the solid melted.) A small head fraction of about 10 c.c. was collected in A which was sealed off, and a head fraction of 50 c.c. was distilled into B. A main fraction of about 150 c.c. was collected in C and a tail of about 50 c.c. in D, the amalgam in the original container being left quite dry.

The "hammer" of silicon tetrachloride in a vacuum at temperatures near its freezing point was considerable enough to render cautious handling absolutely necessary.

*Second Vacuum Distillation of Main Fractions.*—This was carried out after fusing to the train the main fraction containers obtained above (Fig. 4). The material was now so pure that head and tail fractions were worth preserving, and thus B and D, in addition to C, had special joints. C was specially constructed with a long neck so that it could be introduced into a water-bath, and before fusing on, into it were placed the two floats to be used subsequently in determining the density of the liquid. Very special precautions were taken in the washing and drying of the whole apparatus before the final evacuation: before the various parts were actually fitted together, each piece was treated with chromic-nitric acid for about 12 hours, well washed with tap water, then with ordinary distilled water, and finally with pure alcohol and ether and left to dry. On the day before assembling, each piece was treated with four large washings of special distilled water, followed by two with pure dry alcohol and two with pure ether. In assembling, the vessels which had to be sealed off during the course of the fractionation were held by clamps lined with asbestos paper—a provision which entirely prevented the sticking of cork and glass by repeated heating.

Each complete train was tested on the pump, and any minute leaks, which occasionally occur in such a high-melting glass as Durosil, were fused up. When finished, the apparatus was heated to about 120°, twice evacuated and slowly filled with dry air, and allowed to stand overnight protected by a new phosphorus pentoxide guard-tube. It was then evacuated six times with heating and slow refilling with dry air, the final evacuation, lasting 30 minutes, being made with the whole of the glass as near 200° as possible, and the manometer recording zero pressure when the apparatus was sealed off from the pump.

In distilling, the procedure was first to cool the whole of A with liquid air, at the same time heating C to 120°, and thus to remove any moisture from the surface of C and deposit it in A. With

these conditions still obtaining, the special joint was broken, and *instantly* a snow of solid silicon tetrachloride covered the surface of A, thus fixing any moisture and retaining it in that part of the apparatus. Further cooling was at once applied, and in about 5 minutes a small head fraction (6—9 c.c.), most of the residual air, and probably all the products of hydrolysis, if any, were removed from the system by sealing off A. This was followed by a head of about 30 c.c. in B, a main of about 60 c.c. in C, and a tail fraction of about 30 c.c. in D, leaving the original vessel dry and with the merest trace of white residue, which was greatest in the French and least in the Scottish sample. During the distillations into A and B the container C was kept warm, and the greater part of most of the distillations took place at below 0° as shown by a coating of ice on the outside of the vessels.

Before introducing them into C, the floats were gently polished with clean, well-washed linen, and a careful record was made of the destination of each float.

#### *The Preparation and Standardisation of the Floats.*

Since no method of density determination which involved exposure to air could be used with silicon tetrachloride, recourse was had to the use of glass floats. This method appeared likely to give results of much greater comparative accuracy than the older means, and actually proved to do so. It involved the preparation of two sets of floats with densities slightly above and slightly below the density of the liquid at the proposed temperature of the measurement; the determination of the relative density of these to the highest degree of accuracy attainable; and finally the observation of the flotation-temperature of pairs of these floats in the various specimens of liquid under examination. Thus, at these two temperatures the density of the liquid was known, and could be calculated very accurately at an intermediate temperature provided the interval was small. The use of two floats gave the necessary information as to the coefficient of thermal expansion of the liquid.

*Construction of Floats.*—Floats were made from thin-walled Durosil glass tubing of about 3 mm. external diameter and were of the form shown in Fig. 5. The barrel was about 12—15 mm. long, and the solid tail, which was about the same length, was in the form of a long taper. The finished floats had a smooth surface without any indentations which might serve as a place of lodgment for small bubbles. Large numbers were made and those for final adjustment were chosen by elimination. The final adjustment of the two sets was made using bromobenzene at constant temperatures

of 22.5° and 29.5°, respectively, and small amounts of glass were added to, or removed from the tails of the floats until their densities very closely approximated to that of the liquid at one of these temperatures. The magnitude of this apparently simple task will be recognised when it is remembered that 1.0° difference in flotation temperature is equivalent to about 0.001 density unit.

These bromobenzene temperatures had been chosen after comparing the flotation-temperatures of three floats in fairly pure silicon tetrachloride and then in the bromobenzene.

*Determination of the Density of the Floats.*—The density of the floats was determined by ascertaining very precisely the flotation-temperature of each float in a liquid, the density of which was afterwards determined at that particular temperature. It was realised that for the present purpose high accuracy in relative density was more important than the absolute value.

The ideal flotation-liquid would be a pure substance stable in air, non-hygroscopic, of comparatively high boiling point and having a density and a coefficient of thermal expansion about those of silicon tetrachloride. Bromobenzene approaches this ideal very closely; its density is 1.494 at 20° (Young, *Journ. de Phys.*, 1909; Perkin, J., 1896, 69, 1202); its coefficient of expansion is very near that of silicon tetrachloride, 1° change in temperature altering the densities to the extent of 0.0010 and 0.0011 unit, respectively, and its boiling point is 156° (Young, *loc. cit.*). The material first used was as supplied by The British Drug Houses, Ltd., since absolute purity seemed to be immaterial, but after it had been in use for some days a redetermination of the flotation-temperatures of three floats indicated that the liquid was changing in density (see Table IV). The liquid was therefore redistilled with the

TABLE IV.

\* Not corrected for exposed stem.

rejection of considerable head and tail fractions. The main fraction gave a very constant boiling point (155.4°/754.1 mm.), and if the distillate was not now chemically pure, it was at least composed of substances not readily separated by the conditions obtaining during the flotation tests. The distilled liquid was exposed to the atmosphere for 7 days, being adequately protected from dust, in order to acquire a normal moisture content. A redetermination

of the flotation-temperatures of Floats C, D, and H indicated that the density of the liquid had changed considerably (Table V).

TABLE V.

Float.	2nd Flotation-temp.*	3rd Flotation-temp.*	Difference.
C	20.765°	25.856°	5.091°
D	20.650	25.736	5.086
H	20.758	25.838	5.080

\* Not corrected for exposed stem.

On November 12th and 13th a complete set of flotation-temperatures was obtained, this being followed by the determination of the density of the liquid, and between November 17th and 20th another complete set was added. The second set showed a fall, varying between 0.007° and 0.020°, increasing with the passage of time throughout the 3 days, indicating a fall in density of the liquid which was attributed to the further absorption of moisture from the atmosphere.

The flotation-vessel was of Durosil glass in the form shown in Fig. 5, the body being about 3.5 cm. by 16 cm., and was about three-quarters filled with liquid. A was a narrow tube normally closed by a rubber cap, while B was a wider opening through which the floats were introduced and removed, and which was closed by a small cork with a groove for the passage of the float-lifter, C. This was made of No. 19 S.W.G. nichrome wire carefully cleaned and polished, and appeared to suffer no attack by the liquid. The spiral at the end served to hold the floats in a vertical position during their passage through B. The floats were handled carefully by means of nickel-plated forceps and were polished by clean, well-washed linen on entering and leaving the liquid. The wire was not lifted farther out of the liquid than was absolutely necessary and was allowed to fall back into its place after use; and, except when changing floats, B was corked and protected from dust by an inverted test-tube D. Thus every endeavour was made to ensure the permanence of the liquid during the period of the flotation-tests.

The temperature of the flotation-liquid was regulated by submerging the vessel in a tank of square cross-section holding about 27 litres of water and having large plate-glass windows at the front and back. The bath was provided with a large, mechanically-driven, propeller-shaped stirrer, an electric heater consisting of a nichrome element inside a vitreosil tube, and a cooling coil consisting of several turns of  $\frac{3}{8}$ -inch "compo" gas-piping connected to the ordinary water supply which, at the particular season of the year in question, was cold enough.

The thermometers used were: (a) Thermometer 1—a special open-scale thermometer reading from  $+9.5^{\circ}$  to  $+25^{\circ}$ , graduated in  $0.02^{\circ}$  and easily read to  $0.005^{\circ}$ ; (b) Beckmann I; (c) Beckmann II. In use, the bulb of each thermometer was about 8 inches below the surface of the water and the portion remaining was surrounded by a jacket containing water in which was a second ordinary thermometer giving the stem temperature. The observed temperature was corrected by means of the usual formula  $s = an(T - t)$  with  $a = 0.000143$  (Thorpe, J., 1880, 37, 160). Thermometers (a) and (b) were set in definite relationship, the permanence of the setting being tested from time to time, and, finally, each of the three thermometers was carefully compared with a  $0^{\circ}$ – $50^{\circ}$  open-scale thermometer, graduated in  $0.02^{\circ}$ , and recently calibrated at the National Physical Laboratory to  $0.01^{\circ}$  at each degree. All temperatures were thus accurately converted from the various arbitrary scales into degrees Centigrade.

Two methods suggested themselves for the purpose of obtaining flotation-temperatures: (a) by maintaining such a temperature that the float remained balanced in the liquid for a considerable period, say 20–30 minutes; (b) by making such slight variations in temperature as would cause the floats to rise or fall, and to take the mean of the last closely-agreeing pair of readings as the flotation-temperature. As some of the temperatures were  $15^{\circ}$  above that of the air in the room, the static method presented considerable difficulties in maintaining a constant temperature and, furthermore, failed to disclose any lag between flotation-liquid and bath temperatures. The second method was, therefore, adopted and was later modified by taking the mean of a number of *rise* and *fall* temperatures, and, by a series of time-temperature readings, ascertaining the rate at which the temperature of the bath varied. No useful purpose would be served in giving in detail all the readings from which the flotation-temperatures were ultimately derived, but a general idea of the accuracy may be obtained from the fact that out of 40 flotation-temperatures, 6 were derived from values  $0.005^{\circ}$  apart, 24 from values  $0.010^{\circ}$  apart, and 9 from values  $0.015^{\circ}$  apart.

The density of the flotation-liquid (bromobenzene) was determined at  $25.655^{\circ}$ ,  $25.666^{\circ}$ ,  $33.213^{\circ}$ , and  $33.210^{\circ}$ , the same pyknometers and method of filling being used as already described in a recent publication (Briscoe, Robinson, and Stephenson, *loc. cit.*), and only the special precautions taken to secure accuracy need be mentioned here. The pyknometer was weighed against a tare with calibrated weights on a No. 7 S.W. Oertling balance with a sensitivity of 21 divisions per mg. The vacuum weight of the

pyknometer was calculated from three separate weighings before, during, and at the conclusion of the determination, and its absolute volume was obtained by duplicate water-fillings at the two temperatures and the use of the value for the specific volume of water (Kaye and Laby, "Physical and Chemical Constants," 1911, p. 22). The liquids were delivered into the pyknometer at as near the correct temperature as possible; then the vessel was held in the bath at about  $0.10^\circ$  below the required temperature for upwards of 30 minutes, after which heat was gently applied and the temperature maintained for about 5 minutes at  $0.01^\circ$  below and then finally raised to the required temperature. In order to eliminate both speculation and observational error the temperature at the latest stage was taken at half-minute intervals and when it had remained fixed for about 4 minutes the setting was made. These temperatures were probably less than  $\pm 0.001^\circ$  in error and their accuracy was far beyond that justified by the precision of the pyknometer setting. The densities (g. per c.c.) of the flotation liquid are in Table VI, where some corresponding values by Perkin (J., 1896, 69, 1202) are given for comparison.

TABLE VI.

<i>t.</i>	<i>d.</i>	<i>d</i> (Perkin).	
25.665°	1.48766	25°/25°	1.4886
33.210	1.47741	30°/30°	1.4841
		35°/35°	1.4798

The flotation-temperatures (corrected for exposed stem) determined before and after the density work are in columns 2 and 3 respectively of Table VII, while in column 4 are the absolute flotation-temperatures derived from column 2 by the application of the calibration correction. The densities of the floats (in g. per c.c.) calculated by assuming a straight-line relationship between density and temperature over the  $7.6^\circ$  range are in column 5.

*The Density of the Five Samples of Pure Silicon Tetrachloride at 20°.*

The flotation-temperatures of the two floats in the various samples gave data for the calculation of the densities of the liquids at 20.000° and their coefficients of expansion over the range 17.1° to 21.7°. In this case again a straight-line relationship was assumed over the 4.6° range.

The peculiar behaviour of the floats in silicon tetrachloride calls for comment, if for no other reason, because of the trouble it gave. The main fractions were removed from the fractionating train almost entirely in the solid condition; on the solid melting, the released floats came to the surface, and when the liquid attained room temperature (18—20°) one in each case went slowly to the bottom: in brief, the floats moved quite normally in the liquid, but with a greater velocity than in the bromobenzene for an equal temperature change on account of difference in viscosity. It was found, however, that movement of the liquid in the vessel, by shaking or even by the tremor set up by a small motor running on the same bench, caused each float to assume a positive electrical charge. These charges have not yet been completely investigated, but they were sufficient at the time to cause the floats to stick so firmly to the side of the vessel that only the most violent shaking could dislodge them, and then only for the moment, for, once released, they immediately stuck fast elsewhere. The charges gradually decreased in magnitude with the passage of time, but they were easily acquired again and evidence up to the present appears to indicate that they are not lost completely after a period of several weeks, though they may be so small as not to affect the movement of the floats.

*The Flotation-Temperatures in Silicon Tetrachloride.*—To avoid any tremor in the liquid the water-bath was fitted up in a room reserved for the purpose: the permanent, wall-side bench carried the bath, with stirrer, etc., while in front of this bench, but not touching it, was a small, absolutely steady, heavy table on which was the retort-stand carrying the container, the body of which was submerged 1.5 to 2 inches below the surface of the water. It was found that when the floats had very little charge they left the side or bottom with extreme readiness when the density was reached, and that once in the centre they could be made to go up and down several times without touching the side, surface, or bottom. When the charge was slightly greater, the floats could be dislodged by giving the retort-stand a smart tap, and when once moving even these floats could be made to go up and down several times before attaching themselves to the sides again. When the behaviour of the floats was worse than this, the container was

removed from the bath and allowed to stand for several days without disturbance. In all, 105 rising and falling temperatures were taken on the ten floats, and concordant repetitions had to be obtained before the values were accepted, but this checking, whilst it ensured absolute satisfaction, was in reality hardly necessary, for, invariably, once a float was moving freely it gave concordant results, whereas the presence of a charge too great to allow of proper freedom was immediately evident. It is probable that these flotation-temperatures in spite of the above difficulty were, by reason of increased experience and the reduced viscosity of the liquid, more accurate than the earlier ones taken in bromobenzene. Table VIII gives these flotation-temperatures in respect of each float, the corresponding density of the liquid at that temperature, and the calculated density at 20·000°.

### Discussion of Results.

*The Densities.*—The densities of silicon tetrachloride above have an extreme variation of 0·000050, and have a mean value of 1·481245. A careful review of the method leads to the belief that these densities have a relative accuracy greater than  $\pm 0·000005$ , but their absolute value is more difficult to assess because it is based on the densities of bromobenzene, and these may possibly deviate as much as  $\pm 0·0002$  from the truth but probably not more than this. Unless the errors in the densities of bromobenzene at the upper and lower temperatures respectively are both in the same direction, their effect will be reduced in the process of computation and the absolute density of the floats is likely to be less than  $\pm 0·0002$  in error, whilst in the same way the calculation used to arrive at the density of the silicon tetrachloride probably further diminishes the error here. Thus the density of silicon tetrachloride under the pressure of its own vapour (*i.e.*, 21 mm., Becker and Meyer, *loc. cit.*; Regnault, *Mem. Acad.*, 1826, 26, 476) at 20·000°  $\pm 0·0005^\circ$  is 1·481245  $\pm 0·00005$ . This figure bears little

relationship to the previous results given below, and the reasonable presumption is that the material used by these workers was of doubtful purity.

*The Coefficients of Thermal Expansion.*—The figures given in Table VIII may obviously be used to calculate the coefficient of thermal expansion of the liquid. There seems to be no *a priori* reason for supposing that a slight difference in the isotope ratio should have any effect on this physical constant; furthermore, this constant is in a measure independent of the density determination, depending as it does upon the temperature interval only and not upon the actual readings giving the interval, and it should therefore afford an excellent check upon the soundness of the method. These coefficients of thermal expansion are given in Table IX, in which, for ease of comparison, the densities also are recorded. The former have an extreme variation of 0.0000080, and a mean value of

Scotland .....	1.481266	+0.000021	0.0014083	-0.0000041
France.....	1.481273	+0.000028	0.0014129	+0.0000005
Mean .....	1.481245	±0.000020	0.0014124	±0.0000022

0.0014124, which has an error probably less than  $\pm 0.0000022$ . This figure is decidedly lower than the previous determinations, 0.001430, due to Pierre (*Ann. Chim. Phys.*, 1851, 33, 241), and 0.001446, due to Thorpe (*Proc. Roy. Soc.*, 1876, 24, 283). Without criticising the methods of the earlier workers, it will suffice to examine briefly the basis of the present determinations, *viz.*, the density and temperature intervals. The density interval depends on the densities of bromobenzene at the two temperatures: the greater the density difference the greater the coefficient of expansion indicated. Reference to p. 1277 will show that the difference in density for the given interval of temperature, 7.545°, is 0.01025 unit, whilst Perkin (*loc. cit.*) found for 10° a difference of only

0.0088 unit. Thus if Perkin's densities had been used the resulting coefficients would have been still lower. Enough has been said about flotation-temperatures to make it clear that considerable confidence may be placed in results based on them. The concordance shown by the results lends additional weight to the suggestion that they should be accepted with complete rejection of the previous data.

As criteria of the accuracy of the densities it is important to note that considerable departure from the mean seems to alternate between density and expansion in each case except in the sample from Scotland. The sample from Sweden shows the best figures. The table indicates that the causes producing the deviations are acting fortuitously, and that the errors are evenly and accidentally distributed. Thus a consideration of either column increases confidence in the other.

*The Relative Atomic Weights.*—Taking 1.481245, the mean density of the various samples, as equivalent to  $\text{Si} = 28.060$ , the atomic weights corresponding to the various densities found are set out in Table X.

TABLE X.

Origin.	Density.	At. wt.	Origin.	Density.	At. wt.
Canada .....	1.481231	28.059	Scotland .....	1.481266	28.062
U.S.A. ....	1.481230	28.059	France .....	1.481273	28.063
Sweden .....	1.481223	28.053	Mean .....	1.481245	28.060

Assuming the relative accuracy of the densities given above, these are capable of indicating changes in the atomic weight of the order of 0.001 unit, and it may reasonably be asked whether they are actually doing so here. The high value found for the French sample may perhaps be explained by the cracking of the container (see p. 1270)—a view which gains support from the observation subsequently made (see p. 1273) that this sample yielded the greatest trace of residue in the second vacuum distillation. Nothing is known against the sample from Scotland, but the considerable deviation of the coefficient of thermal expansion from the mean is probably not without significance. The evidence indicates that no greater variation than 0.005 unit in the atomic weight is to be expected in the samples of silicon under consideration.

*The Use of Floats Generally.*—It has been shown that carefully calibrated floats are capable of giving densities of liquids to a very high degree of accuracy, but it is also clear that the method could be greatly refined now that a knowledge of the technique has been obtained. To just what limit the method could be extended is not yet known. It has the advantage, however, of being applicable to any liquid which does not attack glass or silica, and may

be used to determine the coefficients of expansion and compressibility, and to follow the changes in liquids undergoing treatment in closed vessels.

The authors wish to express their deep indebtedness to Professor Briscoe for the facilities he has afforded and the interest he has constantly taken in this investigation; and they desire to acknowledge a grant from the Department of Scientific and Industrial Research which has enabled one of them (H. C. S.) to take part in this work. They have also to thank Capt. F. P. Mills, of the Northumberland and Durham Rescue Brigade, for kindly supplying the necessary liquid air.

## CLXV.—*The Reactivity of meso-Substituted Anthracenes. Part I.*

By JAMES WILFRED COOK.

It has already been shown (Barnett, Cook, and Grainger, J., 1922, 121, 2060; Barnett, Cook, and Matthews, J., 1923, 123, 1997; Barnett and Cook, J., 1923, 123, 2631; 1924, 125, 1084; Barnett, J., 1925, 127, 2040) that in many cases *meso*-substituents in the anthracene ring system render compounds formed by addition to the "bridge" unstable or incapable of existence. The investigation of 9-benzoylanthracene (anthraphenone) has now shown that the presence of the benzoyl group hinders the formation of additive compounds. Thus with bromine no additive compound could be obtained, the sole product being 10-bromoanthraphenone. With chlorine, a similar result was obtained, although in one instance an additive compound (I) was isolated which, slowly at the ordinary temperature and rapidly on heating, lost both hydrogen chloride and benzoyl chloride and passed into a mixture of 10-chloroanthraphenone (II) and 9-chloroanthracene (III):

This behaviour suggests that the additive compound had the *trans*-configuration, but unfortunately all attempts to repeat the preparation failed, the sole product being 10-chloroanthraphenone.

The action of nitric acid on anthraphenone leads to 10-nitro-

anthraphenone (IV) (compare Lippmann and Keppich, *Ber.*, 1900, **33**, 3086), no additive compound being isolated, but with nitrogen dioxide addition takes place easily and leads to a moderately stable dinitro-compound (V) which readily loses nitrous acid under the influence of cold pyridine and passes into 10-nitroanthraphenone :

The "negative" or unsaturated benzoyl group thus resembles other negative groups in its ability to render *meso*-additive compounds unstable, and this behaviour is in general harmony with the idea of valency developed by Werner. Thus an unsaturated group at position 9 will appropriate some of the free affinity of that carbon atom; the carbon atom at 10 will accordingly have relatively more free affinity, encouraging substitution by addition at 10 rather than by addition to the "bridge." In derivatives of 9:10-dihydroanthracene (VI) the union of each *meso*-carbon atom with two unsaturated benzene nuclei results in a comparatively small amount of affinity being available for holding the other groups. These groups are thus endowed with considerable free affinity and are consequently very reactive. Thus, direct bromination of dihydroanthracene takes place with great ease, and in anthracene dibromide (R = H; X = Y = Br) the bromine atoms are very much more reactive than in a simple aliphatic bromo-compound. The tenacity with which X is held should be decreased by increasing the unsaturated nature of R, since unsaturation in R will lead to this group appropriating more affinity and hence leaving less available for holding X. A phenyl group is more unsaturated in nature than a benzoyl group (Werner, *Ber.*, 1906, **39**, 1278), so that phenylanthracene should give less stable additive compounds than benzoylanthracene. This is in accordance with fact, since, as already stated, benzoylanthracene gives an additive compound with nitrogen dioxide, whereas phenylanthracene does not (Barnett, *loc. cit.*). On the basis of the above argument the more saturated benzylanthracene should show greater capacity for undergoing additive reactions and should yield more stable additive compounds. That this is the case will be shown in a future communication.

The nature of the group R is not, of course, the only factor which influences the stability of these additive compounds. The influence of their geometrical configuration has been shown in the case of the two stereoisomeric 1:5-dichloro-9:10-dihydroanthraquinols (Barnett, Cook, and Matthews, *Rec. trav. chim.*, 1925, **44**, 729) and

the ease with which re-establishment of the "bridge" takes place must also be affected by the affinity which the groups at 9 have for the groups at position 10.

The acyl group in the *meso*-ketones of the anthracene series is less firmly held than is usually the case with aromatic ketones. Thus anthraphenone and its chloro- and bromo-derivatives are completely hydrolysed by brief boiling with sulphuric acid in acetic acid (compare Krollpfeiffer, *Ber.*, 1923, **56**, 2360) and anthroylbenzoic acid exhibits similar instability (Heller, *ibid.*, 1921, **54**, 3627). It has already been shown (Barnett, Cook, and Matthews, *loc. cit.*) that the facile hydrolysis of anthranyl ethers is due to primary addition to the "bridge," and the hydrolysis of the ketones may be due to a similar cause, but rigorous proof is lacking. The fact that hydrogen bromide is liberated during the hydrolysis of bromoanthraphenone cannot be cited as an argument, as 9-bromoanthracene behaves in the same way under similar experimental conditions. This view of the mechanism receives support from the observation that 10-nitroanthraphenone, 10-benzoylanthraphenone and 9:10-dihydroanthraphenone are not hydrolysed by boiling with sulphuric acid in acetic acid. In the first two cases the attachment of an unsaturated group at position 10 may be regarded as diminishing the free affinity of this carbon atom and thus inhibiting 9:10-addition. In the last case addition of this nature is not possible.

Neither anthraphenone nor any of its derivatives shows any signs of visible fluorescence, so that the carbonyl group is presumably a powerful bathoflore.

#### EXPERIMENTAL.

*Anthraphenone.*—The condensation of anthracene with benzoyl chloride in presence of aluminium chloride or zinc dust (Perrier, *Ber.*, 1900, **33**, 816; Lippmann and his co-workers, *ibid.*, 1899, **32**, 2249; 1900, **33**, 3086; 1901, **34**, 2766; Krollpfeiffer, *loc. cit.*) is troublesome to carry out and tarry by-products are formed. Benzoic anhydride was therefore substituted for benzoyl chloride (compare Noller and Adams, *J. Amer. Chem. Soc.*, 1924, **46**, 1889).

To a suspension of finely ground anthracene (90 g.) in carbon disulphide (750 c.c.) was added powdered anhydrous aluminium chloride (150 g.), followed by benzoic anhydride (175 g.\*). Reaction took place with liberation of hydrogen chloride and was brought to completion by 4 hours' heating on the water-bath.

\* If only one molecule of benzoic anhydride is employed there is formed the eutectic mixture of anthraphenone and anthracene, m. p. 158°, described by Lippmann and Keppich (*loc. cit.*) and the anthracene cannot be removed by any simple treatment.

The dark aluminium compound was decomposed with water and hydrochloric acid, the carbon disulphide removed by steam distillation, and the benzoic acid extracted from the residue by treatment with sodium hydroxide solution. After drying, the brown reaction product was treated with boiling glacial acetic acid (750 c.c.). The filtered solution, on cooling, deposited crystals which, recrystallised from benzene and then from acetic acid, yielded 85 g. of pure anthraphenone, m. p. 148°. This developed a fugitive, pure blue coloration in sulphuric acid.

The residue insoluble in acetic acid was recrystallised twice from nitrobenzene (yield, 15 g.), then from pyridine and alcohol, and finally from xylene. It formed a cream-coloured, crystalline powder, m. p. 320°, and gave a purplish-red solution in sulphuric acid (Found : C, 87.0; H, 4.8; *M*, in naphthalene, 401. Calc. for 9 : 10-dibenzoylanthracene : C, 87.0; H, 4.7%; *M*, 386). Lippmann and Fleissner (*Ber.*, 1899, **32**, 2249) obtained this substance as a by-product in the preparation of anthraphenone, but in a later paper (Lippmann and Keppich, *ibid.*, 1900, **33**, 3086) the by-product was described as tribenzoylanthracene. This compound gave anthraquinone on oxidation and this and other properties of the substance indicate that it was really impure dibenzoylanthracene.

9 : 10-Dibenzoylanthracene is obtained in 20% yield when anthraphenone is treated with an excess of benzoic anhydride in presence of anhydrous aluminium chloride. The positions assigned to the benzoyl groups follow from a study of the reduction products (future communication).

**10-Bromoanthraphenone.**—A suspension of anthraphenone (2.5 g.) in carbon disulphide (15 c.c.) was cooled in a freezing mixture, and bromine (0.5 c.c.; 1 mol.), dissolved in carbon disulphide (5 c.c.), was added slowly. Hydrogen bromide was liberated and since the addition of pyridine yielded only pyridine hydrobromide and no quaternary salt it is unlikely that addition of bromine had occurred. The bromo-derivative was obtained by evaporating the solution and crystallising the residue from acetic acid, benzene, and finally ethyl acetate (Found : Br, 22.0.  $C_{21}H_{13}OBr$  requires Br, 22.2%).

**10-Bromoanthraphenone** forms pale yellow nodules, m. p. 175—176°. It gives a deep blue solution in sulphuric acid, the colour being less fugitive than in the case of anthraphenone itself. The same compound is obtained when the bromination is carried out in boiling glacial acetic acid solution. If two molecules of bromine are employed and the boiling is continued for an hour, the bromoanthraphenone is contaminated with 9 : 10-dibromoanthracene, this compound being formed by partial hydrolysis of the bromoanthraphenone and subsequent bromination.

**10-Chloroanthraphenone.**—Anthraphenone (5.6 g.) was added to a solution of chlorine in carbon tetrachloride (20 c.c.; 7.5%, wt.-vol.), the mixture boiled for 15 minutes, cooled, and light petroleum added. The resulting solid crystallised from glacial acetic acid, benzene and finally ethyl acetate in yellow nodules, m. p. 164—165° (Found : Cl, 11.3.  $C_{21}H_{13}OCl$  requires Cl, 11.2%).

**9 : 10-Dichloro-9 : 10-dihydroanthraphenone.**—A solution of anthraphenone (11.4 g.) in carbon tetrachloride (40 c.c.) was cooled in ice, chlorine in carbon tetrachloride solution (40 c.c.) added, the mixture kept in ice for 2 hours, and light petroleum added. The resulting solid crystallised from warm benzene-light petroleum in colourless needles, m. p. 110—111° (decomp.). After being kept in a vacuum desiccator for 2 days, the substance smelled strongly of benzoyl chloride, so the sample for analysis was recrystallised from benzene and light petroleum and dried in a vacuum desiccator for 3½ hours (Found : Cl, 19.8.  $C_{21}H_{14}OCl_2$  requires Cl, 20.1%).

The dichloride (0.5 g.) was suspended in cold pyridine (1 c.c.) and after an hour ether was added and the solid recrystallised from alcohol and ether. It formed colourless needles completely soluble in water, and although analysis showed that the substance was not pure it was evident that both chlorine atoms of the dichloride had suffered displacement by pyridinium groups (Found : Cl, 14.4.  $C_{31}H_{24}ON_2Cl_2$  requires Cl, 13.9%).

**Thermal Decomposition of Anthraphenone Dichloride.**—The dichloride (0.1 g.) was heated to its melting point; hydrogen chloride and benzoyl chloride (identified by its smell) were then liberated. The resulting mixture was fractionally crystallised from alcohol into (a) 10-chloroanthraphenone, identified by the method of mixed melting points, and (b) slender, yellow needles, m. p. 96—98°, which gave solutions having a strong violet fluorescence. The identification was completed by direct comparison with an authentic sample of 9-chloroanthracene.

**10-Nitroanthraphenone.**—Anthraphenone, suspended in acetic acid, was slowly nitrated by nitric acid (1 mol.;  $d$  1.42) in the cold without the production of an additive compound. The reaction was best completed by heating on the water-bath for a few minutes; the nitro-compound was then obtained pure without the elaborate purification recommended by Lippmann and Keppich (*loc. cit.*).

**9 : 10-Dinitro-9 : 10-dihydroanthraphenone.**—A stream of nitrogen dioxide (2.6 g.) prepared by heating a mixture of lead nitrate and sand, was led into a solution of anthraphenone (5.6 g.) in chloroform (10 c.c.), cooled in a freezing mixture; after an hour light petroleum was added. The resinous substance that separated became solid when ground under ether. Thrice recrystallised from chloroform

and light petroleum and dried in a vacuum desiccator, it was obtained in colourless needles, m. p.  $175^{\circ}$  (decomp.) (Found: N, 7.8.  $C_{21}H_{14}O_5N_2$  requires N, 7.5%). Suspended over-night in cold pyridine diluted with alcohol, it lost nitrous acid and passed into 10-nitroanthraphenone (identified by the method of mixed melting points).

*Fission of Anthraphenone Derivatives.*—In order to compare the influence of the substituent in the 10-position the same conditions were employed in all cases. Krollpfeiffer (*loc. cit.*) has shown that if this substituent is hydroxyl, hydrolysis can be effected by boiling with hydrochloric acid in acetic acid, whereas anthraphenone itself is unaffected under these conditions.

10-Chloro-, 10-bromo-, and 10-nitro-anthraphenone were all recovered unchanged after 4 hours' boiling with hydrochloric acid in acetic acid. Chloroanthraphenone was not affected by heating for 5 hours at  $170^{\circ}$  with acetic acid saturated with hydrogen chloride.

Hydrolysis with sulphuric acid was attempted by boiling the substance (1 g.) with acetic acid (10 c.c.) containing sulphuric acid (1 c.c.) for  $\frac{1}{2}$  hour. Krollpfeiffer's observation that anthraphenone is completely decomposed into benzoic acid and anthracene was confirmed. Bromoanthraphenone and chloroanthraphenone gave tarry products (in the former case hydrogen bromide was liberated), whilst 9:10-dihydroanthraphenone, 10-nitroanthraphenone and 9:10-dibenzoylanthracene were recovered unchanged (in the last case after 3 hours' boiling).

The author desires to express his thanks to the Research Fund Committee of the Chemical Society for a grant which has defrayed some of the expenses of this investigation, and to Dr. E. de Barry Barnett for gifts of materials.

## CLXVI.—*The Solubility of Beryllium Oxide in Solutions of its Salts.*

By NEVIL V. SIDGWICK and NEIL B. LEWIS.

AQUEOUS solutions of beryllium salts are known to be able to dissolve considerable quantities of the oxide, a property also possessed, but in a much smaller degree, by salts of iron, aluminium, and some other metals. A concentrated solution of the beryllium

salt of a strong acid continues to dissolve the basic carbonate with brisk effervescence even after the addition of more than one mole of base to each mole of salt present.

With the sulphate, Parsons (*J. Amer. Chem. Soc.*, 1904, **26**, 1433) found that the solubility of the oxide increased with the concentration of the salt, and in strong solution exceeded two moles to one mole of salt. No definite basic salts could be isolated : on dilution the more highly basic solutions gave flocculent precipitates ; on evaporation all left glassy residues with varying ratios of  $\text{Be} : \text{SO}_4$ . The basic sulphates described by Berzelius and others were shown not to be definite compounds. Similar results were obtained with the oxalate (Parsons and Robinson, *ibid.*, 1906, **28**, 555). Parsons, Robinson, and Fuller (*J. Physical Chem.*, 1907, **11**, 651) showed that the f. p. of beryllium sulphate solution is slightly raised by the addition of the oxide, and its conductivity slightly diminished ; they concluded that the basic solutions are not colloidal, since they cannot be separated by dialysis, and are not coagulated by electrolytes. The only suggestion they make to explain the results is that the salt solution acts as a mixed solvent, the oxide dissolving in the salt as camphor dissolves in acetic acid even when it is diluted with water.

Recently Britton (*J.*, 1925, **127**, 2121) has examined electrometrically the effect of adding sodium hydroxide to beryllium sulphate solution. He finds that no precipitation occurs until 1.04 moles of sodium hydroxide have been added for each mole of beryllium sulphate. He concludes that the solution is mainly colloidal, although he admits that it is not coagulated by electrolytes and that it " betrays no sign of colloidality."

We have examined the question by measurements of (1) the solubilities and (2) the viscosities and conductivities of these basic solutions. Parsons's investigation of the system  $\text{BeO}, \text{SO}_4, \text{H}_2\text{O}$  did not extend beyond solutions containing 5%  $\text{BeSO}_4$ , and his results were vitiated, as he admits, by the absence of any definite solid phase. The only such phase appears to be the normal sulphate  $\text{BeSO}_4 \cdot 4\text{H}_2\text{O}$ , and we have therefore determined the effect of addition of the oxide on the solubility of this salt : similar measurements were also made with the selenate and the oxalate. As the existence of an acid oxalate has been asserted and denied, the system  $\text{BeC}_2\text{O}_4, \text{H}_2\text{C}_2\text{O}_4, \text{H}_2\text{O}$  also was examined.

In addition, the conductivities of neutral and basic chloride and oxalate solutions and the viscosities of neutral and basic chloride, oxalate, sulphate, and selenate solutions were measured.

## EXPERIMENTAL.

*Solubility of Beryllium Sulphate.*—The sulphate was purified by recrystallisation from water. The hydroxide, precipitated with ammonia, was dissolved in ammonium carbonate, precipitated as the basic carbonate by passing in a current of steam, washed, and heated for several hours in water through which a current of air was drawn.

Suitable complexes were made by dissolving this basic carbonate in concentrated solutions of the sulphate, boiling to expel carbon dioxide, and filtering. They were rotated in the thermostat at  $25.00^\circ \pm 0.05^\circ$  in rubber-stoppered tubes for periods varying from 20 hours for the more dilute to 200 hours for the most concentrated and viscous solutions, from which the salt crystallised rather slowly. For each analysis two samples were withdrawn through cotton-wool filters into calibrated pipettes, and weighed, giving approximate values of the density. One of these was evaporated to dryness with excess of sulphuric acid and weighed as  $\text{BeSO}_4$  (which is stable up to  $500^\circ$ : Kraus and Gerlach, *Z. anorg. Chem.*, 1924, **140**, 69) or heated in a muffle and weighed as  $\text{BeO}$ . In the other, the  $\text{SO}_4$  was determined with barium chloride. The moist solids obtained by filtration were analysed in the same way. The increasing viscosity made it impossible to measure the complete isotherm. The solid phase was shown by the residue method to be in all cases  $\text{BeSO}_4 \cdot 4\text{H}_2\text{O}$ . As the amount of dissolved beryllium oxide is obtained by difference, and also on account of its very low equivalent weight, the experimental error is necessarily large.

The results are in Table I.

TABLE I.  
Solubility of  $\text{BeSO}_4 \cdot 4\text{H}_2\text{O}$  in presence of  $\text{BeO}$ .

—	36.46	6.10	6.72	0.703	3.81
1.416	37.48	7.73	7.74	0.867	4.19
				Mean	4.14

The solubility of the pure sulphate at  $25^\circ$  was found to be 29.74%, which agrees fairly well with the value, 29.94%, obtained by Britton and Allmand (*J.*, 1921, **119**, 1463).

In the last column is given the molecular ratio of the oxide present to the increase of solubility of the sulphate. It thus appears that 1 molecule of salt dissolves for every 4 molecules of oxide added.

In the analogous case of increasing solubility of lead acetate in the presence of lead oxide (Jackson, *J. Amer. Chem. Soc.*, 1914, **36**, 2346) the results calculated in this way show a much more rapid increase of solubility (about 3 moles of acetate to one of oxide).

To see whether the effect is general, other beryllium salts should be examined. Most of the salts, however, are excessively soluble, and many (*e.g.*, the chloride) crystallise with difficulty, especially in presence of the base. The perchlorate,  $\text{Be}(\text{ClO}_4)_2 \cdot 4\text{H}_2\text{O}$ , was prepared, but its solubility at 25° was found to be 59.5% (anhydrous salt). The *benzenesulphonate* and the *p-toluenesulphonate*, which have not been previously described, were prepared by crystallisation from a solution of the basic carbonate in slightly more than its equivalent of the acid. These salts gave off their water of crystallisation at 100°; decomposition also commenced at that temperature. The salts were recrystallised from water. The *benzenesulphonate* formed small, elongated tablets [Found:  $\text{BeO}$ , 6.3.  $\text{Be}(\text{C}_6\text{H}_5\text{SO}_3)_2 \cdot 4\text{H}_2\text{O}$  requires  $\text{BeO}$ , 6.33%. Solubility at 25° = 53.8% (of anhydrous salt)]. The *p-toluenesulphonate* formed a mass of minute crystals which were only slightly denser than their saturated solution [Found:  $\text{BeO}$ , 5.9.  $\text{Be}(\text{C}_7\text{H}_7\text{SO}_3)_2 \cdot 4\text{H}_2\text{O}$  requires  $\text{BeO}$ , 5.91%. Solubility at 25° = 39.2% (of anhydrous salt)].

The great solubility of these three salts, and the difficulty of estimating the anions accurately, make them unsuitable: the only suitable salts seem to be the selenate and oxalate.

*Solubility of Beryllium Selenate.*—The salt was prepared by dissolving the basic carbonate in a slight excess of selenic acid, made by the oxidation of selenious acid with chloric acid (Meyer and Moldenhauer, *Z. anorg. Chem.*, 1921, **116**, 193), and was twice recrystallised from water. It was free from selenite, and had the composition  $\text{BeSeO}_4 \cdot 4\text{H}_2\text{O}$  (Found:  $\text{BeO}$ , 11.3; Se, 35.4;  $\text{H}_2\text{O}$ , 32.7. Calc.:  $\text{BeO}$ , 11.15; Se, 35.3;  $\text{H}_2\text{O}$ , 32.1%). The selenate was determined by reduction to selenium (Jannasch and Müller, *Ber.*, 1898, **31**, 2388). The salt loses rather more than half its water at 100–105°, and the rest at 300°, at which temperature the anhydrous salt is quite stable.

The solubilities were measured as before. The results at 25° are in Table II, each being the mean of two determinations.

The molecular ratio is the same as with the sulphate, within the limits of experimental error.

TABLE II.

Solubility of  $\text{BeSeO}_4 \cdot 4\text{H}_2\text{O}$  in presence of  $\text{BeO}$ .

Per cent.		Extra $\text{BeSeO}_4$ .	Molecular ratio.

37.05	0.60	0.83	0.098	4.0
38.84	1.98	2.62	0.311	4.5
40.23	2.98	4.01	0.451	4.4
42.11	3.71	5.89	0.536	3.8
				Mean 4.2

*Solubility of Beryllium Oxalate.*—The salt was prepared from the basic carbonate and slightly more than its equivalent of oxalic acid and the measurements were carried out in the same way as before. Parsons and Robinson (*loc. cit.*) state that the slightest excess of base entirely prevents the crystallisation of the oxalate. This was not confirmed, although the crystallisation from the more basic solutions is rather slow, lasting about a day.

The results at  $25^\circ$  are in Table III.

The analysis of the moist solids from experiments 2, 3, and 4 showed the solid phase to be in each case the normal oxalate  $\text{BeC}_2\text{O}_4 \cdot 3\text{H}_2\text{O}$ . In calculating the results in the last column, the small quantity of oxide present in the first experiment was subtracted. The calculated solubility of the pure oxalate at  $25^\circ$  is 27.97%.

The oxalate thus resembles the sulphate and selenate in that its solubility is increased by the addition of the oxide, but the rate of increase is three times as great: 3 molecules of salt for every 4 molecules of oxide added.

In view of the possible formation of complex oxalates, the system was examined on the acid side ( $\text{BeC}_2\text{O}_4 \cdot \text{H}_2\text{C}_2\text{O}_4 \cdot \text{H}_2\text{O}$ ). Rosenheim and Woge (*Z. anorg. Chem.*, 1897, **15**, 283) obtained from a solution containing excess of oxalic acid crystals of the composition

$2\text{BeC}_2\text{O}_4 \cdot \text{H}_2\text{C}_2\text{O}_4 \cdot 5\text{H}_2\text{O}$ . Parsons and Robinson (*loc. cit.*) could not obtain this, but only mixtures of crystals which were recognised under the microscope as those of the normal oxalate and of oxalic acid; they observed that the last traces of oxalic acid were very difficult to remove from the salt by recrystallisation. Wirth (*Z. anorg. Chem.*, 1914, **87**, 7) found the solubility of  $\text{BeC}_2\text{O}_4 \cdot 3\text{H}_2\text{O}$  in water at  $25^\circ$  to be 24.85% (of anhydrous salt), and in *N*/10-oxalic acid 27.75%, from which he concludes that complex acid salts are formed. The former value does not agree with our results, but the latter does, our values for the corresponding solubilities being 27.8% and 27.5%, respectively.

The system  $\text{BeC}_2\text{O}_4 \cdot \text{H}_2\text{C}_2\text{O}_4 \cdot \text{H}_2\text{O}$  was measured at  $25^\circ$  by the methods already described. The complexes were heated until homogeneous, and rotated 18–36 hours in the thermostat to crystallise. The results are in Table IV. Compositions are in weights %.

TABLE IV.

The results are plotted in Fig. 1. The curve AB gives solutions in equilibrium with  $\text{H}_2\text{C}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ ; curve BC those in equilibrium with solids ranging from B' to C' which are obviously mixed crystals of  $\text{BeC}_2\text{O}_4 \cdot 3\text{H}_2\text{O}$  and  $\text{H}_2\text{C}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ . It will thus be seen that there is no evidence for the existence of an acid salt such as that described by Rosenheim and Woge. This mixed crystal formation also explains the difficulty of Parsons and Robinson in removing the last of the oxalic acid impurity from beryllium oxalate by recrystallisation. It is very unusual for a salt to form mixed crystals with its own acid.

*Measurement of Viscosities.*—Concentrated solutions of the sulphate and the selenate were made up from the crystalline salts; those of the chloride and oxalate by dissolving the basic carbonate

in the necessary amount of acid, and determining the composition by analysis. The basic solutions, likewise analysed, were made up in the same way. They were all carefully filtered, and the dilute solutions made up from them by weight. The densities were measured in a pycnometer, and the viscosities in an Ostwald viscometer of period 84.6 seconds with water at 25°. Every value is the mean of two or more concordant results. The values given in Tables V and VI are of the equivalent normality of the salt, and of the relative viscosity (water at 25° = 1).

It will be seen that the increase of viscosity caused by the base in dilute solutions is relatively small, and is little affected by the nature or concentration of the salt. The viscosity of the solution did not change on standing, or on heating to 100° and cooling again, which indicates that the phenomenon is not colloidal.

*Conductivities.*—These were measured in the usual way for neutral and basic chloride and oxalate solutions made up and analysed as above described, the results being given in Tables VII—X. The conductivity of the water ( $1.3$  to  $1.9 \times 10^{-6}$ ) was subtracted. The concentrations are equivalent normalities of salt present; the

conductivities are also equivalent. The fourth column gives the product of the conductivity and the viscosity. Temperature  $25^\circ \pm 0.02^\circ$ . The values for the chloride solutions are in Tables VII and VIII ( $b$  = moles of BeO per mole of salt).

In Fig. 2, the product of equivalent conductivity and viscosity is plotted against the cube root of the concentration, the crosses representing the values of Fricke and Schützdecker (*Z. anorg. Chem.*, 1924, 131, 130) for solutions obtained by double decomposition from beryllium sulphate and barium chloride. It will be seen that the conductivity is less in the basic solutions, but only by about 5%.

The hydrogen-ion concentration in beryllium chloride solutions at  $25^\circ$  has been measured colorimetrically by Mr. W. J. Worboys in this laboratory (results not yet published). He finds this to vary from 1.24% of the salt concentration in  $N/8$ -solution to 3.68% in  $N/512$ . If we assume that the hydrolysis takes place thus:  $\text{BeCl}_2 + \text{H}_2\text{O} = (\text{BeOH})\text{Cl} + \text{HCl}$ , the practical result will be to

+ denotes observations by Fricke & Schützdelier (*loc. cit.*).

increase the conductivity by an amount corresponding to the hydrogen ion present. By subtracting this amount we find the conductivity of the non-hydrolysed solutions (last column in Table VII). As will be seen, this correction brings the values of the neutral very near to those of the basic solutions, except at high dilutions, where even the latter may still be perceptibly hydrolysed.

The corrected conductivities of the solutions of the neutral chloride extrapolate to a value for the mobility at  $25^\circ$  of  $\frac{1}{2}\text{BeCl}_2 = 118.5$ , corresponding to 43 for  $\frac{1}{2}\text{Be}$ . Fricke and Schützdelier (*loc.*

*cit.*) give a value of 30 for the mobility of  $\frac{1}{2}\text{Be}$ . This is based on their values for the conductivities of solutions from 0.05*N* to 0.5*N*; but their correction for hydrolysis is rather uncertain, being founded on a measurement by Wood (J., 1910, 97, 878) of its value (2.2%) at 0.35*N*, from which they calculated the values at greater dilutions.

The values for the oxalate solutions are in Tables IX and X.

The results are plotted in Fig. 3, the crosses representing those of Rosenheim and Woge (*loc. cit.*).

TABLE X.

Conductivities of beryllium oxalate (basic,  $b = 0.974$ ) solutions.

Normality.	$\eta$ .	$\lambda$ .	$\lambda\eta$ .	Normality.	$\eta$ .	$\lambda$ .	$\lambda\eta$ .
0.00574	1.001	16.79	16.81	0.1897	1.052	8.85	9.31
0.01144	1.003	13.93	13.98	0.3397	1.094	8.02	8.78
0.02359	1.007	11.88	11.96	0.6236	1.178	7.60	8.95
0.05392	1.015	10.35	10.51	1.0245	1.307	6.90	9.02
0.1012	1.028	9.53	9.80				

The conductivities of the oxalate are very small, as may be seen by comparing them with those of the sulphate (Ley, *Z. physikal. Chem.*, 1899, 30, 245) at the same dilutions.

Dilution (litres per equiv.) .....	32	128	512
Equiv. cond. of sulphate .....	66.4	88.7	112.6
„ „ of oxalate .....	10.8	15.1	29.8

Further, the equivalent conductivity of the oxalate solution increases at concentrations above about 0.15*N*, which behaviour is probably unprecedented.

*Freezing Points of Oxalate Solutions.*—The depression of freezing point of aqueous solutions of the oxalate was measured in a Beckmann apparatus. The results are

Mole of salt per 1000 g. of water.	$\Delta$ .	Molecular depression.	$i$ .
0.0224	0.048°	2.14°	1.15
0.0532	0.119	2.24	1.20
0.1049	0.220	2.10	1.13
0.1771	0.363	2.05	1.10
0.3665	0.720	1.96	1.05

The values of the van 't Hoff factor  $i$  are, in the stronger solutions, of the same order as those observed by Parsons, Robinson, and Fuller (*loc. cit.*), but at greater dilutions they are considerably lower.

#### *Discussion of Results.*

(1) *Sulphate, Selenate, and Chloride.*—The solubility of beryllium oxide in solutions of its salts may be due to three causes. (1) The salt may make the oxide form a colloidal solution; (2) the oxide may form a basic salt, for example of the univalent ion  $[\text{BeOH}]^+$ , or (3) it may attach itself to one of the ions of the normal salt, in which case, since the property is common to beryllium salts in general, it must combine with the beryllium ion. The first hypothesis, that of colloid formation, has not been entirely disproved. The most basic solutions are somewhat turbid, and although they cannot be separated by dialysis, they may contain some colloidal material. But the whole of the dissolved oxide cannot be in this form. Some of the solutions described above contain more than 2, and they can be prepared with as many as 5 moles of oxide per

litre, a concentration enormously greater than is reached by the colloidal solutions of other metallic hydroxides. Further, the stability of these solutions to the action of heat and of electrolytes is against the view that they are highly concentrated colloids, a view which also fails to explain why the salt is more soluble in presence of the oxide. The bulk of the oxide must be present in some other form. (2) The formation of basic salts of an ion  $[\text{BeOH}]^+$  would not allow of the solution of more than one mole of oxide for every mole of salt, whereas more basic solutions can be prepared. It would also involve an increase of one ion for every molecule of oxide dissolved— $[\text{Be}]A + \text{Be}(\text{OH})_2 = [\text{BeOH}]_2A$ —and hence the addition of oxide should lower the freezing point and probably increase the conductivity, whereas it actually has the opposite effect.

We are therefore left with the third hypothesis, that the oxide combines with the beryllium ion to form a complex kation  $[\text{Be}_x\text{BeO}]^{++}$ . This would account for the small change in conductivity (3—7%, mainly due to the disappearance of hydrolysis), since the number of ions would not alter, but the "beryllated" ion might have a slightly different mobility and degree of ionisation. It is also supported by the slight decrease (about 10%) in the freezing point depression of the sulphate observed by Parsons, Robinson, and Fuller (*loc. cit.*). It explains the increase in the solubility of the salt in presence of the oxide as due to the formation of a new complex salt. If we could assume the solubility of the normal salt to be the same in presence of the complex salt as in water, the molecular ratio of the added oxide to the increased solubility of the salt (4.14 with the sulphate and 4.2 with the selenate) would indicate that the complex ion was  $[\text{Be}_4\text{BeO}]^{++}$ . The accompanying increase of the anion in the basic solution must, however, somewhat diminish the solubility of the normal salt, although we cannot at such high concentrations calculate the magnitude of this effect. Hence the observed ratio of 4.14 or 4.2 must be greater than the average number of BeO molecules attached to a "beryllated" Be ion.

Now there is good evidence that while the covalency of beryllium cannot exceed 4, it has a strong tendency, particularly in the ionised state, to reach this value. Its soluble salts never have more than 4 molecules of water, but seldom fail to attain this number (the case of the oxalate is discussed below). The same tendency of the atom to pass from the ionised to the covalent state is shown by the low conductivity of the fused chloride and the stability of many of its covalent organic compounds (*e.g.*, the non-ionised basic acetate). Its oxide may thus be expected readily

to assume the covalent form  $\text{Be}=\text{O}$ , which could replace the water of crystallisation of the ion :

This replacement will no doubt be incomplete, a series of mixed ions being formed, with the water only partly replaced by  $\text{BeO}$ , so that on the average there will be less than 4  $\text{BeO}$  groups attached to each "beryllated" ion, as we find to be the case.

(2) *Beryllium Oxalate*.—The above hypothesis accounts for the behaviour of basic solutions of the sulphate, selenate, and chloride, and should be applicable to any solution containing beryllium ion : but the behaviour of the oxalate, which increases in solubility by about 3 molecules for every 4 of the oxide added, needs further explanation. This salt is peculiar in many ways. It is unique among the oxalates of bivalent metals in being very soluble in water (nearly 30% at  $25^\circ$ ) : the oxalates of  $\text{Mg}$ ,  $\text{Ca}$ ,  $\text{Sr}$ ,  $\text{Ba}$ ,  $\text{Zn}$ ,  $\text{Cd}$ ,  $\text{Hg}''$ ,  $\text{Sn}''$ ,  $\text{Cr}''$ ,  $\text{Mn}''$ ,  $\text{Fe}''$ ,  $\text{Co}''$ , and  $\text{Ni}$  are all very slightly if at all soluble. It is also almost unique among beryllium salts in not forming a tetrahydrate but only a trihydrate. These facts clearly indicate that it is not a normal oxalate. Further peculiarities which we have found are (1) the conductivity, which even at  $V = 512$  is barely a quarter of that of the sulphate, and at greater concentrations falls to about a sixth, showing that (assuming the ionic mobilities to be about the same) the number of ions formed is only about a quarter of that produced by a normal bi-bivalent salt. (2) The increase of solubility of the salt on addition of oxide is three times as great as with the sulphate or selenate (1 : 1.3 instead of 1 : 4.1). (3) Finally the f. p. experiments show that the number of molecules (including ions) in the solution is not much less than it would be with a normal salt.

The last fact proves that the compound formed cannot have a high molecular weight, and suggests that the ions have combined to form a non-polar molecule :

which is not improbable in view of the strong tendency (already mentioned) of the beryllium ion to pass into the covalent state, and that of the oxalate ion to form a covalent oxalato-ring, as in Werner's optically active  $\text{K}_3[\text{Cr}(\text{C}_2\text{O}_4)_3]$ . On this simple assumption

we should conclude, since the conductivity is reduced to about a quarter, that the solution contains about 3 molecules of oxalato-compound to 1 molecule of salt. The value of  $i$  found by the f. p. method would be  $1 + \frac{1}{4}\alpha$ , if  $\alpha$  is the true degree of dissociation of the salt: the observed values of  $i$  are from 1.2 at 0.05 molar normal to 1.1 at 0.37. This assumption is further supported by the fact that the compound crystallises with 3 molecules of water. The oxalate group is usually monohydrated, both as an ion and in oxalato-compounds: for example, we have  $\text{K}_2\text{C}_2\text{O}_4 \cdot \text{H}_2\text{O}$ ;  $(\text{NH}_4)_2\text{C}_2\text{O}_4 \cdot \text{H}_2\text{O}$ ;  $(\text{NH}_4)_2[\text{Hg}(\text{C}_2\text{O}_4)_2] \cdot 2\text{H}_2\text{O}$ ;  $\text{K}_3$  and  $(\text{NH}_4)_3[\text{Cr}(\text{C}_2\text{O}_4)_3] \cdot 3\text{H}_2\text{O}$ , all salts of kations which are rarely if ever hydrated. Thus one of the  $\text{H}_2\text{O}$  molecules can be attached to the oxalate group. The other two must be joined to the beryllium atom (formula I) if it is to have the stable covalency of 4 which beryllium always attains if possible, and the attainment of which always promotes the formation of covalent links, as in the sodium compound of benzoylacetone (Sidgwick and Brewer, J., 1925, 127, 2383); this when anhydrous is a salt, but it readily takes up two molecules of water and becomes covalent (formula II), as is shown by its then being soluble in hydrocarbons.

A non-polar structure of this kind also makes the formation of solid solutions with oxalic acid less inexplicable.

One peculiarity of the oxalate is unexplained: the large increase (1 : 1.3 instead of 1 : 4.1) of solubility on addition of the oxide. If the latter combines only with the beryllium ion, as it does in the solutions of the strong acid salts, the ratio should be the same in both cases; for on the removal of part of the ions in the "beryllated" form, the equilibrium between the polar and non-polar modifications will be restored. The only explanation would seem to be that the oxide mainly combines with the non-polar form in the ratio 1 : 1 (presumably replacing a molecule of water), but partly also with the ion, as in the sulphate and selenate, thus lowering the ratio of increased solubility to added oxide from 1 : 1 to 1 : 1.3.

The peculiar form of the conductivity curve, which scarcely falls (and if corrected for viscosity, rises) from  $N/5$ - to  $N$ -solution, seems to be without parallel. Since with increasing concentration the molecular conductivity of the true salt must diminish (as it does with all other salts), and likewise presumably the proportion of true salt to non-polar compound, some other reaction must intervene; but it is difficult to see what this is.

Our thanks are due to Messrs. Brunner Mond and Co. for a grant towards the cost of this work, and one of us (N. B. L.) wishes to express his gratitude to the Commissioners of the 1851 Exhibition for a scholarship which made it possible for him to take part in it.

## CLXVII.— $\omega$ -Mono- and Dibromo-derivatives of Quinaldine and Nitroquinaldines and their Products of Hydrolysis.

By DALZIEL LLEWELLYN HAMMICK.

It has been shown (J., 1923, 123, 2882) that quinaldine can readily be brominated to  $\omega$ -tribromoquinaldine, which can be hydrolysed to quinaldinic acid. A similar route to the corresponding  $\alpha$ -aldehyde and alcohol has now been investigated. Unfortunately, quinaldine cannot be selectively brominated to the  $\omega$ -mono- and dibromo-derivatives;  $\omega$ -tribromo-quinaldine, however, can be reduced to the two other  $\omega$ -bromoquinaldines by the action of the calculated quantities of titanous or stannous chloride in alcoholic or acetone solution.  $\omega$ -Dibromoquinaldine can also be obtained in about 60% yield by the action of excess of sodium arsenite on the tribromo-compound in aqueous-alcoholic solution.

Unlike  $\omega$ -tribromoquinaldine, the mono- and dibromo-derivatives cannot be hydrolysed by the action of acids; even oleum acting at 50° for 12 hours is ineffective. Alkalis yield coloured and resinous products. Silver nitrate, however, in aqueous alcohol converts these derivatives quantitatively into the alcohol and aldehyde respectively.

The mononitro-compounds obtained by the direct nitration of quinaldine have been directly brominated to the  $\omega$ -di- and tri-bromo-derivatives. The latter, on hydrolysis, yield nitrocarboxylic acids which give nitroquinolines on fusion; these have been identified as the 5- and 8-nitro-compounds. The orientation of the products of the direct nitration of quinaldine given by Decker and Remfrey (Ber., 1905, 38, 2773) is thus confirmed.

### EXPERIMENTAL.

$\omega$ -Dibromoquinaldine.—A solution of 23.7 g. (2 mols.) of stannous chloride in 100 c.c. of acetone was slowly added, with constant shaking and cooling, to 20 g. (1 mol.) of  $\omega$ -tribromoquinaldine

(*loc. cit.*) in 250 c.c. of acetone. After 1 hour, the acetone was removed, the solution neutralised with chalk and distilled with steam for about 9 hours. The white, crystalline solid in the distillate crystallised from ligroin in colourless needles, m. p.  $120^{\circ}$  (yield 9.0 g.; 60%) (Found: Br, 52.8.  $C_{10}H_7NBr_2$  requires Br, 53.1%).

*Quinoline-2-aldehyde*.—A mixture of  $\omega$ -dibromoquinaldine (8 g.) in 50 c.c. of boiling alcohol with 8.6 g. (2 mols.) of silver nitrate in 10 c.c. of hot water was boiled for 10 minutes and, after addition of hydrochloric acid and filtration, distilled with steam to remove the alcohol. The solution was now neutralised with chalk and again distilled with steam; the oil that slowly solidified in the distillate separated from ligroin in colourless crystals, m. p.  $71^{\circ}$  (yield 4.6 g.; 100%) (Found: N, 8.9. Calc. for  $C_9H_6N\cdot CHO$ : N, 8.0%). The aldehyde gave an oxime, m. p.  $184^{\circ}$ , and a phenylhydrazone, m. p.  $204^{\circ}$  (compare Kaufmann and Vallette, *Ber.*, 1913, 46, 56).

$\omega$ -*Monobromoquinaldine* was prepared exactly as  $\omega$ -dibromoquinaldine, twice the amount of stannous chloride in acetone solution being used. The *monobromoquinaldine* distilled in steam as a readily solidifying oil and crystallised from ligroin in colourless needles, m. p.  $83^{\circ}$  (Found: Br, 36.1.  $C_{10}H_8NBr$  requires Br, 36.0%). The yield was about 50%.

$\omega$ -*Hydroxyquinaldine* was obtained in quantitative yield from  $\omega$ -monobromoquinaldine by the action of the calculated quantity of silver nitrate in alcoholic solution, exactly as in the preparation of quinoline-2-aldehyde (*vide supra*). The *carbinol* is volatile in steam and crystallises from ligroin or alcohol in fine needles, m. p.  $64^{\circ}$  (Found: N, 8.65.  $C_9H_6N\cdot CH_2\cdot OH$  requires N, 8.8%). It is readily oxidised by chromic acid to quinoline-2-aldehyde.

$\omega$ -*Tribromo-8-nitroquinaldine*.—A solution of quinaldine in excess of cold concentrated sulphuric acid was shaken with the calculated quantity of potassium nitrate crystals until these had dissolved. After heating for 20 minutes on the water-bath, the mixture was poured into water and nearly neutralised with sodium hydroxide, whereupon 8-nitroquinaldine separated (compare Doebner and Miller, *Ber.*, 1884, 17, 1700, who added quinaldine nitrate to concentrated sulphuric acid). A solution of 7 g. of the recrystallised nitroquinaldine (m. p.  $130^{\circ}$ ) in 150 c.c. of glacial acetic acid saturated with sodium acetate was slowly treated with 20 g. (3 mols.) of bromine in 50 c.c. of glacial acetic acid. After 20 minutes' heating on the water-bath, the mixture was poured into water; the  $\omega$ -tribromo-8-nitroquinaldine that separated crystallised from alcohol in faintly yellow needles, m. p.  $132^{\circ}$  (yield 100%) (Found: N, 6.5.  $C_{10}H_5O_2N_2Br_3$  requires N, 6.6%).

8-*Nitroquinaldinic Acid*.— $\omega$ -Tribromo-8-nitroquinaldine (10 g.)

was boiled with 20% sulphuric acid for 10 hours; the 8-nitro-quinaldine acid obtained on pouring the mixture into water and partly neutralising it separated from alcohol in almost colourless crystals, m. p.  $182^{\circ}$  (Besthorn and Ibele, *Ber.*, 1906, 39, 2329, give m. p.  $177^{\circ}$ ). The acid on fusion gave 8-nitroquinoline which, recrystallised from ligroin, melted at  $89^{\circ}$  alone or mixed with a pure specimen.

$\omega$ -Dibromo-8-nitroquinaldine was prepared in the same way as  $\omega$ -tribromo-8-nitroquinaldine, except that two molecular proportions of bromine were used instead of three. The compound crystallises from alcohol in pale yellow needles, m. p.  $183^{\circ}$  (Found: N, 7.9.  $C_{10}H_5O_2N_2Br_2$  requires N, 8.1%).

8-Nitroquinoline-2-aldehyde.—Hydrolysis of  $\omega$ -dibromo-8-nitroquinaldine in the usual way with alcoholic silver nitrate gave about 50% yields of 8-nitroquinoline-2-aldehyde, which crystallises from alcohol in golden needles, m. p.  $152^{\circ}$  (Found: N, 13.7.  $C_9H_5O_2N_2 \cdot CHO$  requires N, 13.9%).

$\omega$ -Tribromo-5-nitroquinaldine.—The second nitroquinaldine, m. p.  $82^{\circ}$ , obtained by the direct nitration of quinaldine is described by Doebner and Miller (*loc. cit.*) as the 7-nitro-compound. The bromination of this substance does not proceed so readily or so smoothly as in the cases already described and the products were obtained in poor yield and mixed with much gummy material. A solution of 11 g. of the above nitroquinaldine in glacial acetic acid saturated with sodium acetate was slowly treated with 28 g. (3 mols.) of bromine in 75 c.c. of acetic acid. After heating for an hour on the water-bath, the mixture was poured into water. The gummy mass that separated was extracted with hot alcohol, from which an oil separated on cooling. The oil solidified on keeping and after recrystallisation from ligroin melted at  $93^{\circ}$  (yield 4 g.; 17%) (Found: N, 6.5.  $C_{10}H_5O_2N_2Br_3$  requires N, 6.6%).

This  $\omega$ -tribromonitroquinaldine was boiled for 10 hours with 20% sulphuric acid. The solution on neutralisation gave an acid which was not purified but, after drying, was decarboxylated by fusion; the product, crystallised from ligroin, melted at  $72^{\circ}$  alone or mixed with pure 5-nitroquinoline. Doebner and Miller's "7-nitroquinaldine" is thus shown to be the 5-nitro-derivative, in accordance with the conclusions of Decker and Remfrey (*loc. cit.*).

Acknowledgment is made of a grant from the Chemical Society which has partly defrayed the cost of this investigation.

CLXVIII.—*The Nature of the Alternating Effect in Carbon Chains. Part IV. Some Abnormal Reactions as Evidence of the Incipient Ionisation of Certain Hydrogen Atoms in Hydrocarbon Radicals.*

By ERIC LEIGHTON HOLMES and CHRISTOPHER KELK INGOLD.

HYDROLYTIC reactions have often been utilised to diagnose the relative polarities of atoms in combination, the residue which, after fission, appears in association with hydrogen being regarded as negative in comparison with the other :

Observations are recorded in this paper which show that, in certain circumstances, the direction of fission may be changed by altering the experimental conditions even in cases in which the relative polarity of the atoms at the point of fission is fixed by the presence, according to modern theory, of a real electrical charge on one of them.

In the following formulæ for the sulphonamide group,

the sulphur atom is represented as carrying a double positive charge, and each of the oxygen atoms a single negative one, whilst the nitrogen atom remains neutral. That is to say, the sulphur atom is necessarily positive with respect to the nitrogen atom, and, accordingly, a sulphonamic acid and an amine,  $\text{R} \cdot \text{SO}_2 \cdot \text{OH} + \text{H} \cdot \text{NR}'\text{R}''$ , are the expected products of fission.

*p*-Toluenesulphonbenzylmethylamide (I) behaves in this way on treatment with mineral acids, but with concentrated alkalis it gives products equivalent, as regards state of oxidation, to a sulphinic acid and a hydroxylamine,  $\text{RSO}_2 \cdot \text{H} + \text{HO} \cdot \text{NR}'\text{R}''$ . Two of the products obtained, toluene and sulphurous acid, must almost certainly have been formed from *p*-toluenesulphinic acid, which is known to undergo decomposition into these substances in the presence of strong alkalis; whilst the third, benzyldidenemethylamine, is the expected dehydration product of benzylmethylhydroxylamine. The possibility of its formation from the hydroxylamine under the conditions used was controlled by subjecting the

dibenzylhydroxylamine to the same conditions, when benzylidenebenzylamine was obtained.

Precisely analogous decompositions were observed in the case of *p*-toluenesulphonbenzylamide (II), only in this instance the benzylideneimine was largely hydrolysed to ammonia and benzaldehyde, which underwent further change into benzoic acid (and, probably, benzyl alcohol) under the action of the alkali.

In attempting to account for these remarkable reactions (Type B), we have formed the view that the decomposition with alkali, essentially an attack by negative hydroxyl ions, commences not at the sulphur atom (in spite of its positive polarity), but at a carbon-hydrogen linking in an alkyl group attached to the nitrogen atom.

Owing to the diminished additive power of the ionised double linkings in the sulphonic acid group (they are single linkings from the standpoint of co-valency), we regard the sulphur atom as largely protected from the direct attack of hydroxyl ions by the additive mechanism discussed by Gane and Ingold (this vol., p. 10) in connexion with the alkaline hydrolysis of carboxylic esters. The attack therefore commences, in the above instances, at the  $\text{CH}_2$  group in which, we believe, the hydrogen atoms are in a condition of incipient ionisation, ready to give up their nuclei (but not their electrons) to a hydroxyl ion to form undissociated water (compare Goss and Ingold, J., 1925, 127, 2777). As the extraction of a hydrogen ion from the benzyl group proceeds, a charged unsaturated residue is left, which in rearrangement necessarily gives a Schiff's base and splits off the ion of a sulphinic acid :

The changes here represented as taking place in steps are regarded as being actually continuous and simultaneous. According to this view, the hydroxylamine does not intervene in the formation of the Schiff's base, but the ready dehydration of hydroxylamines to

Schiff's bases under the action of alkali can be explained by a somewhat similar mechanism.

In order to test the view that the attack by hydroxyl ions commences at the benzyl group, the sulphonamides  $C_6H_4Me \cdot SO_2 \cdot NMePh$  (III) and  $C_6H_4Me \cdot SO_2 \cdot NHPh$  (IV) were treated with potash under the same conditions.

In case (III), an opportunity still remains for the suggested mechanism to function if the attack could begin at one of the hydrogen atoms of the methyl group: the initial products would be toluenesulphinic acid and methyleneaniline, and the formation of these would be shown by the identification of toluene, sulphite, formaldehyde, and aniline. However, for reasons indicated below, the extraction of a hydrogen nucleus (ion) from the methyl group would be expected to offer much greater difficulty than its extraction from the benzyl group in examples (I) and (II). Consequently fission of Type (B) should occur only to a small extent or not at all. Actually a reaction of Type (B) can be detected, but the principal change is that which corresponds with Type (A).\*

In case (IV), the mechanism by which reaction (B) has been explained cannot operate at all, and actually there is no evidence of fission to form a sulphinic acid, the observed decomposition being wholly of type (A). The occurrence of reaction (A) in the last two cases and, under the influence of acids (hydrogen ions), in all four cases, we attribute to the direct ionic fission of the sulphur-nitrogen bond, a process which occurs only when more facile modes of decomposition are impossible.

In our opinion, then, the remarkable action of alkalis on the sulphonamides (I) and (II) provides clear evidence of the occurrence of the benzyl hydrogen atoms in a state of incipient ionisation. The cause of this condition we attribute to general polarity (Lewis), the inherent tendency of hydrogen to function as a positive ion (separate as a proton) being augmented by the presence of a group such as phenyl, which is assumed to be capable of drawing electrons towards itself, thus leaving the hydrogen nuclei in a loosely-combined, active state. This condition obtains in all  $\psi$ -acids, and bears on the questions of hydrogen-tautomerism and meta-substitution (next paper). The opposite condition, in which a group, by allowing electrons to be withdrawn from it, increases a pre-existing, inherent tendency for an atom or group (e.g., hydroxyl) to separate as a negative ion, is similarly illustrated in  $\psi$ -bases, mobile hydroxyl tautomerism, and ortho-para-substitution (see next paper). In the first case, the activating group may be said to act as an "electron-

\* Excepting that, of course, *p*-cresol and potassium sulphite are obtained in place of *p*-toluenesulphonic acid.

sink," and in the second as an "electron-source," towards the rest of the molecule :

### EXPERIMENTAL.

(I) *Hydrolysis of p-Toluenesulphonbenzylmethylamide* (I).—The amide (8 g.) was cautiously warmed with moist fused potassium hydroxide (20 g.) during about 0.5 hour, the volatile decomposition products being distilled towards the end of that period. The distillate, on being dried and redistilled, gave two fractions, b. p. 110—120° (a) and b. p. 180—190° (b). Fraction (a) (2.5 g.) had the odour of toluene, on redistillation boiled close to 110° and on nitration yielded 2 : 4-dinitrotoluene (m. p. 71°), which was identified by comparison with an authentic specimen. Fraction (b) (3.75 g.) consisted essentially of benzylidenemethylamine (Found : C, 80.4; H, 7.6. Calc. : C, 80.7; H, 7.0%). On treatment with dilute hydrochloric or nitric acid, an oil separated, which was identified as benzaldehyde by its odour, and semicarbazone (m. p. 224°, which is the correct m. p., not 214° as stated in the literature). The hydrochloric acid solution on evaporation gave methylamine hydrochloride (m. p. 226°; mixed m. p. with genuine specimen 226°. Found : Cl, 52.0. Calc. : Cl, 52.6%), and similarly, the nitric acid solution yielded methylamine nitrate (m. p. 99—101°; mixed m. p. with genuine specimen 99—101°. Found : C, 13.0; H, 7.0. Calc. : C, 12.8; H, 6.7%). An authentic specimen of benzylidenemethylamine prepared as described by Zaunschirm (*Annalen*, 1888, **245**, 281) behaved in the same way. The residual alkali on dilution and acidification evolved sulphur dioxide.

(II) *Hydrolysis of p-Toluenesulphonbenzylamide* (II).—The hydrolysis of 8 g. of this amide was carried out as in the previous case, but a considerable amount of ammonia was evolved. The volatile liquid products were shaken with dilute acid, and the undissolved portion was distilled; 0.9 g. of pure toluene was then obtained. The acid extract deposited benzaldehyde and gave ammonia on being made alkaline, so that the presence of benzalimine in the original distillate may be inferred. The residual alkali was extracted with ether to remove any neutral or basic products (which, however, were absent) and then acidified. The solution was boiled to expel most of the sulphur dioxide and then extracted with ether. The solid residue (1.5 g.) from the ether consisted largely of benzoic acid contaminated by some substance or substances

which instantaneously decolorised permanganate and could only be removed by distillation (b. p. 240—245°/750 mm.) followed by several crystallisations from carbon disulphide and ligroin. (Found: C, 68·6; H, 5·0; *M*, 120. Calc.: C, 68·9; H, 4·9%; *M*, 122). *p*-Cresol was searched for, but could not be detected.

(III) *Hydrolysis of p-Toluenesulphonphenylmethylamide* (III).—This *amide*, m. p. 93°, was prepared by the action of *p*-toluenesulphonyl chloride on a sample of Kahlbaum's methylaniline which qualitative tests showed to contain no trace of a primary base. The hydrolysis of 8 g. was carried out as before, the gas evolved being passed through Schiff's reagent acidified with dilute sulphuric acid, when a permanent red colour was produced. The volatile liquid products were separated into neutral and basic portions. The former was small in amount, had the odour of toluene, and yielded a solid which was identified as unchanged *amide*. The basic portion (2·9 g.) had b. p. 185—190°, and gave the qualitative reactions both of a primary and of a secondary base, and both aniline and methylaniline were identified as their *p*-toluenesulphonyl derivatives (Hinsberg's method of separation). The alkaline residue on acidification evolved sulphur dioxide, and extraction with ether yielded a dark oil which slowly deposited a small quantity of crystals, m. p. 190—200° (0·1 g.). After crystallising twice from water, these yielded prisms, m. p. 210°, which were identified as *p*-hydroxybenzoic acid by analysis (Found: C, 60·5; H, 5·0. Calc.: C, 60·8; H, 4·4%) and comparison with a genuine specimen. The oil from which the crystals separated was distilled (b. p. 190—195°) and was identified as *p*-cresol by conversion into its benzoyl derivative. *p*-Hydroxybenzoic acid is known (Barth, *Annalen*, 1870, 154, 359) to be formed by the action of potassium hydroxide on *p*-cresol.

(IV) *Hydrolysis of p-Toluenesulphonanilide* (IV).—This *amide* (8 g., m. p. 99°) was treated as in the previous cases and the products were separated similarly. The volatile portion of the hydrolysis products (3·7 g.) consisted of aniline, whilst the alkaline residue yielded *p*-cresol (3·0 g.) and *p*-hydroxybenzoic acid (0·1 g.).

(V) *Action of Potassium Hydroxide on Dibenzylhydroxylamine*.—Dibenzylhydroxylamine (5 g.), prepared as described by Schramm (*Ber.*, 1883, 16, 2104), was treated in the usual way, and the volatile products were isolated by distillation at 5 mm. Redistilled at 2 mm., these gave a small fraction (*a*) boiling up to 160°, and a main fraction (*b*), b. p. 160°. Fraction (*b*) consisted of benzylidenebenzylamine (Found: C, 85·8; H, 7·2. Calc.: C, 86·1; H, 6·7%), since on treatment with dilute hydrochloric acid it gave benzaldehyde (identified as its semicarbazone) and benzylamine (identified as hydrochloride). Fraction (*a*), although too small to purify, must

have contained much of the same azomethine, since the same amine and aldehyde were obtained from it.

We wish to thank the Chemical Society for a grant, with the aid of which part of the cost of this research has been met.

THE UNIVERSITY, LEEDS.

CLXIX.—*The Nature of the Alternating Effect in Carbon Chains. Part V. A Discussion of Aromatic Substitution with Special Reference to the Respective Rôles of Polar and Non-polar Dissociation ; and a further Study of the Relative Directive Efficiencies of Oxygen and Nitrogen.*

By CHRISTOPHER KELK INGOLD and EDITH HILDA INGOLD.

THE preceding parts of this series describe a partial examination of the theories of the alternating polarisation of atoms (A), and of the alternating affinity content of valencies (B), as applied to aromatic substitution :

The criterion adopted was that, according to the first view, the more electronegative atoms of the series N, O, F, should produce the larger effects ( $F > O > N$ ), whilst, according to the second, the reverse should hold, the most "unsaturated" atom being the most potent ( $N > O > F$ ).

In Part III, a comparison of benzylamines and benzyl ethers was recorded, from which it was concluded that nitrogen is more effective than oxygen, which appeared to agree with theory (B). Observations have since been made, however, which show that even this theory is not adequate without extension, and that special factors must enter into the problem of the orientation of substances in which the "key-atom" is separated from the nucleus by a chain of one or more carbon atoms. It is therefore necessary to examine the application of other considerations. Nevertheless, the general conclusion previously reached with regard to the directive efficiencies of oxygen and nitrogen accords with that to which the present experiments on the nitration of derivatives of *o*-aminophenol have led.\*

The results of these experiments are represented in the following

\* The case of O versus F is dealt with in the following paper.

formulae, in which the figures connote material accounted for in units per cent. of the theoretical :

It will be clear from these data that whether we disregard *o*-substitution as possibly subject to special influences and consider only substitution in positions 4 and 5, or whether we accept the total *op*-direction by each group as the best measure of its efficiency, the group containing nitrogen is the more effective, for (except in case II, in which the total recovery is not very satisfactory) more than 50% of the material was accounted for as the 5-nitro-derivative. Strictly speaking, these conclusions apply only to the cases dealt with, but it seems likely that they will hold fairly generally in the simpler analogous cases. Possible abnormality arising from indirect substitution *via* the amino-hydrogen atom is controlled by case (III), the results of which differ little from those of (I), and the differing effects of alkyl and acyl groups in modifying the directive efficiency of an oxygen or nitrogen atom are partly controlled by example (II). In any case, other data show that the distribution of alkyl and acyl groups in examples (I) and (III) is such as would handicap the nitrogen atom.

The depressing effect of acyl as compared with alkyl groups on *op*-directive power may be illustrated by the 4-nitration of acetyl-guaiacol,

and is of importance in connexion with Smedley's formula for the carboxyl group (J., 1909, 95, 231), a modernised interpretation of which would involve the recognition of a betaine-like phase,\* the bond joining the oxygen atoms being an electrovalency. In the carboxylamide group, the nitrogen atom will necessarily constitute the positive end of the betaine linking, and thus forms arise which (on any theory, and by analogy also) would be expected to diminish the tendency towards *op*-substitution :

\* Or a condition corresponding with partial conversion into such a phase.

The low value found by Sugden (J., 1924, **125**, 1185) for the parachor of the group  $\text{CO}_2$  in carboxylic esters would then be attributed to shrinkage arising from electrostatic attraction.

The above results, whilst they appear inconsistent with the idea of alternating polar charges (A), agree either with Flürscheim's theory of alternating affinity content (B), or with Robinson's theory (*Chem. and Ind.*, 1925, **44**, 456) of *op*-substitution by electronic displacement in conjugated systems (C).<sup>\*</sup> This theory leads to much the same key-efficiency series as Flürscheim's, if residual affinity be interpreted as an indication of the presence of loosely held, active electrons. The arrows represent the assumed electron displacements originating in a latent valency:

It will be obvious that the distribution of forces here involved is qualitatively the same as that in Flürscheim's theory, the completed change (C) corresponding with his figure for *op*-substitution:

In applying these suggestive ideas to the cases of substitution previously described, we would regard the above formulæ as expressing only the direction of imaginary gross changes which actually do not at any time proceed to more than a limited (in some cases an exceedingly small) extent. This interpretation is placed upon the formulæ partly to cover the case of direction by methyl, which, we assume, has not electrons available for a complete co-valency change (even a momentary one), and is expressed by a slight change of symbolism ( $C_1$ ),<sup>†</sup> the dotted arrows representing electronic strain:

<sup>\*</sup> Since the above was written, a fuller statement has become available (this vol., p. 401).

<sup>†</sup> In this formula, and those which follow,  $\delta+$  and  $\delta-$  are used to signify small fractions of a unit charge;  $n$  represents neutrality, and the signs  $+$  and  $-$  connote unit charges.

It may then be supposed that the *incipient* negative polarisation of the *o*- and *p*-carbon atoms (in different electromeric phases) would be sufficient to attract the positive end of an *incipiently* ionised molecule (*e.g.*, nitric acid or chlorine).<sup>\*</sup> This corresponds with Flürscheim's theory of molecular addition at a point by *residual* (not real) valencies, and may be termed the "directive process." This having occurred, the tendency for hydrogen to unite as a *positive ion* (compare Part IV) with, for instance, hydroxyl or chlorine acting as a negative one, would lead to reaction in a four-cycle † (the "subsequent change") with the unit electron displacements shown, and without the necessity for any further electronic displacement in the benzene system itself :

The case of *m*-substitution is regarded as an effect produced by groups which tend to withdraw electrons from the nucleus (*loc. cit.*). Combining this suggestion with the evidence, discussed in Part IV, of incipiently ionised hydrogen in combination with carbon, and of its extraction in the form of a true ion by the hydroxyl ion, the view may be expressed (formula C<sub>2</sub>) that the meta-hydrogen atom in these cases reaches a state of incipient ionisation, owing to a pull on the electrons involved in its linking with the nucleus. The meta-carbon remains approximately neutral, and the attack of an incipiently ionised reagent therefore begins at the positively polarised hydrogen atom : ‡

<sup>\*</sup> Since ortho- versus para-substitution is not now under consideration, the operation of direct exchange with the *p*-position is disregarded to abbreviate description.

† Or, a third molecule might enter into the reaction, giving a six-cycle.

‡ The assumption of a less direct type of activation preceding *m*-substitution is consistent with the generally smaller velocities of these reactions as compared with *op*-substitutions.

Formula  $C_3$  corresponds with the direction of negative ions to the *op*-positions (Robinson, *loc. cit.*) and need not be expanded, since the "subsequent change" may pursue different paths (leading to the same goal) according as the ionisation of the reagent is incipient, or actual \* (hydrolysis of *p*-chloronitrobenzene).†

In applying these three principal directive effects, we bear in mind that they can determine only the (reversible) *initial attraction* of the reagent, and that the substitution cannot ensue unless the conditions necessary for the "subsequent change" are present. An essential condition in cases  $C_1$  and  $C_2$  is that the displaced atom should be one (*e.g.*, hydrogen) which tends to function as a *positive* ion, and can be extracted from the molecule as a positive ion under the conditions employed. Similarly, in  $C_3$  the "subsequent change" can occur only if the expelled atom is one (*e.g.*, chlorine) which tends to function as a *negative* ion and is capable of being removed in this form by the reagent used. The importance of these auxiliary conditions may be illustrated by the fact that, neglecting them,  $C_3$  necessitates that nitrobenzene and nitric acid should yield *p*-nitrophenol and nitrous acid, and many similar absurdities.

Taking count of "general" electronic restraint, subsidiary directive effects may be perceived which need not be stated. It has also to be remembered that the dissociation of a reagent into *neutral* atoms, or radicals, may lead to substitution in positions determined by the consideration that those neutral atoms (*e.g.*, Cl) which have to *gain* electrons to form their stable ions will seek out negative centres, and in this respect simulate a *positive* group, and *vice versa*. This may well be the mechanism of chlorination by phosphorus pentachloride, iodine trichloride and aryl iodide di-

\* In this case there can be no reaction in a cycle, and the "subsequent change" may involve a complete reversible conversion into the quinonoid condition.

† Whether a particular group will act as an "electron-source" or "electron sink" (this vol., p. 1307) towards the benzene ring is, in general, determined by the fact that electronic strain can in each case operate only in one way if all octets are to be preserved. Thus -OMe is necessarily a source, and -CH<sub>2</sub>O necessarily a sink so far as principal directive effects are concerned. Also, a fluorine atom directly attached to the ring can only act as a source by the mechanism considered, although in saturated chains it should act as a sink, tending towards separation as a negative ion (general polarity). For this reason, when directly joined to the nucleus, it acts as a source only with reluctance, *i.e.*, is only feebly *op*-directing (compare following paper). Direction by methyl and vinyl are special cases which do not appear to be capable of determination *a priori* by generally recognised electronic principles, although *experiment* indicates that each functions as a source in aromatic substitution.

chlorides, each of the two loosely-held chlorine atoms in these compounds being regarded as bound by a single electron (compare Prideaux, *Chem. and Ind.*, 1923, 42, 672) and as in a state of incipient *atomic* dissociation of the following kind : \*

Again, the equation indicates only the direction, and not the extent, of the change (*i.e.*, dissociation) necessary to initiate reaction. Thus it happens that chlorine, although *negative* (0.5 unit charge) in the original group, tends to separate as a *neutral* atom which so desires an electron that it simulates a *positive* group. Thus the apparent anomaly of negative chlorine leaving positive iodine or phosphorus to become attached to negative carbon is explained. On this view, chlorination through the neutral atom can take place in system C<sub>1</sub>, but not in C<sub>2</sub> or C<sub>3</sub>, since only the first contains a negative centre; accordingly, phosphorus pentachloride readily chlorinates anisole in the *p*-position, but has no action on nitrobenzene.

The apparently anomalous introduction of the "negative" hydroxyl group into the *op*-positions of phenols, etc., in electrolytic oxidation is evidently an analogous phenomenon. If the substance oxidised is stable to alkalis (as is usually the case), the hydroxyl *ion* has, of course, no action; but when the anode strips an electron from it, it becomes a neutral free radical with a septet, and hence attacks the incipiently negative carbon atoms of the aromatic compound. Again, mechanism C<sub>1</sub> can function (*op*-substitution) but not C<sub>2</sub> (*m*-substitution), which corresponds precisely with ascertained fact: many electrolytic *op*-oxidations are on record, but, so far as we are aware, no *m*-oxidations.

Sulphuryl chloride may be regarded as having two electromeric forms, the stable one containing two semipolar double bonds (X), and the other only one semipolar double bond and two semipolar single bonds (Y). It is the latter which contains the labile chlorine, and it would be this form rather than the first which is concerned in chlorination by sulphuryl chloride. The action of this reagent is therefore not anomalous (compare Flürscheim, *Chem. and Ind.*,

\* The small electrical conductivity of phosphorus pentachloride in nitrobenzene (Holroyd, Chadwick, and Mitchell, J., 1925, 127, 2492) appears to favour this view, as against the ionic structure  $(\text{PCl}_4)^+\text{Cl}^-$ . The bonds by which the labile chlorine atoms are held might be termed "semi-polar single bonds" and written  $\rightarrow$  to avoid the use of signs such as  $\frac{1}{2}+$  and  $\frac{1}{2}-$ .

1925, 44, 172, 427; Robinson, *ibid.*, p. 259); it is another instance of attack by a neutral radical:

Thus, in conformity with the two known kinds of dissociation of co-valency compounds, it is suggested that both polar and non-polar dissociation may be concerned in aromatic substitution, the main determining condition being the electronic constitution of the reagent. This view, we think, interprets the data more consistently than is possible by means either of a purely ionic or of a purely non-ionic conception; it is advanced, however, mainly to facilitate discussion, for it is clear that the main principles, even if true, must be held as subject to possible modifications arising from other influences.

#### EXPERIMENTAL.

##### (I) Nitration of Aceto-*o*-anisidide.

Mulhauser (*Annalen*, 1899, 207, 242) nitrated aceto-*o*-anisidide and obtained a mononitro-derivative, m. p. 143°. Meldola, Woolcott, and Wray (*J.*, 1896, 69, 1330) found m. p. 145–146°, and suggested that it was the 5-nitro-derivative (for numbering, see Formula I, p. 1311) but did not prove this orientation. The Fabrik de Produits Chimique de Thann et de Mulhause (D.R.-P. 98637) stated that the substance was in reality a mixture of two isomerides, m. p. 153° and 131–132° respectively. We find that, whilst the first of these is a pure compound, identical with 5-nitroaceto-*o*-anisidide synthesised by Vermeulen (*Rec. trav. chim.*, 1905, 25, 12), the second is a mixture containing, besides the 5-nitro-compound, its 4-nitro-isomeride, m. p. 174–175°. Small quantities of the 3-nitro-compound, m. p. 158–159°, and, probably, of the 6-nitro-compound, m. p. 103–104°, are also produced in the nitration. The 4-nitro-compound was synthesised by Meldola, Woolcott, and Wray (*loc. cit.*) and by Vermeulen (*loc. cit.*). The properties of the 3- and 6-nitro-derivatives and their orientation are described below.

*Qualitative Separations.*—(I) A well-cooled solution of 1.5 c.c. of nitric acid (*d* 1.5) in 5 c.c. of acetic anhydride was added to the paste obtained by cooling a solution of 5 g. of acetanisidide in 10 c.c. of acetic anhydride to 0°. Heat was generated, but the temperature was not allowed to rise above 45°. The mixture was kept at the ordinary temperature for 24 hours and, after addition of water,

shaken to destroy acetic anhydride. The solid product (6.0 g.) was subjected to about 20 fractional crystallisations from absolute alcohol, which yielded the following apparently pure substances, here named in the order of their appearance: (a) large, stout, prisms, m. p. 153—154° (2.0 g.); (b) long, silky needles, m. p. 173.5—175° (0.1 g.); (c) rosettes of small needles, m. p. 129—131° (0.5 g.). By direct comparison (a) was shown to be 5-nitroaceto-*o*-anisidide, and (b) 4-nitroaceto-*o*-anisidide. The crystals (c) we assume to be identical with the product, m. p. 131—132°, described in D.R.-P. 98637, but direct comparison showed that it was neither 3-, 4-, 5-, nor 6-nitroaceto-*o*-anisidide. It had the correct composition (Found: C, 51.7; H, 4.9.  $C_9H_{10}O_4N_2$  requires C, 51.4; H, 4.8%), and, since its m. p. was depressed by the addition of the 3- and 6-nitro-compounds and raised by the addition of either the 4- or the 5-derivative, we regard it as a difficultly separable mixture of the last two isomerides. After hydrolysis of the acetyl group, the corresponding free bases can be separated in the pure condition, the 5-derivative being isolated in larger quantity than the 4-isomeride.

(II) Another experiment using 40 g. of aceto-*o*-anisidide was carried out in the same way, excepting that the most soluble fractions obtained after a rough separation were combined with the product isolated by neutralising the dilute acetic acid solution and extraction with ether, and fractionally crystallised as completely as possible. Fractions identical with (a) and (c) were obtained, and also a very small amount of a substance, m. p. 99—103°, which did not depress the m. p. (103—104°) of synthetic 6-nitroaceto-*o*-anisidide, but was insufficient for analysis.

Further experiments did not lead to the isolation of the 3-isomeride, although the presence of this was proved indirectly.

*3-Nitroaceto-o-anisidide*.—3-Nitro-*ON*-diacetyl-*o*-aminophenol (see below) (0.5 g.) was treated at 30—40° with 2 c.c. of cold 2*N*-sodium hydroxide and the deep red solution was shaken with successive small quantities of methyl sulphate, additional alkali being added as it became necessary. When the red colour had given place to lemon-yellow, the precipitate was collected and crystallised from alcohol; pale yellow needles, m. p. 158—159°, were then obtained (Found: C, 51.7; H, 4.8.  $C_9H_{10}O_4N_2$  requires C, 51.4; H, 4.8%). The m. p. of this substance was depressed 20° to 60° by the addition of its isomerides, 4-, 5-, and 6-nitroaceto-*o*-anisidide. Since the 4-, 5-, and 6-compounds were all synthesised by methods which showed their constitutions, the orientation of the 3-derivative follows. It was confirmed by conversion of the substance into 3-nitroguaiacol by boiling for 36 hours with 2*N*-sodium hydroxide

and acidifying the resulting solution. This guaiacol was not synthesised for comparison, but the specimen obtained had the m. p. (60—61°) and properties recorded in the literature, and had the large volatility with steam characteristic of *o*-nitrophenols (see below). The base, 3-nitro-*o*-anisidine, was obtained by heating the acetyl derivative for 30 minutes with 20% hydrochloric acid on the steam-bath and extracting the product with ether from the solution basified with ammonia. The same base was obtained along with 3-nitroguaiacol when the acetyl compound was boiled for 6 hours with 2*N*-aqueous sodium hydroxide. It separated from alcohol in bright scarlet needles, m. p. 75—76° (Found: C, 50.0; H, 4.8.  $C_7H_8O_3N_2$  requires C, 50.0; H, 4.8%).

4-Nitroaceto-*o*-anisidide.—This was prepared by Meldola, Woolcott, and Wray's method (*loc. cit.*). It had m. p. 174—175°, and the corresponding free base, m. p. 117—118°. On boiling either the base or its acetyl derivative for 30 hours with 2*N*-aqueous sodium hydroxide under the conditions in which the 3- and 5-isomerides yield nitroguaiacols, deep-seated decomposition took place, although some unchanged base was recovered. A specimen of 4-nitroguaiacol, m. p. 103—104°, was prepared by the direct nitration of acetylguaiacol (Reverdin and Crepieux, *Ber.*, 1903, 36, 2258; 1906, 39, 4232; Paul, *Ber.*, 1906, 39, 2779) but, even on seeding with a crystal of this, the same compound could not be obtained from the small quantity of acidic tar isolated from the product of hydrolysis. A few crystals, m. p. 80—90°, were obtained, but the amount was insufficient for purification.

5-Nitroaceto-*o*-anisidide.—Vermeulen's method (*loc. cit.*) was used for the preparation of this substance, which was obtained in large, pale yellow, nearly cubical prisms, m. p. 153—154°. On cooling a solution of it in warm concentrated hydrochloric acid, a sandy precipitate was obtained, which on treatment with water turned yellow. Its solution in much boiling water was rendered alkaline with sodium carbonate and cooled; the free base then separated as golden-yellow, flattened needles, m. p. 139—140°. On boiling for 36 hours with 2*N*-aqueous sodium hydroxide, either the acetyl derivative or the base is converted fairly smoothly into 5-nitroguaiacol, which is precipitated on acidification, the filtrate containing a further quantity isolable by extraction with ether. This nitroguaiacol had m. p. 99—100° and depressed the m. p. of 4-nitroguaiacol.

6-Nitroaceto-*o*-anisidide was synthesised from 2 : 6-dinitroanisole by partial reduction and acetylation of the nitro-base. An alcoholic solution of 2 : 6-dinitroanisole was treated for 30 minutes with a rapid stream of hydrogen sulphide. During the first 10 minutes

much heat was developed. Water was added, and the base extracted from the precipitate by digestion with 20% hydrochloric acid, from which it was reprecipitated on addition of ammonia. Having been dried as rapidly as possible, the crude base was repeatedly extracted with boiling ligroin until the extracts failed to crystallise on cooling. 6-Nitro-*o*-anisidine was thus obtained as bright yellow, flattened needles, m. p. 65–66°, a further quantity being recoverable from the ligroin solution. An additional crystallisation from ligroin raised the m. p. to 67° (Found: C, 50.0; H, 4.7.  $C_7H_8O_2N_2$  requires C, 50.0; H, 4.8%). The *acetyl* derivative was obtained by boiling the base for 2 hours with acetic anhydride, and crystallised from methyl alcohol or dilute acetic acid in pale yellow prisms, m. p. 103–104° (Found: C, 51.5; H, 4.8.  $C_9H_{10}O_4N_2$  requires C, 51.4; H, 4.8%). Attempts to convert either of these substances into 6-nitroguaiacol by the method used for the corresponding reaction in the 5-series led to deep-seated decomposition and products from which no crystalline substance could be isolated.

*Attempted Estimation of the Proportions of the Isomerides.*—(i) The nitration of 40 g. of aceto-*o*-anisidide was carried out in acetic anhydride as described above and the product allowed to crystallise over-night, when 9.1 g. of the 5-nitro-compound separated. The acetic anhydride was then removed by desiccation at a low pressure over potassium hydroxide. The residue was fractionally crystallised from alcohol, and a further quantity of 5-nitro-compound (1.5 g.) and some 4-nitro-compound (1.0 g.) were obtained. The weights are those of the fully purified isomerides. The unseparated residue was hydrolysed with hydrochloric acid and the bases were fractionated from alcohol, the 5-nitro-base (3.7 g.) and the 4-nitro-base (0.65 g.) being isolated. The unseparated portions were reacylated and by further crystallisation the 5-nitro-*acetyl* derivative (2.1 g.) and its 4-isomeride (1.4 g.) were obtained. About 1 g. of a mixture remained which was not resolved. The total pure substances isolated corresponded with 68% of 5-nitro-compound and 13% of 4-nitro-compound.

(ii) In a similar experiment to the above, 37% of 5-nitroaceto-*o*-anisidide separated from the acetic anhydride. The residue obtained on complete evaporation was boiled for 36 hours with 10 times its weight of 2*N*-sodium hydroxide, and the resulting solution diluted to dissolve the red, rather sparingly soluble sodium salt of 5-nitroguaiacol, and extracted with ether. The bases thus recovered (2.8 g., and in another similar experiment 3.5 g.) were contaminated with products of deep-seated decomposition, but yielded some crystalline 4-nitroanisidine. On acidification of the alkaline solution 5-nitroguaiacol (11.2 g.), m. p. 96–99°, was obtained, and the

mother-liquors yielded a mixture of guaiacols, which were recovered by extraction with ether and purified and partly separated by distillation in steam. Experiments with artificial mixtures of 3-nitroguaiacol and 5-nitroguaiacol showed that the former passed over completely in the early stages of distillation, but that a small quantity of the latter was present in all fractions. Further experiments to determine the volatility of 5-nitroguaiacol in steam indicated that, under the usual conditions of distillation, the steam reaching the condenser is not quite saturated; but by working under uniform conditions as regards apparatus and rate of distillation a fairly consistent figure of 1.20 g. per litre was obtained and this was regarded as sufficiently accurate in experiments carried out under like conditions. In the distillation of the mixed guaiacols described above, the first 500 c.c. of distillate yielded 1.26 g., m. p. 60–80°, whilst the succeeding 500 c.c. fractions each gave 0.6 g., m. p. 97–100°, so that 0.66 g. of the more volatile 3-nitroguaiacol was assumed to be present in the original mixture. This corresponded with a yield of 1.5%, whilst the total quantity of 5-nitroguaiacol was equivalent to 37% of the theoretical, a further 37% of 5-nitroaceto-*o*-anisidine having been also obtained as described above.

Combining these results, it follows that in the original nitrations the 5-nitro-derivative was formed to the extent of at least 74%, the 4-nitro-compound to the extent of at least 13% and the 3-isomeride to the extent of about 1.5%, a small quantity of the 6-compound probably also being produced. The total yield was 88.5%.

## (II) Nitration of *ON*-Diacetyl-*o*-aminophenol.

The nitration of *ON*-diacetyl-*o*-aminophenol was carried out by Meldola, Woolcott, and Wray (*loc. cit.*), who isolated the 5-nitro-derivative, m. p. 189°, which they definitely oriented. They did not notice the formation of a second isomeride. Our attempts to follow their method yielded either dinitro-compound, or mixtures of unchanged material with mono- and di-nitro-derivatives. On the other hand, treatment with the theoretical quantity of nitric acid in warm acetic anhydride led to smooth mononitration.

**Dinitration.**—A solution of the diacetyl compound (10 g.) in a mixture of 40 c.c. of ordinary concentrated nitric acid and 20 c.c. of fuming acid at –5° was kept for 2 hours at 2–4°, and ice then added. The precipitate, which was collected on the next day, crystallised from boiling water in long, yellow needles, m. p. 202°. Since analysis (Found: C, 40.2; H, 3.2; N, 17.8.  $C_8H_7O_6N_3$  requires C, 39.8; H, 2.9; N, 17.5%) indicated that one acetyl group had been eliminated, and the substance gave an immediate

precipitate of the red potassium salt when treated in alcoholic suspension with cold dilute potassium hydroxide solution, we regard it as 3:5-dinitro-*N*-acetyl-*o*-aminophenol. The compound was not definitely oriented, but the positions of the nitro-groups are inferred from the study of the mononitration of diacetylaminophenol described below.

*Mononitration. Qualitative Separation of Isomerides.*—The paste obtained by cooling a solution of diacetyl-*o*-aminophenol (20 g.) in acetic anhydride (40 g.) to 15° was treated gradually with an ice-cold mixture of 5 c.c. of nitric acid (*d* 1.5) and 20 c.c. of acetic anhydride. The crystals dissolved and the temperature rose rapidly, but was kept from exceeding 35° by external cooling. When self-heating had ceased, the mixture was allowed to cool to the ordinary temperature; a stiff paste of yellow crystals then formed. Several hours later, the acetic anhydride was destroyed by shaking with water, and the solid product, m. p. 140–160°, collected. This was fractionally extracted with boiling alcohol; the less soluble product, m. p. 165–180°, thus obtained, after four crystallisations from alcohol, yielded very characteristic, long, pale yellow needles, resembling glass wool, the m. p., 189°, of which was not further changed by crystallisation. The more soluble fractions were subjected to a prolonged series of fractional crystallisations from alcohol, when stout, pale yellow tablets, m. p. 183°, were obtained. The isolation of these was facilitated by the observation that, after slow crystallisation, they could be partly separated from the filamental needles by shaking and rapidly decanting the mother-liquor, but the process was slow, and after about 40 crystallisations, only 6.0 g. of the needles, m. p. 189°, and 3.1 g. of the tablets, m. p. 183°, had been obtained. Needles, m. p. about 160°, were also obtained, but these appeared to be a difficultly separable mixture of which the needles, m. p. 189°, formed one constituent.

*3-Nitro-ON-diacetyl-o-aminophenol.*—This constitution is assigned to the tablets, m. p. 183° (Found: C, 50.3; H, 4.1.  $C_{10}H_{10}O_5N_2$  requires C, 50.4; H, 4.2%), since the corresponding free phenol is converted by methylation into 3-nitroaceto-*o*-anisidide, the orientation of which is described above. 3-Nitro-*o*-acetylaminophenol was formed as its sodium salt when the acetyl compound (0.5 g.) was treated with 2 c.c. of 2*N*-aqueous sodium hydroxide. The temperature rose to 40° and the solid dissolved, but the deep red solution did not crystallise. The phenol was precipitated on acidification and crystallised from hot water in orange-yellow needles, m. p. 169°.

*4-Nitro-ON-diacetyl-o-aminophenol.*—4-Nitro-*o*-aminophenol (3 g., obtained by reduction of 2:4-dinitrophenol with hydrogen sulphide)

was boiled with acetic anhydride (4.5 g.) and acetic acid (2 g.) for 2 hours. The excess of acetic acid was removed over potassium hydroxide in an evacuated desiccator, and the solid product drained on porous porcelain and crystallised twice from ethyl alcohol, when needles, m. p. 183—184°, were obtained (Found : C, 50.2; H, 4.2.  $C_{10}H_{10}O_5N_2$  requires C, 50.4; H, 4.2%). 4-Nitro-*o*-acetylaminophenol was prepared as in the preceding series, but it yielded an orange sodium salt which separated from the alkaline solution in rosettes of needles. The free phenol crystallised from alcohol in colourless prisms, m. p. 278° (decomp.) (Found : C, 48.8; H, 4.1.  $C_8H_8O_4N_2$  requires C, 49.0; H, 4.1%).

5-Nitro-ON-diacetyl-*o*-aminophenol.—This structure is assigned to the filamental needles, m. p. 189°, obtained by nitration, since the corresponding phenol on methylation gave 5-nitroaceto-*o*-aniside. 5-Nitro-*o*-acetylaminophenol was prepared as in the last case. Crimson needles separated from the alkaline solution, which, on addition of water and acid, yielded the phenol. After crystallisation from ethyl alcohol, this was obtained in small, yellow prisms, m. p. 269° (decomp.) (Found : C, 48.8; H, 4.1.  $C_8H_8O_4N_2$  requires C, 49.0; H, 4.0%).

*Attempted Estimation of the Proportions of 3- and 5-Nitro-derivatives.*—The nitration of diacetylaminophenol (40 g.) was carried out as described above, and the acetic anhydride removed in a vacuum, without separation of the part of the nitration product which crystallised spontaneously, since this was a mixture of isomerides. The solid residue was mixed with 120 c.c. of water and 180 c.c. of 4*N*-aqueous potassium hydroxide, the temperature being kept below 35°. When the decomposition (elimination of the *O*-acetyl group) was completed, the deep red liquid was acidified and the precipitated phenols were collected; a small additional quantity of solid was obtained by extracting the mother-liquor with ether. The whole solid was then mixed with 100 c.c. of 2*N*-potassium hydroxide and shaken at 25—35° with 10 c.c. of methyl sulphate. The methylation was almost complete in an hour, and was finished with the aid of small additional amounts of methyl sulphate and alkali. The precipitated solid was washed with water, boiled for 36 hours with 400 c.c. of 2*N*-aqueous potassium hydroxide (ammonia ceased to be evolved after the first 24 hours), and the cooled product extracted with ether to remove unchanged bases, and basic tars (7.0 g.). After the dissolved ether had been removed in a current of air, the solution was acidified. The mixed guaiacols thus precipitated were kept in contact with the mother-liquor for 24 hours to become thoroughly crystalline, and then collected, the dissolved portions being isolated by extraction with ether (total 25 g.). They

were separated and estimated by steam distillation, as described in the previous example. In this case, owing to the relatively large proportion in which it was present, the *O*-compound crystallised (5.8 g.) in a pure form (orange needles, m. p. 60—61°) from the first 2 l. of distillate. A further 2.2 g. was estimated to be present in solution in the first 3 l. of distillate, by extracting it with pure ether and correcting for the volatility in steam of the *p*-compound with which it was contaminated. Of this 2.2 g., about 1.1 g. were separated in the pure condition by fractional crystallisation from water. The distillate following the first 3 l. contained only the *p*-compound which, without crystallisation, melted at 96—99° and, after crystallisation, at 99—100°. These yields correspond with 23% of 3-nitrodiacetylaminophenol and 48% of the 5-nitro-compound. No solid product could be isolated from the tarry basic fraction, so the quantity of 4- and 6-derivatives formed is left undetermined.

### (III) Nitration of *N*-Methylaceto-*o*-Anisidide.

*N*-Methyl-*o*-anisidine was prepared by methylating the formyl derivative of *o*-anisidine and, after hydrolysis of the formyl group, was isolated by means of the nitrosoamine, which was reduced to the secondary base as described by Diepolder (*Ber.*, 1899, 32, 3515).

*N*-Methylaceto-*o*-anisidide was prepared by boiling the base for 2 hours with a slight excess of acetic anhydride and distilling the product. The fraction, b. p. 158—160°, set on cooling to a mass of large, inclined prisms, m. p. 46—50°, which, after crystallisation from ether-ligroin, melted at 51—53° (Found: C, 67.4; H, 7.3.  $C_{10}H_{13}O_2N$  requires C, 67.0; H, 7.3%).

*Mononitration: Isolation of 5-Nitro-, 4-Nitro-, and 3- or 6-Nitro-derivatives.*—A cooled mixture of fuming nitric acid (2.5 c.c.) and acetic anhydride (12 c.c.) was added to *N*-methylaceto-*o*-anisidide (10 g.) dissolved in acetic anhydride (24 c.c.), the temperature being kept below 35°. Two methods of isolating the crude nitration product were employed. (i) The solution was poured into water, shaken to decompose the acetic anhydride, and made alkaline with sodium carbonate. Any solid which separated was collected, and the filtrate extracted with ether. The extract was dried with calcium chloride and reduced by evaporation to a small bulk, the crystals being separated fractionally. (ii) The acetic anhydride was removed by evaporation in a vacuum over potassium hydroxide.

Methylaceto-*o*-anisidide (20 g.) on nitration, followed by treatment in accordance with method (i), yielded 12.5 g. of a crystalline solid, m. p. 117—119°, which on crystallisation from ether formed

pale yellow prisms, m. p. 119—120.5°. This was shown to be 5-nitro-*N*-methylaceto-*o*-anisidide by direct comparison with a specimen synthesised as described below (Found : C, 53.8; H, 5.4.  $C_{10}H_{12}O_4N_2$  requires C, 53.6; H, 5.4%).

On evaporating the ethereal extract to small bulk, very pale yellow prisms, m. p. 120—125°, which depressed the m. p. of the 5-nitro-compound, separated (0.9 g.). On crystallisation from benzene-ligroin the m. p. was raised to 126.5—127.5°. This substance was identified as 4-nitro-*N*-methylaceto-*o*-anisidide by comparison with a specimen synthesised as described below (Found : C, 53.8; H, 5.4; N, 12.7.  $C_{10}H_{12}O_4N_2$  requires C, 53.6; H, 5.4; N, 12.5%).

The ethereal solution from which this had separated, on cooling to -15°, deposited crystals (1.6 g.), m. p. 98—99°, from which 0.65 g. of pure 5-nitro-compound was separated by fractional crystallisation. The second substance present in this fraction could not be definitely identified.

On long standing, the residual ethereal solution deposited large, colourless prisms, m. p. 103—105°, which after crystallisation from ether melted at 105—106° (0.08 g.). This m. p. was not changed by further crystallisation (Found : C, 53.6; H, 5.3.  $C_{10}H_{12}O_4N_2$  requires C, 53.6; H, 5.4%). We believe this substance to be 3-nitro-*N*-methylaceto-*o*-anisidide, which is certainly formed in the nitration (see below), but there is no definite proof that it is not the 6-nitro-isomeride. A further quantity of these crystals (0.16 g.) separated after a few weeks, but the remainder of the nitration product refused to crystallise. The compound, m. p. 105—106°, yielded on hydrolysis a base melting at about the ordinary temperature, but the quantity obtained was too small for purification. In another nitration carried out as far as possible under similar conditions, none of the above nitro-compound was isolated, only the 4-derivative, m. p. 126.5—127.5°, being obtained on cooling the ethereal solution to -20°.

Preliminary experiments having shown that 5-nitro-*N*-methylaceto-*o*-anisidide only slowly evolves methylamine on boiling with 2*N*-alkali, but that this reaction occurs at 120° in sealed tubes (although not so smoothly as the analogous reaction described previously), the presence of 3-nitro-*N*-methylaceto-*o*-anisidide was proved by the following experiment. *N*-Methylaceto-*o*-anisidide (7.3 g.) was nitrated in the usual way, and the product treated in accordance with method (ii). The crude product (8.7 g.; theory 9.0 g.) having partly crystallised (4.3 g. of the 5-nitro-derivative), a portion (3.4 g.) of the mechanically separated oil was heated with 30 c.c. of 2*N*-aqueous potassium hydroxide for 12.5 hours at 120°.

After extraction of the basic portion \* (1.0 g.) with ether, the solution was acidified and the guaiacols (1.8 g.) were extracted. Fractional distillation in steam indicated the presence of 0.29 g. of 3-nitroguaiacol, and a small portion of this was obtained from the early fractions of the steam distillate; after crystallisation from water, it was identified by comparison and a mixed m. p. determination with the specimen obtained as described previously.

*5-Nitro-N-methyl-o-anisidine*.—The acetyl derivative (above) (0.9 g.) was heated with concentrated hydrochloric acid for 1.5 hours on the steam-bath, and the reaction completed by boiling for 45 minutes. Neutralisation with ammonia precipitated the base, which separated from methyl alcohol or light petroleum in long, bright yellow, flattened needles, m. p. 101–102°. It was identified as 5-nitro-*N*-methyl-*o*-anisidine by comparison with a specimen prepared by synthesis (below) (Found: C, 52.6; H, 5.4.  $C_8H_{10}O_3N$  requires C, 52.7; H, 5.5%).

*4-Nitro-N-methyl-o-anisidine*.—Prepared in the same way from its acetyl derivative (above), this base separated from light petroleum in orange, hair-like crystals, m. p. 87°, which were identified by comparison with a synthesised specimen (below) (Found: C, 52.6; H, 5.5.  $C_8H_{10}O_3N_2$  requires C, 52.7; H, 5.5%).

*Synthesis of 5-Nitro-N-methyl-o-anisidine*.—5-Nitroanisidine (1 g.), methyl iodide (0.9 g.), and methyl alcohol (2 c.c.) were heated together for 1.5 hours at 100° in a sealed tube. The alcohol was then evaporated, and dilute potassium hydroxide was added to precipitate the bases which, after partial purification with chloroform, yielded the secondary base on crystallisation from dilute methyl alcohol and from light petroleum.

*Synthesis of 4-Nitro-N-methylaceto-o-anisidine and 4-Nitro-NN-dimethyl-o-anisidine, 4-Nitro-N-methyl-o-anisidine, and 4-Nitro-3(or 5)-methylaceto-o-anisidine*.—4-Nitroanisidine (6 g.), methyl iodide (5.4 g.), and methyl alcohol (12 c.c.) were heated for 2 hours at 100°, and the mixture of bases was isolated, as in the previous preparation. Many attempts were made to separate these by fractional crystallisation, but without success, and the mixture was therefore heated with acetic anhydride for 45 hours. After the excess of this reagent had been evaporated, water was added and the mixture made alkaline with sodium carbonate and extracted with ether, the extract

\* As in the two cases previously described, the bases recovered after alkali treatment contained products of some more complex change than the mere elimination of an acetyl group from the 4- or 6-nitro-derivative. In this experiment, the basic fraction, even after distillation and attempted acetylation, yielded liquids which could not be crystallised and the nature of which was not revealed by analysis.

being washed with 15% hydrochloric acid. This was intended to remove the tertiary base from the mixture of acetyl compounds of the primary and secondary bases, and in the earlier experiments by this method 4-nitro-*NN*-dimethyl-*o*-anisidine was isolated in this way, the material obtained by basifying the hydrochloric acid solution and extraction with ether setting to a solid mass, which, on crystallisation from ligroin, yielded bright yellow, short needles, m. p. 38—39.5° (Found: C, 54.7; H, 6.0.  $C_9H_{12}O_3N_2$  requires C, 55.1; H, 6.1%).

In certain subsequent experiments, carried out as far as possible under the same conditions, the bases obtained from the hydrochloric acid extract did not solidify immediately, but on keeping for several weeks in an evacuated desiccator, partly crystallised. The crystals thus obtained separated from benzene-ligroin in very pale yellow prisms, m. p. 127—128°, which did not depress the m. p. of the specimen of 4-nitro-*N*-methylaceto-*o*-anisidine obtained by nitration. On hydrolysis with hydrochloric acid, the substance yielded 4-nitro-*N*-methyl-*o*-anisidine, m. p. 87°, which was similarly identified with the base prepared from the 4-nitration product. As an isomeric base, in which the methyl group has apparently migrated to the ring, was also isolated in the course of these experiments (see below), the secondary character of this base, m. p. 87°, was confirmed by the preparation of its *nitrosoamine*, which was precipitated at once when sodium nitrite was added to a solution of the hydrochloride. Crystallised from benzene-ligroin, this compound formed very pale yellow needles, m. p. 119—120° (Found: N, 20.3.  $C_8H_9O_4N_3$  requires N, 19.9%). From these experiments, it must be concluded that 4-nitro-*N*-methylaceto-*o*-anisidine is fairly easily soluble in hydrochloric acid of the strength used. The oil from which the crystals of this compound were obtained set, some weeks later, to a solid mass consisting principally of the tertiary base described above.

The ethereal solution from which the above-mentioned substances were extracted by hydrochloric acid, on evaporation, yielded a solid residue which examination with a lens showed to contain at least two compounds. One of these was easily separated by fractional crystallisation and proved to be the acetyl derivative of the original primary base. The second compound was separated partly by crystallisation and partly mechanically, and, after a final crystallisation from benzene-ligroin, was obtained as pearly plates, m. p. 127—128°. It therefore had the same m. p. as 4-nitro-*N*-methylaceto-*o*-anisidine, but its crystalline form was entirely different, and a mixture of the two compounds melted at about 100°. Analysis showed the new compound to be an isomeride (Found: C, 53.2; H, 5.1; N, 12.2.  $C_{10}H_{12}O_4N_2$  requires C, 53.6; H, 5.4; N, 12.5%),

and it must therefore be 4-nitro-3(or 5)-methylaceto-o-anisidide, a methyl group having wandered to the ring. To confirm this, the compound was boiled with hydrochloric acid for 0.5 hour to eliminate the acetyl group, and the hydrochloride of the base diazotised in the usual way. No precipitate separated, indicating that secondary bases were absent, but on pouring the product into alkaline  $\beta$ -naphthol solution, a deep crimson dye was immediately precipitated.

*Action of Methyl Iodide on 6-Nitro-o-anisidine.*—The base (2.2 g.), methyl iodide (2.0 g.), and methyl alcohol (4.5 c.c.) were heated together, and the products treated as in the methylation of 4-nitro-anisidine. The mixture of acetyl compounds only partly solidified after long keeping. After several crystallisations from ether, colourless prisms were obtained, m. p. 106–107°, which depressed the m. p., 103–104°, of 6-nitroaceto-o-anisidide (Found: C, 52.7; H, 5.2.  $C_8H_{10}O_3N_2$  requires C, 52.7; H, 5.5%). These analytical figures agree moderately well with those required for a nitromethylanisidine, but as the crystals were colourless, whilst the nitromethylanisidines described above are orange or yellow, it seems unlikely that this compound is a nitro-base of the series. Owing to the limited quantity of 6-nitro-o-anisidine available, we were not able to make a more detailed study of its methylation products, or to carry out further experiments with the substance described.

*Attempted Estimation of the Proportions of the Nitration Products.*—

(a) *N*-Methylaceto-o-anisidide (20 g.), nitrated as described above and treated by method (ii), gave 11.8 g. of crystalline 5-nitro-derivative and 12.0 g. of an oily mixture (total 23.8 g.; theory 25.0 g.). A part of the oil (9.3 g.) gave guaiacols consisting, as estimated from fractional distillation in steam, of 3.3 g. of 5-nitro- and 1.0 g. of 3-nitro-guaiacol. A basic oil (2.7 g.) and a neutral tar (1.0 g.) were also obtained.

(b) In another experiment, 20 g. of *N*-methylaceto-o-anisidide yielded 14.0 g. of the 5-nitro-derivative and 0.9 g. of the 4-nitro-derivative, both isolated as such in the pure condition. In another experiment, in which the material was treated by method (i), similar quantities of the 5- and 4-nitro-compounds were isolated, and also 0.24 g. of an isomeride believed to be the 3-nitro-derivative.

Combining these results, 73% of the material is accounted for as follows: 5-nitro-derivative, 64%; 4-nitro-derivative, 4%; 3-nitro-derivative, 5%.

*Addendum.* ON-Diacetyl-*N*-methyl-o-aminophenol.—*N*-Methyl-o-aminophenol, which we found to melt at 88° instead of 80° as recorded in the literature, (44 g.) was boiled for 1 hour with acetic anhydride (70 c.c.), and the product distilled. The fraction, b. p. 160–170°/2 mm., at once solidified to crystals (61 g., m. p. 58–60°) which, after

crystallisation from ether-ligroin, had m. p. 63—64° (Found : C, 64.0; H, 6.2.  $C_{11}H_{13}O_3N$  requires C, 63.8; H, 6.3%).

Originally it was intended to include a study of the nitration of this substance in this investigation, but this project was abandoned when it was found that a considerable amount of oxidation took place under the conditions which had been used for the mononitration of the other three substances.

We wish to thank the Royal Society for a grant with the aid of which part of the expense of this investigation has been met.

# CLXX.—*The Nature of the Alternating Effect in Carbon Chains. Part VI. A Study of the Relative Directive Efficiencies of Oxygen and Fluorine in Aromatic Substitution.*

By ERIC LEIGHTON HOLMES and CHRISTOPHER KELK INGOLD.

IN continuation of the work, described in the preceding part, on the establishment of the sequence  $N > O > F$  for the *op*-directive powers of these atoms in the neutral state and directly attached to the benzene ring, the method previously used for comparing the relative directive efficiencies of nitrogen and oxygen atoms has now been applied to the comparison of oxygen with fluorine. *o*-Fluoroanisole has been nitrated with the results indicated in the following formula :

The methods by which these figures have been determined are fully described in the experimental portion, and it need only be stated here that the 3- and 5-nitro-derivatives were estimated together (2.7%) by taking advantage of the lability of their fluorine towards alkaline reagents, and that the 4-nitro-compound was estimated colorimetrically after reduction, utilising the fact that *p*-anisidine gives a violet coloration with ferric chloride, whilst the *o*-compound does not. The 4-nitro-derivative was isolated as such from the nitration mixture and identified by synthesis, whilst the 6-nitro-compound, which was also synthesised and was a liquid at

the ordinary temperature, was reduced with elimination of fluorine and identified as *o*-anisidine hydrochloride.

From the data given, it is clear that whether we disregard the large amount of *o*-substitution as an effect to which special influences contribute and consider only substitution in positions 4 and 5, or whether we accept the total *op*-direction by each group as the better measure of its directive power, the oxygen atom is the more effective directing agent. So great is the difference that although only one case has been investigated it appears reasonable to infer that the conclusion drawn will hold generally amongst derivatives of *o*-fluorophenol.

The sequence  $N > O > F$  is thus established; and this is the expected sequence, since the electronic grouping of fluorine most closely approaches the internally satisfied condition exemplified in neon (preceding paper).

#### EXPERIMENTAL.

*Preparation of o-Fluoroanisole.*—Some difficulty was experienced in obtaining this substance, but it was ultimately prepared by the action of hydrofluoric acid on the *diazopiperidide* obtained from *o*-anisidine. A solution of 25 g. of *o*-anisidine in 60 c.c. of hydrochloric acid was diazotised below  $0^\circ$  by a solution of 15 g. of sodium nitrite in 50 c.c. of water, the mixture being mechanically stirred. On pouring the product into a solution of potassium hydroxide (30 g.) and piperidine (17 g.) in 150 c.c. of water, an oil was precipitated which rapidly solidified (yield 35–37 g.) and on crystallisation from methyl alcohol yielded lemon-yellow prisms, m. p.  $30^\circ$  (Found: C, 65.0; \* H, 7.6.  $C_{12}H_{17}ON_3$  requires C, 65.8; H, 7.8%).

This *diazopiperidide* (35 g.) was heated for 1 hour on the steam-bath with 150 c.c. of concentrated aqueous hydrofluoric acid. Ice was then added and the mixture poured into an excess of 30% aqueous sodium hydroxide, care being taken to avoid over-heating, since the fluoroanisole is very volatile with steam. The *fluoroanisole* was isolated by distillation in steam and separated from the piperidine contained in the steam-distillate by extraction with ether after acidification. It is a colourless, mobile liquid, b. p.  $154$ – $155^\circ$  (Found: C, 66.6; H, 5.6.  $C_7H_7OF$  requires C, 66.7; H, 5.6%). The average yield was 6% of the theoretical.

*Dinitration.*—In a preliminary experiment in which 1 g. of *o*-fluoroanisole was run through a fine capillary tube into 2 c.c. of

\* A better analysis is, unfortunately, not available; difficulty was experienced in burning the substance owing to the rapidity with which it decomposed.

nitric acid ( $d$  1.5) at  $-10^{\circ}$ , and the product mixed with crushed ice, a solid dinitro-compound was obtained which on crystallisation from ethyl alcohol formed pale yellow needles, m. p.  $86-87^{\circ}$ . Judging from the results of mononitration (below), we believe this to be 4:6-dinitro-2-fluoroanisole, although no special proof of its constitution is here offered (Found: C, 38.7; H, 2.2.  $C_7H_5O_5N_2F$  requires C, 38.9; H, 2.3%).

*Mononitration.*—*o*-Fluoroanisole (6.5 g.), mixed with acetic anhydride (25 g.), was treated at  $0^{\circ}$  with a mixture of fuming nitric acid (2.20 c.c.) and acetic anhydride (9 c.c.). The nitration proceeded smoothly with evolution of heat, and the mixture was kept at the ordinary temperature for 3–4 hours and then poured into water. The oil which separated was collected and diluted with ether, the aqueous solution was extracted with ether, and the combined ethereal solutions were dried and evaporated. The residue, after drying for a short time over potassium hydroxide, was distilled, practically the whole boiling at  $114-116^{\circ}/2$  mm. (Found: C, 49.2; H, 3.4.  $C_7H_6O_3NF$  requires C, 49.1; H, 3.5%).

*3-Nitro- and 5-Nitro-o-fluoroanisole.*—These were estimated together by taking advantage of the lability of their fluorine in the presence of boiling 0.5*N*-aqueous sodium carbonate, or dilute methyl-alcoholic sodium methoxide prepared from 2 g. of sodium and 200 c.c. of methyl alcohol. With the first of these reagents at its boiling point, and with the second at  $60^{\circ}$ , a quantity of fluoride ion corresponding with the decomposition of about 2.5–3.0% of nitrofluoroanisole was liberated rapidly, whilst prolonged treatment produced very little further action. After 3 hours' treatment with boiling sodium carbonate, the liberation of fluoride ion corresponded to 2.7% of decomposed nitrofluoroanisole (average of three concordant determinations) and almost the same figure, 2.8%, was obtained on using sodium methoxide. To ascertain if any correction was needed for the possible decomposition of the 4- and 6-nitro-derivatives, these two substances (see below) were treated for the same period under the same conditions. With 4-nitrofluoroanisole and sodium carbonate, the decomposition was zero (two determinations), and the same result was obtained with sodium ethoxide. Only a small quantity of 6-nitrofluoroanisole was available, but a single determination by the sodium carbonate method indicated the decomposition of 0.2%. From these results it is evident that the 4- and 6-nitro-derivatives do not decompose appreciably under the conditions used. On the other hand, 4-nitrofluoroanisole is decomposed at a measurable velocity at  $85^{\circ}$  by sodium methoxide of the dilution stated above, and, in this connexion, reference may be made to Holleman and Beekman's experiment on the alcoholysis of

*m*-nitrofluorobenzene (*Rec. trav. chim.*, 1904, 23, 235). The mixed 3- and 5-nitroguaiacols were isolated from the above decompositions with sodium, but the quantity was too small for the estimation of their relative proportions by the steam distillation method employed by Ingold and Ingold (preceding paper). A small quantity of pure 5-nitroguaiacol was isolated by taking advantage of the sparing solubility of its potassium salt in 4*N*-aqueous potassium hydroxide.

4-Nitro-*o*-fluoroanisole.—The nitrofluoroanisoles recovered after decomposition of the 3- and 5-derivatives with sodium carbonate formed a mixture which was liquid at the ordinary temperature but, on cooling in an efficient freezing mixture, set to a paste of crystals. These were collected below  $-20^{\circ}$ , and when freed from adhering oil, had m. p.  $47-49^{\circ}$ . By crystallisation from ligroin pale yellow prisms were obtained, m. p.  $52-52.5^{\circ}$ , which were identified by direct comparison and a mixed m. p. determination with a specimen synthesised as described below. The yield accounted for about 10% of the nitration product.

*Synthesis of 4-Nitro-*o*-fluoroanisole.*—4-Nitro-*o*-anisidine (25 g.) prepared from 2:4-dinitrochlorobenzene, *via* 2:4-dinitroanisole, was dissolved in 50 c.c. of boiling 20% hydrochloric acid, and the solution cooled with rapid stirring to ensure fine division of the solid. Diazotisation was effected in the usual way with 11 g. of sodium nitrite, and the mixture poured into a solution of 30 g. of potassium hydroxide and 13 g. of piperidine in 150 c.c. of water with the addition of sufficient ice to maintain the temperature at  $0^{\circ}$ . The oily precipitate soon solidified (yield, 35 g.), and crystallisation from ethyl alcohol gave buff needles, m. p.  $95-96^{\circ}$  (Found: C, 54.5; H, 6.0.  $C_{12}H_{16}O_3N_4$  requires C, 54.2; H, 5.9%). This *diazopiperidide* (35 g.) was warmed on the steam-bath for 1 hour with 175 c.c. of concentrated hydrofluoric acid, the mixture being rapidly stirred at the commencement of the process. After the addition of ice the mixture was poured into 1.5 l. of 30% sodium hydroxide kept at  $0^{\circ}$ , and after complete neutralisation the mixture, which contained a brown precipitate of unknown constitution, was distilled in a current of steam. The nitrofluoroanisole crystallised in the receiver, but it was found convenient to extract it with ether. It melted at  $45-49^{\circ}$  in the crude condition and at  $52-53^{\circ}$  after crystallisation from ligroin (Found: C, 49.3; H, 3.5.  $C_7H_6O_3NF$  requires C, 49.1; H, 3.5%). The yield was 1.3 g., that is, 7% of the theoretical.

On reduction by boiling for 15 minutes with stannous chloride and hydrochloric acid it was converted smoothly into *p*-anisidine, the elimination of fluorine being quantitative. The anisidine thus obtained melted at  $56-57^{\circ}$ , alone and when mixed with a genuine specimen (Found: C, 68.8; H, 7.5. Calc.: C, 68.9; H, 7.4%).

Calc. for  $C_7H_8ONF$ : C, 59.6; H, 5.7%). An application of this reaction is described below.

*Synthesis of 6-Nitro-o-fluoroanisole.*—The silver salt of 2:6-dinitrophenol was boiled with a benzene solution of methyl iodide, and the dinitroanisole so obtained was reduced by hydrogen sulphide in methyl-alcoholic ammonia solution to 6-nitro-*o*-anisidine (yield 35%). The *hydrochloride* of this base separated from hydrochloric acid in clusters of pale yellow needles, m. p. 198°.

The base was converted into its *diazopiperidide* by the method described in the preceding paragraph. The *diazopiperidide*, after draining on porous porcelain, but without further purification, was decomposed with hydrofluoric acid, and the 6-nitro-*o*-fluoroanisole isolated by distillation in steam. After redistillation it was obtained as a pale yellow oil, b. p. 110°/1 mm. (Found: C, 49.6; H, 3.7.  $C_7H_8O_3NF$  requires C, 49.1; H, 3.5%).

On reduction by stannous chloride and hydrochloric acid *o*-anisidine was obtained unaccompanied by any fluoro-base.

*Estimation of the Proportions of 4- and 6-Nitro-o-fluoroanisoles obtained by Nitration.*—The mixture of 4- and 6-nitrofluoroanisoles obtained after decomposition of the 3- and 5-nitro-isomerides by sodium carbonate was reduced with stannous chloride as described above. The yield of distilled bases was 90% of the theoretical, and analysis showed that the whole of the fluorine had been eliminated (Found: C, 69.1; H, 7.2%).

A weighed portion of these mixed bases was treated with hydrochloric acid; *o*-anisidine hydrochloride (m. p. 225°, alone and mixed with an authentic specimen; a mixture with *p*-anisidine hydrochloride, m. p. 215°, melted at 170–180°) was thus obtained. The yield corresponded with 48% of 6-nitrofluoroanisole in the original mixture.

In order to estimate the relative proportions of *o*- and *p*-anisidine in the mixture of these bases, a series of artificial mixtures, in the proportions 20 : 80, 40 : 60, 60 : 40, and 80 : 20, was prepared in the form of 1% solutions in ethyl alcohol. Each of these was tested in turn against a 1% solution of the experimental mixture, equal volumes of the solutions under comparison being added to equal portions of a solution of ferric chloride in similar colorimeter tubes. By comparing the colours, it was found that the proportion of *p*-isomeride in the experimental mixture lay between 20% and 40%. The process was repeated with three more standards, containing 25%, 30%, and 35%, respectively, of *p*-compound. As these tests indicated that the proportion of *p*-isomeride lay between 30% and 35%, an additional standard, containing 32.5% of *p*-anisidine and 67.5% of *o*-anisidine, was made. This agreed as exactly as could be

ascertained with the experimental mixture, both as regards rate of development of the colour and its maximum intensity. The conditions being so adjusted that about 2—4 minutes were required for the colour to reach its maximum intensity, it was found that the rate of development of colour was more sensitive than maximum intensity to changes of composition and served as a better means of comparison. In the final experiments, therefore, all solutions were immersed in the same bath before mixing, and to avoid differences of temperature during the readings the two tubes were surrounded by a metal screen and symmetrically illuminated. The results are believed to be correct to 2%.

On acetylation of the experimental mixture of bases, a mixture of acetyl derivatives was obtained which set at 59°, and admixture with small amounts of either aceto-*o*-anisidide or aceto-*p*-anisidide raised this setting point, whence it appears that the proportion in which the two substances were present in the acetylation product corresponds approximately with the eutectic composition. The following approximate setting points of mixtures of aceto-*o*-anisidide and aceto-*p*-anisidide indicate that the eutectic contains about 31% of the *p*-compound and sets at 60°, and this supplies confirmation of the figure obtained colorimetrically :

Proportion of para- ...	17.3%	21.4%	24.4%	30.6%	35.0%	39.1%
Setting point .....	71°	67.5°	64°	60°	63.5°	67°

These values were determined by the cooling curve method.

We wish to thank the Chemical Society and the Royal Society for grants with the aid of which the expenses of this investigation have been met.

## CLXXI.—*A Method for Determining the Solubility of Sparingly Soluble Substances.*

By STOTHERD MITCHELL.

THE methods available for determining the solubility of sparingly soluble substances are of limited application. Electrical measurements are restricted to electrolytes, and chemical analysis is useful for only a few substances. The optical method now described can, however, be employed more generally.

For this work, an interferometer of the type described by Jamin (*Ann. Chim. Phys.*, 1858, 52, 171) was constructed. Mercury green

light ( $\lambda = 5461$ ) was used throughout as the source of illumination. A special form of double cell was required in which liquids could be circulated through each compartment (Fig. 1). It was cut from a rectangular block of brass (2.5 cm. broad), and was fitted with inlet and outlet tubes of the same metal. The sides were made of the best quality optical glass cemented in position. Both compartments of the cell were first filled with water, and the compensator was adjusted so that the cross wires of the observing telescope coincided with one of the interference bands. When a dilute aqueous solution was gradually allowed to displace the water in one half of the cell, there was a movement of the bands. By means of a fine adjustment on the compensator the same band could be kept on the telescope cross wires.

FIG. 1.

Over the range considered, the compensator readings increased in proportion to the number of bands displaced, and therefore to the difference in refractive index between

the contents of the two compartments of the cell (Table I).

TABLE I.

Bands.	0.	2.	4.	6.	8.	10.	12.	14.	16.	18.	20.
Compensator readings ...	10	13.6	17.0	20.5	24.0	27.7	31.5	35.0	39.0	43.0	46.5

As a preliminary it was necessary to investigate the nature of the curves correlating compensator readings and concentration. To do this, a number of saturated solutions of substances slightly soluble in water were prepared at room temperature. A series of dilutions of each was made, and these together with a quantity of water were allowed to stand until all were at the same temperature. Both divisions of the cell were then filled with water, and the zero-reading was taken. Water was allowed to circulate through one compartment, and the most dilute solution through the other. When no further movement of the bands took place, the reading was noted. The next solution was then allowed to displace the more dilute, and so on till the saturated solution was reached. A number of results are shown in Table II and Fig. 2. All substances so far investigated give straight lines with the exception of benzene. In view of this exception, it will always be necessary to plot a graph of % *saturation* against *compensator readings* as a preliminary to a solubility determination by this method. When the graph is a straight line, only one weighing is necessary to calibrate the concentration scale, and if the reading for the saturated solution is

blurring. Should the graph not be a straight line, a number of weighings would be necessary and the method would lose its merit of simplicity.

When a solubility is required at a temperature other than room temperature, a saturated solution is prepared at that temperature and separated off; then, if necessary, a known quantity of water is added so that the solute will remain completely in solution at the temperature of the room in which the readings are taken. The saturated solutions were prepared in stoppered bottles which were rotated in a thermostat with excess of solute for several hours at the required temperature. Table III shows a number of results.

As an indication of the accuracy with which these results could be reproduced, it may be mentioned that a duplicate determination with lead sulphate gave the same value as shown, *i.e.*, 0.032 at 15°,

TABLE III.

## CLXXII.—*The Inhibition of the Glow of Phosphorus.*

By HARRY JULIUS EMELEUS.

THE slow luminous oxidation of phosphorus is influenced by the addition of a gas or vapour in one of two ways. Gases such as hydrogen, nitrogen, and carbon dioxide effect a dilution, and the kinetics of the reaction continue to obey the law of mass action. In other cases, however, (e.g., many organic vapours) a small concentration of the added substance stops the reaction and the accompanying phenomena of ionisation and formation of ozone. Phosphorus has, moreover, the remarkable property of oxidising much more slowly, and without luminescence, in pure oxygen when the partial pressure of this gas exceeds a limiting value determined by the temperature. The existence of such a pressure is readily demonstrated by gradually evacuating a vessel containing phosphorus and oxygen. At atmospheric pressure, the reaction is imperceptible, but when the "glow pressure" is reached the phosphorus surface lights up suddenly as the normal oxidation begins. Apparently in this case the oxidation is inhibited by oxygen itself.

Various suggestions have been made to account for these anomalies. One of the earliest was that the ozone formed during the reaction was an essential catalyst, and that it was destroyed by the poisons (Schönbein, *J. pr. Chem.*, 1845, **36**, 246). It is remarkable how often such a reaction is found to be possible. For example, turpentine, ethylene, and benzene can all act as inhibitors, and all react readily with ozone, yet in other cases any such action is very much feebler. Qualitative tests were made to examine the action of ozone on acetone, methyl ethyl ketone, hexane, chlorobenzene, and ethyl iodide. The first three gave definite evidence of a slow reaction, whilst the last two were more readily attacked. It is evidently wrong to assert that any of these substances is quite inert. If this were the true explanation of inhibition, however, the relative activity of different poisons would presumably be that of their reactivity towards ozone, and in some cases this is not so; e.g., acetone is a stronger poison than benzene, but is less readily attacked by ozone.

The alternative suggestion that poisons form protective surface films on the solid phosphorus is unlikely, for Centnerszwer has shown that phosphorus exerts its normal vapour pressure in presence of inhibitors (*Z. physikal. Chem.*, 1913, **85**, 99).

The view now generally held is that the propagation of the glow is a process analogous to the passage of a flame through a combustible gas mixture, and that poisons prevent this from occurring. Lord Rayleigh has, in fact, shown that this is probably correct in the particular case of inhibition by excess of oxygen (*Proc. Roy. Soc.*, 1923, *A*, **104**, 322). Extending the earlier experiments of Bloch (*Compt. rend.*, 1908, **147**, 842), he measured the blast of gas necessary to blow the glow from a given phosphorus surface in various oxygen-nitrogen mixtures, and found that it became less as the percentage of oxygen was increased. Assuming that the blast required to maintain the glow in a stationary position downstream is a measure of the virtual rate of propagation upstream, it follows that successive increases in the oxygen concentration decrease the rate of propagation.

The position of oxygen is unique, since it both supports and inhibits combustion, and it cannot be assumed *a priori* that the more active poisons act in the same way. In the experiments to be described, this point has been studied by applying Lord Rayleigh's method of investigation to the propagation of the glow in presence of the strong inhibitors ethylene, benzene, chloroform, and aniline, and results similar to those for oxygen have been obtained.

*The Propagation of the Glow of Phosphorus in the Presence of Inhibiting Substances.*

The phosphorus used throughout was purified by an acid dichromate solution, as described by Downey (J., 1924, 125, 347). Oxygen was obtained from a cylinder.

The apparatus consisted of a large bottle, A (Fig. 1), into which water was run from the tap. The gas stream so produced was passed through the metal coil, B, where it attained the temperature of the bath, C, and then over a flat phosphorus surface cast in the cylindrical tube, E (14 cm. long, 1 cm. internal diameter). Round

E, about half-way along, a narrow black band was fixed, and in all the experiments the gas stream was adjusted so as to blow the glow from the phosphorus surface up to this mark. From a direct measurement of the rate at which water was flowing into A, the velocity of the blast through E could be calculated.

*Dependence of the Blast upon the Percentage of Ethylene added to the Air.*—To obtain the low concentrations of ethylene (less than 0.5%), a mixture of ethylene and air in known proportions was prepared in a gas holder connected to F (Fig. 1). A was then evacuated, and the ethylene-air mixture and air were admitted in the desired proportions as indicated by the mercury manometer. The solubility of the ethylene in the water during the short time of contact was neglected as being within the limits of experimental error. The same phosphorus surface was used throughout. Measurements of the

gas stream needed to blow the glow to the mark were made for different ethylene concentrations at a temperature of 20°. In this way, a series of relative values was obtained, showing the influence of the admixed gas on the propagation of the glow:

Velocity of gas stream (cm./sec.)	140	31	24	17	8	1	1
% Ethylene (by volume) .....	0.16	0.26	0.28	0.36	0.38	0.43	0.46

With less than 0.15% of ethylene the greatest gas stream obtainable was insufficient to blow the glow off the phosphorus surface. As the

FIG. 2.

Air saturated (I) with benzene; (II) with chloroform; (III) with aniline.

ethylene concentration was increased it became easier to blow the glow away, and complete inhibition occurred at a concentration of 0.45%.

*Dependence of the Blast upon the Temperature, in the Presence of a Constant Concentration of Inhibiting Substance.*—Three typical poisons, benzene, chloroform, and aniline, were introduced in large excess into A (Fig. 1) in successive series of experiments, and the air was allowed to become saturated with the vapour at room temperature (16°). The blast of saturated gas which just sufficed to clear the phosphorus surface of luminosity was then determined as

ZZ\*

already described for various temperatures of the bath, C. The results are reproduced in Fig. 2. In each case the glow was inhibited below a certain temperature, and above this it became increasingly difficult to blow it away.

If Lord Rayleigh's assumption be adopted, it follows from these results that the typical poisons studied act by reducing the rate of propagation of the glow in the gas mixture. Complete inhibition of the luminous oxidation marks the limit of this effect with increasing concentration of inhibitor. It is very probable, therefore, that oxygen acts in the same way as the more active poisons. A discussion of the possible mechanism of inhibition is given later. These considerations might seem inapplicable to the conditions under which the glow of phosphorus is generally seen, *viz.*, as a surface luminosity. The establishment of this intense surface oxidation is, however, often preceded by the passage of a luminous pulse through the gas mixture, resulting in the production of ozone, which tends to localise the reaction.

#### *The Influence of Temperature on the Action of Inhibiting Substances.*

The effect of "poisons" depends both on the pressure and on the temperature. The influence of pressure was investigated by Centnerszwer (*Z. physikal. Chem.*, 1898, 26, 1). Phosphorus was introduced into a mixture of oxygen with the inhibiting vapour, and the pressure was reduced until the glow appeared. In every case the limit was lower the greater the concentration of the inhibitor. The present experiments represent an attempt to make a similar systematic study of the influence of temperature. Ethylene has been used, since it is not only a strong poison, but is inert towards phosphorus. Probably it is typical, however, for experiments made with carbon disulphide and ethyl iodide gave similar although less consistent results.

The apparatus used is shown in Fig. 3. Ethylene was prepared from phosphoric acid and absolute alcohol, washed by water and sulphuric acid, and collected over water in A. Between 2—5 g. of purified phosphorus were sealed up in the tube B of 30 c.c. capacity, which was immersed in a freezing mixture and evacuated, with the tap T' closed and the space below it filled with mercury. B was then put in melting ice, and ethylene was admitted from A. After allowing time for diffusion, moist air or oxygen was passed in from C until the total pressure was that of the atmosphere. The tap T'' was then closed and T' opened. B was heated gradually on a water-bath over a resistance mat, and the temperature at which the glow appeared was recorded. During heating, the pressure in the apparatus was kept constant by adjusting the levelling tube,

L. Between successive experiments with different ethylene-air mixtures, the space below T' was filled with mercury, T' was closed, B was cooled, and the apparatus was alternately evacuated and filled with air a number of times. Some consecutive pairs of observations were made with the same phosphorus, in which a definite partial pressure of ethylene was established first in air and then in oxygen. Such readings were strictly comparable, and differed by less than 3°. The oxygen-ethylene mixtures frequently detonated shortly after the phosphorus had begun to glow.

Experiments were made at constant volume by raising the tube L (Fig. 3). The resulting increase in pressure amounted at the

FIG. 3.

highest temperature employed to approximately half an atmosphere, and a corresponding increase in the glow temperature of 5–10° was recorded. The results are shown graphically in Fig. 4.

The main source of error in these experiments was in the observation of the glow. Even with thoroughly rested eyes it was difficult to determine in some cases whether a glow was occurring or not, especially with the high ethylene concentrations.

Two points of special interest are brought out by these results. The temperature at which the glow first occurred appeared to be determined by the concentration of the ethylene, irrespective of whether it was mixed with air or oxygen; also the luminous oxidation was inhibited at temperatures well above the normal ignition-point of phosphorus, which is about 60°.

Although these experiments leave little doubt as to the absence

of luminous oxidation below a definite temperature, a number of tests were made to determine if any non-luminous oxidation occurred. Purified phosphorus (1–2 g.) was sealed in tubes of 40 c.c. capacity (1.5 cm. diameter), having a quill tube fused to one end and drawn down to a capillary about 20 cm. from the wider tube. The whole tube up to the capillary was cooled in a freezing mixture and evacuated; the freezing mixture was replaced by melting ice, moist ethylene and air were admitted in the desired proportions, as indicated by the pressure, and the tube was sealed at the capillary. Two series of bulbs, containing 8% and 26%, respectively, of

FIG. 4.

○ Ethylene-air mixtures at constant volume. × Ethylene-oxygen mixtures at constant pressure. ● Ethylene-air mixtures at constant pressure.

ethylene were heated in the dark in a thermostat at 48° for 2 months, when they were opened by breaking the capillary under mercury, the bulb being inverted and cooled in ice. Any oxidation would be indicated by a rise of mercury in the stem, correction being made for change in barometric height. The bulbs containing 8% of ethylene exhibited a decrease in pressure of 2–12 cm. of mercury, whilst for those with 26% the decrease varied between 2–6 cm. Control tubes containing no phosphorus were unaltered. Further experiments are being made to verify that this slow rate of oxidation is maintained.

These results show that absorption of oxygen occurs when the

luminous oxidation is inhibited, which is analogous to Lord Rayleigh's observation of a slow non-luminous oxidation in moist oxygen at atmospheric pressure (*Proc. Roy. Soc.*, 1924, *A*, 106, 1).

### *Discussion.*

Any account of the mechanism of inhibition must explain why either an increase in temperature or a decrease in pressure tends to produce the glow. The former involves at least two factors, since both the vapour pressure of the phosphorus and the potential rate of reaction increase. The experiments described have shown that inhibition can extend to 90°, which is much above the normal ignition temperature of phosphorus. Moreover, the "glow temperature" does not depend on whether air or oxygen is used as a diluent for the ethylene. When the glow is prevented, the tendency for the reaction to occur is demonstrated by the slow non-luminous oxidation which was observed at 48°. At some stage, depending on the ethylene concentration, the impediment is overcome and a wave of luminosity passes through the mixture, the subsequent oxidation being accelerated by the formation of ozone. Again, on slowly decreasing the pressure in a mixture of ethylene and oxygen, the partial pressure of the phosphorus will remain constant in the presence of the solid. In effect, therefore, the proportion of combustible vapour in the mixture is being increased, which in itself would be expected to favour flame propagation.

Several analogous cases have been recorded. White found that the vapours of benzene, acetaldehyde, acetone, and ether had "a powerful inhibitory effect on the propagation of flame in carbon disulphide-air mixtures" (*J.*, 1922, 121, 2561). The addition of 0.025% of ether, for example, necessitated the use of 25% more carbon disulphide if the mixture was to propagate flame. In Dixon's experiments on the phosphorescent flame of carbon disulphide, a very much higher temperature was required to produce ignition when a small amount of ethylene was added (*Rec. trav. chim.*, 1925, 44, 305). Further examples are furnished by the many organic sulphur compounds studied by Delépine (*Bull. Soc. chim.*, 1922, 31, 762). These contain the group  $C=S$ , or  $P=S$ , and undergo a luminous oxidation at room temperatures, which is inhibited by ether, acetone, and pyridine. Here also a decrease of pressure or an increase of temperature will restart the luminescent reaction after it has been arrested.

The experiments described have shown that the addition to air of typical inhibitors renders it easier to blow the glow from a phosphorus surface, and that increase in temperature diminishes this action. An analogy is thus established between the action of

excess of oxygen and that of stronger poisons, in that both prevent the propagation of the glow in the gas. A tentative explanation of the mechanism was put forward by Lord Rayleigh, who suggested that in the propagation of the glow the products of the reaction in one layer acted as catalysts in the next. These catalytic particles are supposed to be rendered inactive by the adsorption of the inhibiting molecules, when the reaction stops. A similar view has been adopted by Dixon to explain the inhibition of the phosphorescent flame of carbon disulphide.

The author wishes to thank Professor H. B. Baker, F.R.S., for his kind interest and advice throughout this research. He is indebted to the Department of Scientific and Industrial Research for a maintenance grant, and to the Trustees of the Dixon Fund for a grant for the purchase of apparatus.

### CLXXIII.—*An Improved Hydrogen Sulphide Generator.*

By HENRY GEORGE DENHAM and JOHN PACKER.

AN automatic hydrogen sulphide generator for laboratory installation has been described by Steele and Denham (J., 1920, **117**, 527). Since then the present authors have redesigned certain portions of the apparatus and the modified generator has given such highly satisfactory results during constant use for the last two years that a description of it is considered justified. A laboratory fitted with one of these generators would have a potential and practically unlimited supply of hydrogen sulphide always at hand at the negligible cost of the electric current needed to keep the generator heated.

The following is a description of the apparatus. A is the acid-holder of about 6 litres capacity; B a tap-funnel for use in filling A; C a two-way tap so that A can be connected either to the tube D which leads to an outside flue, or to E; F is a large-bore tap situated at a higher level than the acid in A; H is a reservoir of 600–700 c.c. capacity for retaining hydrogen sulphide generated, but not withdrawn from the apparatus; J is a bulb of about 150 c.c. capacity, situated a few cm. above the highest level of acid in A; K is a 100 c.c. bulb; L is a piece of capillary tubing of 2 mm. bore and of about 8 cm. total length, used to prevent a too rapid flow of acid into V, connected to the reservoir H by a piece of pressure

tubing I (wired on); M is a small 10 c.c. bulb, N and P are taps, R is thick-walled rubber tubing, inserted for flexibility so that the rubber stopper S can be easily removed; T is a wash-bottle containing water, through which the hydrogen sulphide is supplied to the distributing taps and mains; V is a tube of fused silica, the upper portion of which is about 50 cm. long and 5 cm. internal diameter whilst the lower part is of 2 cm. internal diameter, fitted by a tight rubber stopper into the reservoir, W, of 6 litres capacity, which receives the spent acid; Y is a tap through which the spent

FIG. 1.

acid is withdrawn, connected to a waste drain. The tube V is heated electrically to a temperature of approximately  $80^{\circ}$ . The winding (total resistance 100 ohms) is made over a thin piece of asbestos paper with nichrome wire of 1 ohm per foot resistance, and is well covered with many thicknesses of asbestos paper. In the authors' generator, this winding is connected through an ammeter and adjustable resistance to a storage battery in such a way that it can be connected either with the full battery of 110 volts or a portion of it giving 60 volts. A current of just over 1 amp. is sufficient to heat the tube V up to the working tem-

perature in from 10 to 15 minutes, whilst a current of 0.6 amp. will maintain this temperature.

*Mode of Operation.*—The tube V is packed with lumps of iron sulphide. The acid-holder is filled by means of the funnel B with commercial hydrochloric acid diluted with an equal volume of water, and the funnel tap turned off. The taps F and N are turned on and the tap C is turned so as to connect the acid-holder to E, through which air is blown until the siphon, G, fills. Tap N is then turned off and tap E turned so as to connect the acid-holder with the tube D. The reservoir H fills to the side-tube level with acid which then runs over into V and, provided the tube V has been sufficiently heated, hydrogen sulphide is generated as soon as a few drops run over, and drives the acid back into H, where the gas is stored until drawn off through the tap P and wash-bottle T. The acid is completely neutralised long before it has percolated through the heated column of sulphide. The side-tube Z and bulbs J and K are provided as an escape for hydrogen sulphide should an excessive amount be generated owing to some abnormal cause. This prevents hydrogen sulphide from getting into the siphon and putting the generator out of action. When the generator is not in operation and the tube V not heated, tap F is kept turned off.

*General Remarks.*—The capacity of this generator is practically the same as that of the one formerly described, whilst almost theoretical yields of hydrogen sulphide are always available at a steady and convenient pressure. It has the following advantages over the older form: (1) It is completely automatic in operation. From this point of view electrical heating is a great advantage over steam heating, whilst the use of silica instead of glass for the tube V overcomes the trouble formerly experienced of cracking, due to alternate heating and cooling. (2) There is no leakage of acid, as it never comes into contact with the rubber stoppers or connexions (except at I during a portion of the cycle of operations). (3) Provided the tube D is carried to a suitable flue, there is no smell of hydrogen sulphide.

The hydrogen sulphide is distributed throughout this building in composition (lead) gas-pipes of  $\frac{1}{4}$  in. internal diameter without any serious loss of pressure. After 3 years the attack on these pipes appears scarcely to have penetrated beyond the inner surface, although in the experience of one of the authors in the sub-tropical climate of Brisbane these pipes were seriously attacked, but this could probably be overcome by the use of drawn copper tube.

CLXXIV.—*The Doubtful Existence of Aurous Oxide.*

By WILLIAM BRANCH POLLARD.

It has been found that mercurous nitrate and chloroauric acid react to form gold and a basic auric compound (this vol., p. 529), and not "aurous oxide" as claimed by Figuier (*Ann. Chim. Phys.*, 1844, **11**, 339) and Krüss (*Annalen*, 1887, **237**, 276). In consequence of this, "aurous oxide," prepared in other ways, has been examined to see if it might not consist of colloidal gold and auric hydroxide. Analogous substances are known, such as Purple of Cassius, in which metallic hydroxides function as protective colloids.

From the equation  $3\text{Au}_2\text{O} = 4\text{Au} + \text{Au}_2\text{O}_3$  it is clear that the determination of gold and oxygen cannot show whether the substance is aurous oxide or a mixture of gold and auric oxide in these proportions. This possibility was overlooked by Krüss, whose analyses are therefore inconclusive. Krüss's claim is, moreover, unsupported by any chemical evidence showing that aurous compounds can be formed from "aurous oxide."

## EXPERIMENTAL.

In attempts to prepare "aurous oxide" from potassium bromoaurate by Krüss's method, if an excess of potassium bromide was present, only metallic gold resulted. "Aurous oxide" was decomposed when heated with solutions of potassium bromide, but was much less decomposed by solutions of sodium chloride. As potassium bromide is a by-product in the formation of "aurous oxide," it is surprising that Krüss was able to obtain his substance in the proportions required by theory.

By the following slight modification it was found possible to work at room temperature. Gold (1.0 g.) was converted into chloroauric acid, made up to 1 litre with saturated sodium chloride solution, and reduced to the aurous state with sulphurous acid. The solution, now colourless, was made slightly alkaline with caustic soda. Very little precipitation occurred at first, but a black, colloidal substance separated on standing. Heat caused the precipitation to occur rapidly. The formation of the substance is therefore quite unlike that of metallic hydroxides, but is highly suggestive of the decomposition of aurous compounds.

The substance formed a dark blue, colloidal suspension when washed with cold water, but could generally be washed with hot water. With hydrochloric or hydrobromic acid it instantly formed metallic gold and chloroauric or bromoauric acid; the reaction did not suggest the slow decomposition which takes place in aurous

compounds. The addition of alkali metal chlorides or bromides to the corresponding acids failed to produce aurous compounds (Lenher, *J. Amer. Chem. Soc.*, 1913, **35**, 547). Hydriodic acid gave gold, aurous iodide, and iodine; with excess of the reagent, aurous iodide passed into solution. This reaction resembles that of hydriodic acid and auric oxide:

Although these reactions were known to earlier workers, no reason has been given to explain why iodine should be liberated by "aurous oxide."

With a solution of sodium sulphite, the substance formed sodium aurosulphite and left a residue of gold which had the same black colour as the original substance. With sodium thiosulphate, it formed sodium aurothiosulphate and left a residue of black gold. In both these cases an aurous compound is formed, but only a third of the gold takes part in the reaction and this has to undergo reduction.

When the substance was heated with strong nitric acid a residue of gold was left and a yellow solution was formed which, on dilution, hydrolysed with the separation of auric hydroxide.

When heated with potassium bromoaurate solution, gold dissolved and was deposited, on cooling, in shining crystals according to the equation  $\text{AuBr}_3 + 2\text{Au} \rightleftharpoons 3\text{AuBr}$ .

When the substance was heated with potassium bromide solution, a residue of brown gold was left and gold passed into the solution, which then became strongly alkaline. Potassium iodide behaved in the same way, but was more energetic in its action. Sodium chloride solutions were much less reactive. Although no previous reference could be found, auric hydroxide was shown to behave in exactly the same way, dissolving even in strong sodium chloride solution which thus became alkaline. The reaction, however, was most marked in the case of potassium iodide.

The substance was scarcely attacked by dilute caustic soda, but with strong solutions sodium aurate and metallic gold were formed. Auric oxide was slowly attacked by weak but rapidly attacked by strong solutions of caustic soda. This explains why Krüss found it necessary to employ "very weak potash" in the formation of his "aurous oxide," strong alkali preventing its formation just as strong hydrochloric acid prevents the formation of Purple of Cassius.

Although numerous reactions have been tried, in no case has any definite aurous reaction been discovered, the substance always behaving as a mixture of gold and auric hydroxide. As the sub-

stance is highly colloidal, any attempts at a mechanical separation into gold and auric hydroxide would present very great difficulty. Experiments were made, however, to see whether auric hydroxide could act as a protective colloid in the manner suggested.

Auric hydroxide prepared by the magnesia process was washed in a centrifuge with cold water until it began to pass into colloidal suspension just as Krüss's "aurous oxide" does. Portions were then taken, made alkaline with caustic soda, and partly reduced to gold by dilute solutions of various reducing agents. Little reaction occurred at first, but when the solutions were warmed or made more alkaline reduction set in. Further additions of reducing agent were made until the action was judged to have proceeded far enough; the precipitates were then separated in a centrifuge and washed. Black precipitates which appeared to be identical with Krüss's "aurous oxide" were thus obtained, with hydrazine, phenylhydrazine and formaldehyde as reducing agents. With sodium peroxide as reducing agent, a brown precipitate was obtained which transmitted red light but was otherwise identical with "aurous oxide."

No evidence has therefore been obtained to show that aurous oxide exists; its chemical and physical properties are those of a mixture of gold and auric hydroxide.

## CLXXV.—*Studies with the Microbalance. Part IV.* *The Photochemical Decomposition of Silver Iodide.*

By ERNST JOHANNES HARTUNG.

EXPERIMENTAL investigation of the action of light on silver iodide has hitherto furnished no definite result; when insolated in air, the substance slowly becomes greenish-grey, but the actual amount of chemical change appears to be very small and no free halogen has been detected. Koch and Schrader (*Z. Physik*, 1921, 6, 127) illuminated very minute particles of silver iodide, suspended between the charged plates of a condenser, but could find no changes in weight greater than 1—2%. Koch and Vogler (*Ann. Physik*, 1925, 77, 495) examined the space lattice of silver iodide by X-ray methods; after exposure to sunlight for 4 months, no free silver could be detected, although this was readily found on illumination of silver chloride and bromide for much shorter periods. Various other methods have given negative or indefinite results, although the consensus of opinion appears to be that the change is different

in nature from the decomposition of the bromide and chloride. Some years ago, the author showed (J., 1922, 121, 689) that very thin films of silver iodide deposited on vitreous silica lost weight appreciably when exposed in air to sunlight; the losses were very much smaller than those found for the bromide and chloride, but there was no doubt as to their reality. A thorough study of the question has now been made by means of the Steele-Grant microbalance, on the general lines used successfully in the cases of the bromide and chloride (J., 1924, 125, 2198; 1925, 127, 2691) and it has been found that the photochemical decomposition of silver iodide is analogous to that of the other halides of silver; iodine is liberated and, under suitable conditions, the action may be made almost complete. The microbalance employed carried a load of 105 mg. and weighed with precision to  $10^{-4}$  mg.; it had been thoroughly tested for 2 years and was used in very favourable circumstances. The general plan of the work was to iodinate thin films of chemically deposited silver until pure iodide had been formed. The films were then exposed to sunlight for various periods in oxygen, hydrogen, or nitrogen in the presence of a suitable iodine absorbent and subsequently reweighed. The insolated material was then treated in various ways in attempts to discover its nature. A series of experiments on the rate of iodination of silver, and of previously insolated silver iodide, was also made.

*Preparation of Films of Pure Silver Iodide.*—Light vitreous silica sheets were silvered in the well-known tartrate solution and ignited at  $400^{\circ}$  in a small electric furnace to drive off all occluded matter. After weighing, these films were hung over carefully purified iodine at room temperature; pearly-yellow iridescent silver iodide was rapidly formed and the films were then reweighed. Comparison of the weights with those calculated from the weight of silver taken showed an average discrepancy of 1 part in 1300 parts; the average weight was 0.34 mg. and the thickness about 0.0002 mm. Precipitated silver iodide is known to adsorb iodine readily, but no evidence of adsorption, or of the formation of polyiodides, was obtained in these experiments.

*Photochemical Decomposition of Silver Iodide.*—The glass apparatus in which the films were sealed, prior to insolation, was similar to that employed for silver bromide and has already been described (*loc. cit.*). Great care was necessary to prevent damage to the films by flame gases during sealing operations, but repeated tests showed that a good counter-current of purified air gave adequate protection. Before exhaustion, the vessel was filled with oxygen, hydrogen, or nitrogen, which had been specially purified and filtered. Experiments showed that at atmospheric pressure decomposition

of the silver iodide was very slow, even after prolonged exposure to strong sunlight, but was hastened by diminution of pressure. The apparatus was therefore exhausted either to 10 mm. pressure or as completely as possible. As heating of the glass walls was inadmissible owing to the sensitive nature of the films, adsorbed gas must have been released slowly during insolation; this is denoted by "res." (*i.e.*, "residual") in Table I, to indicate that the pressure in the apparatus was less than 0.001 mm. at the time of sealing off from the pump. As absorbent for the liberated iodine, a roll of clean copper gauze was employed at first; this metal is particularly efficient in removing chlorine and bromine from a gas phase, but it was not successful with iodine. Inspection of the gauze after prolonged irradiation of the iodide film showed only slight evidence of tarnish, and at the same time the decomposition of the silver iodide had been very slow. Thus, after more than 6 months' exposure on the roof of the laboratory in an exhausted vessel containing copper gauze, a film of silver iodide weighing about 0.4 mg. had lost only 16.6% of its total iodine. This tardiness of decomposition indicated that the partial pressure of iodine vapour above strongly illuminated silver iodide is very small, for copper tarnishes readily above solid iodine at room temperature (partial pressure of vapour 0.2 mm.). It was subsequently found that silver absorbs iodine vapour with extreme readiness, even when the partial pressure of the halogen is very small, and consequently the lower portion and side-tube of the apparatus were silvered internally before introduction of the photosensitive film. During insolation, this silver deposit was shielded from radiation by opaque wrappings and a marked increase in the rate of decomposition of the halide was observed at once. In all subsequent experiments, therefore, silvering was adopted in order to render the absorption of iodine as complete as possible. The amount of radiant energy absorbed during insolation could not be measured, owing to the progressive change in the colour, opacity, and reflecting power of the films, but a fair indication is given in each case by the length of exposure in days. After a definite period of insolation, during which the film became deep slate-grey, the apparatus was opened under exhaust and purified nitrogen gradually admitted. The film was then removed and weighed; subsequent treatment consisted usually of re-iodination, but attempts were also made to analyse the product of insolation. Table I summarises the results of the experiments, weights being given in mg., and the columns headed  $F_1$  and  $F_2$  denoting the weights of the films after exposure and after re-iodination, respectively. It is evident that decomposition of the silver iodide proceeded very extensively, but only when the apparatus was exhausted;

at 10 mm. pressure, the change was hindered in a remarkable manner. The nature of the residual gas in the apparatus seems to exert little influence and, in particular, the claim that oxygen is necessary is seen to be unfounded. Moreover, the extent of decomposition depends less on the period of exposure than on the thickness of the film, this being approximately proportional to the weight in each case. When all the factors are favourable, as in Expt. 7, decomposition is nearly complete. Certain minor irregularities in the results find a ready explanation in small variations in shape of the apparatus, which affect the ease of diffusion of the liberated iodine to the absorbing silver surface. There can be no doubt, however, that the products of insolation of silver iodide are silver and iodine, and the reason why extensive change is found only in very thin films is because of the opacity of the liberated silver and its very powerful attraction for iodine vapour. There is no evidence of the formation of any sub-iodide.

On re-iodinating the product of insolation, rapid restoration of the former yellow colour of the film took place and the weight was then usually rather greater than that of the original silver iodide. This behaviour was found with the chloride and bromide also and is believed to be due to slight oxidation of the insolated film during manipulation; the discrepancies are usually slight and, except for Expt. 1, are largest when oxygen in appreciable amount has been present in the exposing vessel (Expts. 9 and 10). Many attempts were made to analyse the product of insolation by methods which were devised for the filtration of very small amounts of material (this vol., p. 840), but no procedure for the accurate estimation of silver, or of silver iodide, in less than 0.5 mg. of a mixture of the two could be found. It was hoped to effect separation by suitable reagents, but solvents for silver (*e.g.*, nitric acid) removed the metal imperfectly from the iodide, whilst solvents for silver iodide (*e.g.*, silver nitrate, thiosulphates, cyanides) all attacked thin films

of silver rapidly in the presence of oxygen. Solution of both silver and silver iodide was easily effected by ammonium cyanide, which was then treated with acetic or hydrochloric acid; this precipitated all the iodide, and the remainder of the silver as either cyanide or chloride, but in each case the ammonium salt left in solution increased the solubility of the silver salts so markedly that no accurate results could be obtained. Also, estimation by simple evaporation of the ammonium cyanide solution to dryness was rendered useless by the formation of ammonium formate. Another attempted method consisted in evaporating the product of insolation with hydrochloric acid; the iodide was not affected by this treatment, but conversion of the silver presumably present into the chloride was so slow and imperfect that success was impossible. Finally, the attempts at analysis had to be abandoned, after showing that treatment of the product of insolation with silver iodide solvents left a residue of practically pure silver.

*Rate of Iodination of Silver Films.*—Further evidence as to the nature of the product of insolation of silver iodide was obtained by comparing its rates of re-iodination with those of pure silver. The apparatus and method have been described previously for the case of silver bromide (J., 1924, 125, 2204); the experiments were carried out in a thermostat at 25° (regulated to 0.1°) and at first solid iodine was placed in the iodinator, giving a partial pressure in the vapour phase of 0.3 mm. However, silver films were attacked so rapidly that conversion into iodide was complete in less than 2 minutes and accurate measurements were impossible. Solutions of iodine from  $N/10$  to  $N/100$  were therefore made in  $N$ -aqueous potassium iodide, and the partial pressures of the halogen above these solutions (not measured) were sufficiently small to give convenient rates of iodination. The results obtained are shown in Fig. 1, in which the iodine absorbed, as percentage of that necessary to form pure silver iodide, is plotted against the total time of iodination in minutes. The continuous curves indicate iodination of pure silver, and the broken curves iodination of the product of insolation of silver iodide, which contained an average of 14% of the total original iodine at the start. In each case, the total area of the film was 146 sq. mm. and the thickness about 0.00015 mm., so that the curves are fairly comparable. The rapid increase in the speed of addition of the halogen as the solution increases in concentration is shown, as well as the striking similarity in speed between silver and insolated silver iodide for the same concentration of iodine which is evident from the approximate parallelism of each pair of curves. This is strong presumptive evidence that one of the products of insolation is silver itself, although, of course, differ-

ences in the physical state of the liberated metal may be expected to alter the rates of iodination very considerably, and indeed do so in the cases of the chloride and bromide. The peculiar phenomenon of an optimum halogen concentration which was discovered in the case of chlorine (J., 1925, 127, 2696) has no parallel with iodine, where the rate of addition of the halogen steadily increases as the concentration in the gas phase rises. No evidence of the formation of sub-iodides or poly-iodides is indicated.

FIG. 1.

### Summary.

1. The photochemical decomposition of silver iodide has been studied by means of the microbalance.

2. The maximum percentage loss of total iodine in thin films of silver iodide when suitably insulated was: in hydrogen 91.6%, in nitrogen 88.5%, and in oxygen 94.0%.

3. Evidence is adduced to show that the photochemical decomposition products are silver and iodine, that oxygen is not necessary for the change, and that extensive action is found only with extremely thin films at low gas-pressure in the presence of silver as iodine absorbent.

4. The rates of iodination of silver and of previously insulated silver iodide have been studied; close agreement exists between them for similar concentrations of iodine vapour.

5. No evidence of the formation of silver sub- or poly-iodides has been found.

# CLXXVI.—*Trypanocidal Action and Chemical Constitution. Part V. Arylsulphonamides of some Phenylarsinic Acids.*

By LESLIE FRANK HEWITT, HAROLD KING, and WILLIAM OWEN MURCH.

PARTS I to IV in this series were almost solely devoted to the preparation, properties, and trypanocidal activity of arylamides of phenylarsinic acids, the common feature of the compounds described being the amide link,  $-\text{CO}\cdot\text{NH}-$ . The present communication is designed to fill the gap in our knowledge of some of the corresponding sulphonamides, with the common link,  $-\text{SO}_2\cdot\text{NH}-$ , a group of which only two representatives, both non-amphoteric, have hitherto been described.

*m*-Nitrobenzenesulphonyl and *m*-nitro-*p*-toluenesulphonyl radicals have now been introduced into the amino-group of 4-aminophenylarsinic acid (I), and the former radical into the amino-groups of 3-amino-4-hydroxyphenylarsinic acid (II) and 4-amino-2-hydroxyphenylarsinic acid (III).

For this purpose, the most convenient and by far the most effective method is a modification of the Schotten-Baumann method devised by Fischer and Bergell (*Ber.*, 1902, 35, 3779) for the preparation of the  $\beta$ -naphthalenesulphonyl derivatives of amino-acids. The reaction with 3-amino-4-hydroxyphenylarsinic acid (II), an acid which is sensitive to caustic alkali, necessitates the use of sodium carbonate, and under these conditions a complex mixture results containing in all probability *O*-sulphonic esters and disulphonamides.

3'-Nitrobenzenesulphonyl- (IV; R = H) and 3'-nitro-4'-toluenesulphonyl-4-aminophenylarsinic acid (IV; R = Me) on further nitration yield exclusively one dinitro-acid (V), the constitution following from the products of hydrolysis.

3'-Nitro-4'-toluenesulphonyl-4-methylaminophenylarsinic acid (VI), which is the methylation product of (IV; R = Me), was obtained by

the action of methyl sulphate and alkali at 100°. It was unobtainable by methylation at room temperature, although 4'-toluenesulphonyl-4-methylaminophenylarsinic acid (VII) was readily formed under these conditions. The latter acid on solution in sulphuric acid at room temperature was completely hydrolysed and gave an

80% yield of 4-methylaminophenylarsinic acid, an acid which is not new. This is, however, the best method for its preparation.

The seven nitro- and dinitro-arsinic acids aforementioned on reduction with ferrous chloride and alkali gave the corresponding amino-compounds quite smoothly and in good yield. When tested for trypanocidal activity on mice infected with *Trypanosoma equiperdum*, they were found to be without exception completely inactive on any dose, including the maximum tolerated, although in structure they differ from the active amides of previous communications only in the replacement of  $-\text{CO}\cdot\text{NH}-$  by  $-\text{SO}_2\cdot\text{NH}-$ . This is a surprising result. It might be ascribed to the presence of the strongly acidic hydrogen atom of the  $-\text{SO}_2\cdot\text{NH}-$  group in comparison with that contained in the  $-\text{CO}\cdot\text{NH}-$  group, but this was negated by the inactivity of 3'-amino-4'-toluenesulphonyl-4-methylaminophenylarsinic acid derived from (VI) by reduction. It is, however, possible to proceed a step further in the analysis of this anomaly.

Ehrlich first advanced the theory that the real active trypanocidal agent in arsenicals is the tervalent arsenic stage, basing it on the two groups of observations, that cures of small animals artificially infected with trypanosomes could be effected by primary quinquevalent arsenic acids and by the corresponding tervalent arseno-compounds and arsenious oxides, but *in vitro*, i.e., outside the animal body, arsenic acids and arseno-compounds had negligible action on trypanosomes, whereas the oxides were very highly active. The view of the importance of the tervalent arsenious oxide has received further support from the experiments of Voegtlin and his associates in Washington, who show that animal tissues are able to reduce the arsenic acids and oxidise the arseno-compounds to the arsenious oxide stage :

It was therefore of importance to test whether the oxides corresponding to the above-described inactive acids containing the sulphonamide group were trypanocidally active. 3'-Amino-4'-

*toluenesulphonyl-* and 3:3'-diamino-4'-*toluenesulphonyl-4-amino-phenylarsenious oxides* were prepared by reduction of the corresponding acids with sulphur dioxide and hydriodic acid, and the former oxide was examined in detail. It had a maximum tolerated dose of 0.01 mg. per g. of mouse, was thus twenty times as toxic as its parent acid and was completely devoid of trypanocidal activity on the infected animal, but at a dilution of 1 in 10,000 *in vitro* and 30 minutes' exposure, it rendered trypanosomes non-infective to the normal animal. As it can be calculated that this is just one-half the concentration which should obtain in the blood-stream of infected mice when injected intravenously with the maximum tolerated dose, it seems clear that the injected oxide must be de-activated by some body mechanism. Whatever be the ultimate chemical processes involved in the tissues which determine the distribution and fate of these acids or oxides before final excretion, it seems also certain that the sulphonamide linking must confer a general character on these molecules, independent of its orientation with respect to the arsinic acid group, which prevents the oxides from ever attaining a concentration inimical to the continued reproduction of the trypanosomes. Since the toxiphoric grouping is undoubtedly the group containing arsenic, the presence of the  $-\text{SO}_2\cdot\text{NH}-$  group is reflected in an altered distribution of affinities around the arsenic atom. Some light might be thrown on this by precision measurements of the relative reduction potentials of arsinic acids containing the amide link and their analogues with the sulphonamide link.

The *arseno-compounds* of 3'-aminobenzenesulphonyl-4-amino-phenylarsinic acid and 3'-amino-4'-toluenesulphonyl-4-aminophenylarsinic acid are white, whereas the arseno-compounds of their benzamide analogues are orange and almost all previously recorded arseno-compounds are yellow or orange. The colour of arseno-compounds is usually ascribed to the presence of the chromophoric grouping  $-\text{As}=\text{As}-$  analogous to the azo-chromophore,  $-\text{N}=\text{N}-$ . The view might therefore be advanced that the loss of colour in the white arsenobenzenes is due to formation of a bimolecular complex.

Michaelis and Schäfer (*Ber.*, 1913, 46, 1742) had found that the molecular weight of crystalline arsenobenzene and arsenotoluene in phenol as cryoscopic solvent agreed with the simple molecular weight. In the present instances, however, the experimental difficulties due to the peculiar properties of the substances have proved insurmountable.

In connexion with some of the compounds described in this communication, the observation has been made that compounds containing a hydroxyl group ortho to a sulphonamide group give a striking series of colour reactions with iron, nickel, cobalt, and copper salts in sodium hydrogen carbonate solution, which are destroyed by excess of caustic alkali or free mineral acid. The cobalt solutions show an absorption band in the yellow-green parts of the spectrum. If a purple alkaline solution of the iron complex of 3'-aminobenzenesulphonyl-3-amino-4-hydroxyphenylarsinic acid, for instance, be made neutral or weakly acid to litmus, a grey-black precipitate is formed, free from the anion of the precipitating acid, but with an iron-sulphur atomic ratio of approximately 1 : 1 and re-soluble in sodium hydrogen carbonate solution at least in part, with production of the original purple colour. The most reasonable view of the nature of the constituents of the coloured alkaline solutions is that a series of complex anions is formed analogous to the catechol complexes described by Weinland and Binder (*Ber.*, 1912, 45, 148) and based, at least in the case of iron, on the ferricyanide or ferrioxalate model; but whereas the iron-catechol complexes are of a stability to alkali comparable with that of potassium ferricyanide, the iron-*o*-hydroxysulphonamide complexes seem to be of a stability probably inferior to that of the ferrioxalates.

On this view, the acidic hydrogen atoms of the  $\text{-SO}_2\text{NH-}$  and  $\text{-OH}$  groups enter into the co-ordination complex.

In support of this it is found that the benzamide analogues described in Part IV do not give these colour reactions, that *N-p*-toluenesulphonyl-*o*-aminophenol (VIII;  $\text{R} = \text{H}$ ) and *toluenesulphonyl-3-amino-4-hydroxybenzoic acid* (VIII;  $\text{R} = \text{CO}_2\text{H}$ ) give the colour reactions, but that *N-p-toluenesulphonyl-o-methylaminophenol* (IX) does not.

Incidentally Reverdin's so-called *O*-toluenesulphonyl-*N-p*-methylaminophenol (*Ber.*, 1909, 42, 1523) has been shown to be *N*-toluenesulphonyl-*N-p*-methylaminophenol. The greyish-black precipitate previously mentioned as being obtained on acidification of the purple iron solutions possibly has the constitution (X) analogous to the ferric oxalohydroxamate (XI) of Hantzsch and Desch (*Annalen*,

1902, 323, 24), but development of the purple colour by solution of (X) in alkali cannot be mere formation of a soluble salt of the arsenic

acid grouping, because the same colour is obtained from (VIII; R = H), where the salt-forming group is absent.

4-Amino-2-hydroxyphenylarsinic acid (III), its 3'-nitrobenzenesulphonyl- and 3'-aminobenzenesulphonyl-derivatives also give colour reactions with ferric and cupric salts in sodium hydrogen carbonate solution. It is possible that in these cases also co-ordination compounds, involving the arsinic acid and adjacent hydroxyl groups, are formed.

In this communication it is convenient to incorporate some observations on one of the simplest aromatic arsinic acids containing the sulpho-group, namely, *p*-sulphophenylarsinic acid. In 1919, one of the authors (K.) made an unsuccessful attempt to prepare the thiol analogue of salvarsan, and the experiments which follow arose out of that attempt. *p*-Aminophenylarsinic acid was converted into *p*-xanthylphenylarsinic acid (XII) by Leuckardt's method (*J. pr. Chem.*, 1890, **41**, 179) and this on oxidation on the boiling water-bath with 3*N*-nitric acid gave a mixture of the sparingly soluble diphenyl disulphide *pp'*-diarsinic acid (XIII) and the extremely soluble *p*-sulphophenylarsinic acid (XIV).

The latter acid is, however, more readily obtained by oxidation of the disulphide by boiling 6*N*-nitric acid. The disulphide and the sulpho-acid proved to be devoid of trypanocidal action. The sulpho-acid was converted into the corresponding *arseno-acid* by reduction with hypophosphorous acid, but owing to its very ready solubility in water this could not be isolated sufficiently pure for physiological testing. Dr. Voegtlin has also prepared this sulpho-acid and its arseno-derivative (*Physiological Reviews*, 1925, **5**, 91), but he informed us verbally that his method for the preparation was different from ours.

We are indebted to Miss F. M. Durham and Miss J. Marchal of this department for the painstaking care with which they have determined the toxicities and trypanocidal action of the compounds described in this paper.

## EXPERIMENTAL.

*4'-Toluenesulphonyl-4-aminophenylarsinic Acid.*—This acid, briefly described by Little, Cahen, and Morgan (J., 1909, 95, 1482) as being obtained by the Schotten-Baumann reaction, may be obtained in 74% yield by the Fischer-Bergell method of arylsulphonylation. Sodium *p*-aminophenylarsinate pentahydrate (1 mol.) dissolved in 5 parts of water was shaken with finely-powdered *p*-toluenesulphonyl chloride (2 mols.) and a few drops of ether for 30 minutes. *N*-Sodium hydroxide (1 mol.) was then added, and the mixture again shaken for 30 minutes. This sequence was repeated until 3 molecular proportions of *N*-alkali had been added. The arsinic acid obtained on acidification was sparingly soluble in boiling water, crystallising in microscopic rectangular plates, but readily soluble in boiling 90% formic acid, crystallising therefrom in needles and diamond-shaped plates.

*4'-Toluenesulphonyl-4-methylaminophenylarsinic Acid (VII).*—*4'*-Toluenesulphonyl-4-aminophenylarsinic acid (1 mol.) was dissolved in 2*N*-sodium hydroxide (2 mols.) and heated in the boiling water-bath with vigorous stirring while methyl sulphate (16 mols.) and an equivalent quantity of 2*N*-sodium hydroxide were run in simultaneously, the reaction of the fluid being faintly alkaline throughout. On acidification a 90% yield of the methylated acid was obtained. It is readily soluble in boiling water and crystallises in needles which are unstable and pass readily into large, hexagonal plates. From alcohol it crystallises in needles and from 90% formic acid, in which it is extremely readily soluble, in microscopic, rectangular plates (Found: S, 8.0.  $C_{14}H_{16}O_5NSAs$  requires S, 8.3%). This acid can also be obtained by methylation at room temperature.

*4-Methylaminophenylarsinic Acid.*—*p'*-Toluenesulphonyl-4-methylaminophenylarsinic acid was dissolved in  $3\frac{1}{2}$  volumes of concentrated sulphuric acid at room temperature, kept for 30 minutes, and then poured on to ice. The mixture having been made neutral to Congo paper, an 80% yield of *N*-methylaminophenylarsinic acid was obtained (Found: As, 32.6. Calc.: As, 32.4%). It is very soluble in *N*-hydrochloric acid and with nitrite gives an instant precipitate of fine needles of the nitroso-compound. On slight dilution, these rapidly transform into six-sided plates which give the Liebermann nitroso-reaction. This acid had a tolerated dose of 0.05 mg. per g. of mouse, and on this dose mice infected with *T. equiperdum* relapsed in the most favourable cases within 7 days.

*Sodium 3-Nitro-4-toluenesulphonate.*—The following process is an improvement on that of Otto and Gruber (*Annalen*, 1868, 145, 23)

and of Fichter and Bernoulli (*Ber.*, 1909, 42, 4309). *p*-Toluenesulphonic acid (100 g.) was heated with 380 c.c. of nitric acid (*d* 1.42) in the boiling water-bath for 30 minutes. The solution was poured into a litre of water and rapidly evaporated to dryness under reduced pressure. The residue, which crystallised in envelope-shaped plates, was re-evaporated with small quantities of water to remove all nitric acid, and the solution then neutralised with sodium carbonate. On concentration, a 72% yield of the *monohydrated sodium* salt was obtained (Found: Loss at 100°, 7.3.  $C_7H_6O_5NSNa \cdot H_2O$  requires  $H_2O$ , 7.0%. Found on dried salt: Na, 9.9.  $C_7H_6O_5NSNa$  requires Na, 9.6%). The *barium* salt, which is less soluble than the sodium salt and crystallises in creamy, glistening leaflets, was prepared by addition of barium chloride to a solution of the sodium salt (Found: Loss at 100°, 6.2.  $C_{14}H_{12}O_{10}N_2S_2Ba \cdot 2H_2O$  requires  $H_2O$ , 6.0%. Found on dried salt: Ba, 24.3.  $C_{14}H_{12}O_{10}N_2S_2Ba$  requires Ba, 24.1%).

In another experiment using 15 g. of acid and 50 c.c. of nitric acid, the solution obtained on pouring the product into water was extracted thrice with ether. The ethereal extract was freed from acids by extraction with alkali and on evaporation gave 0.75 g., a 6.3% yield, of *p*-nitrotoluene. The main bulk melted at 54°, as did a mixture with pure *p*-nitrotoluene, but a trace melted 10° higher, suggesting the presence of 2:4-dinitrotoluene.

**3'-Nitro-4'-toluenesulphonyl-4-aminophenylarsinic Acid** (IV; R = Me).—Sodium *p*-aminophenylarsinate was submitted to the action of *m*-nitro-*p*-toluenesulphonyl chloride (2 mols.) by the Fischer-Bergell process described above. The yield of required acid was 77%. It is sparingly soluble in boiling water and crystallises therefrom in minute, rectangular plates (Found: S, 7.8.  $C_{13}H_{13}O_7N_2AsS$  requires S, 7.7%). The maximum tolerated dose for mice is 0.3 mg. per g. of mouse and subsequent toxicities are expressed on the same basis.

**3'-Nitro-4'-toluenesulphonyl-4-methylaminophenylarsinic Acid** (VI).—This acid was obtained in 93% yield by methylation of the preceding acid by the process described for its analogue without the nitro-group. It is not formed in recognisable quantity by methylation at room temperature, using a large excess of methyl sulphate and a variety of concentrations of potassium or sodium hydroxide. It is soluble in 200 parts of boiling water and crystallises in feathery needles, but from alcohol in large, hexagonal plates and from 90% formic acid in diamond-shaped plates (Found: S, 7.3.  $C_{14}H_{15}O_7N_2SAs$  requires S, 7.4%). The maximum tolerated dose is 0.03 mg.

**3'-Amino-4'-toluenesulphonyl-4-aminophenylarsinic Acid**.—The nitro-acid (8.3 g.) was reduced with ferrous chloride and alkali as

described in previous papers of this series. The alkaline extracts (0.2*N*-NaOH) of the ferric hydroxide precipitate were neutralised to Congo-paper, and the crystalline amino-acid which separated was kept over-night. It was collected, dissolved in 140 c.c. of *N*-hydrochloric acid at 50°, and when precipitated by careful addition of saturated sodium acetate separated in small, prismatic needles. The first precipitation mother-liquors treated at 100° with ammonia and magnesium chloride gave a small quantity of *magnesium* salt which gave a further small proportion of the required amino-acid. The total yield was 73% (Found: S, 8.3.  $C_{13}H_{15}O_5N_2SAs$  requires S, 8.3%). This *amino-acid* is readily soluble in 2*N*- or 3*N*-mineral acids, the *hydrochloride* being precipitated in small, oblique rhombs by concentrated hydrochloric acid. The maximum tolerated dose is 0.2 mg.

*3'-Amino-4'-toluenesulphonyl-4-aminophenylarsenious Oxide*.—The foregoing acid (1.8 g.) was dissolved in 10.8 c.c. of water with the aid of 8.2 c.c. of concentrated hydrochloric acid. On addition of 0.45 g. of potassium iodide in a few drops of water there was rapid separation of iodine and a brown gum, but on passing sulphur dioxide for successive  $\frac{1}{2}$ -hour intervals with intermediate kneading of the now pale yellow gum, it eventually crystallised completely in almost quantitative yield. It was titrated by Ehrlich and Berthelm's method for *p*-aminophenylarsenious oxide (*Ber.*, 1910, 43, 917) (Found: 0.2185 g., dry, required 9.02 c.c. of *N*/10-iodine. Calc. for  $C_{13}H_{13}O_3N_2SAs$ : 9.06 c.c.). The agreement is fortuitous, as the product contained hydrochloride. It was dissolved in water, and the free *oxide* precipitated as a white, amorphous powder by addition of sodium hydrogen carbonate (Found: 0.2132 g. equiv. to 11.53 c.c. of *N*/10-iodine. Calc.: 12.04 c.c. Whence the purity was 96%). This arsenious oxide reduces ammoniacal silver solution only on warming. It is readily soluble in *N*-hydrochloric acid and diazotises and couples in the usual way. It is also readily soluble in 0.5*N*-sodium carbonate and 2*N*-ammonia but not in sodium hydrogen carbonate.

*3'-Aminotoluenesulphonyl-4-aminoarsenobenzene*.—The foregoing arsenious oxide (1.25 g.) was dissolved in water (6 c.c.) with addition of 6 c.c. of hypophosphorous acid (*d* 1.137) and a crystal of potassium iodide. The solution was stirred and the temperature slowly raised to 80°. The arsenobenzene separated in microscopic needles which were centrifuged off, washed first with water and then with sodium hydrogen carbonate solution, and finally with several changes of water. The crystalline character was retained throughout. The yield was 1.1 g. The same compound was also obtained in the crystalline state very readily by reduction of the corresponding acid

at 50—55° (Found : 0.1158 g. required 13.9 c.c. of *N*/10-iodine in the presence of sodium acetate. Calc. : 13.7 c.c. Found : As, as  $\text{Mg}_2\text{As}_2\text{O}_7$ , 22.6.  $\text{C}_{26}\text{H}_{26}\text{O}_4\text{N}_4\text{As}_2\text{S}_2$  requires As, 22.3%). This arseno-compound is white or of a pale cream colour. It is readily soluble in molten phenol, but insoluble in acetic acid. It is insoluble in mineral acids, but dissolves on addition of nitrite and then couples in the usual way. It dissolves in an equivalent amount of sodium hydroxide, but is precipitated as the sodium salt by a slight excess. It is also slowly soluble in sodium carbonate solution. The dried powder is very easily electrified and consequently very difficult to handle. The maximum tolerated dose is 0.1 mg.

*3'-Amino-4'-toluenesulphonyl-4-methylaminophenylarsinic Acid.*—This acid was obtained in 75.3% yield by reduction of the corresponding nitro-acid with ferrous chloride and alkali. It was purified by solution in *N*-hydrochloric acid and precipitation by sodium acetate (Found : S, 8.1.  $\text{C}_{14}\text{H}_{17}\text{O}_5\text{N}_2\text{SAs}$  requires S, 8.0%). This acid crystallises readily from boiling water in clusters of thin plates. It is readily soluble in warm *N*-hydrochloric acid, the *hydrochloride* crystallising in prisms. The *sulphate* and *nitrate* are sparingly soluble in their respective *N*-acids and both crystallise in fine needles. The maximum tolerated dose is 0.03 mg.

*3 : 3'-Dinitro-4'-toluenesulphonyl-4-aminophenylarsinic Acid* (V; R = Me).—This acid was prepared in 73% yield from 8.3 g. of 3'-nitrotoluenesulphonyl-4-aminophenylarsinic acid, dissolved in 25 c.c. of sulphuric acid and nitrated with 2 g. of nitric acid (*d* 1.42) in 2 g. of sulphuric acid. It crystallises from boiling water, in which it is sparingly soluble, in very small needles, and from glacial acetic acid, in which it is moderately soluble, in bunches of small, prismatic needles (Found : S, 6.9.  $\text{C}_{13}\text{H}_{12}\text{O}_9\text{N}_3\text{SAs}$  requires S, 6.9%). The maximum tolerated dose is 0.1 mg.

*3 : 3'-Diamino-4'-toluenesulphonyl-4-aminophenylarsinic Acid.*—This acid was prepared by reduction of the preceding dinitro-acid (9.2 g.) with ferrous chloride and alkali. The alkaline extracts of the ferric hydroxide gave 2.7 g. of acid by direct precipitation and 2.0 g. by way of the *magnesium* salt in hot ammoniacal solution. The total yield was 60%. This *diamino-acid*, precipitated from acid solution by sodium acetate, separates in small, rhomb-shaped plates. It is very soluble in dilute mineral acids and diazotises and couples with alkaline  $\beta$ -naphthol with a blood-red colour (Found : As, 18.9.  $\text{C}_{13}\text{H}_{16}\text{O}_5\text{N}_3\text{SAs}$  requires As, 18.7%). The maximum tolerated dose is 0.5 mg.

*3 : 3'-Diamino-4'-toluenesulphonyl-4-aminophenylarsenious Oxide.*—One g. of the preceding acid was dissolved in 4.5 c.c. of con-

centrated hydrochloric acid and 6 c.c. of water. Potassium iodide (0.25 g.) was added and sulphur dioxide passed for an hour. A crystalline salt separated in long, yellow needles (Found for anhydrous material: 0.1138 g. equiv. to 3.57 c.c. of *N*/10-iodine. Calc. for the pure dihydriodide: 3.97 c.c.). The remainder was dissolved in water, and the oxide precipitated with sodium hydrogen carbonate. The yield was 0.4 g. (Found for anhydrous oxide: 0.1623 g. equiv. to 8.41 c.c. of *N*/10-iodine.  $C_{13}H_{14}O_3N_3SAs$  requires 8.84 c.c. Hence the purity was 95%).

*3'-Nitrobenzenesulphonyl-4-aminophenylarsinic Acid* (IV; *R* = H).—This acid was prepared from sodium *p*-aminophenylarsinate (1 mol.) and finely powdered nitrobenzenesulphonyl chloride (2 mols.) by the Fischer-Bergell method. The yield was 69% (Found: S, 7.7.  $C_{12}H_{11}O_7N_2SAs$  requires S, 8.0%). It is soluble in boiling 90% formic acid, and crystallises in short prisms, less readily in boiling acetic acid and very sparingly in boiling water. The maximum tolerated dose is 0.4 mg.

*3'-Aminobenzenesulphonyl-4-aminophenylarsinic Acid*.—The corresponding nitro-acid was reduced by ferrous chloride and alkali in the usual way at 0°, and the amino-acid isolated through its *magnesium* salt in hot ammoniacal solution. The yield was 70%. It is best purified as its *hydrochloride*, which is only moderately soluble in cold water and separates readily on addition of stronger acid in rhomb-shaped plates (Found: Cl, 8.5.  $C_{12}H_{13}O_5N_2SAs.HCl$  requires Cl, 8.7%). On addition of saturated sodium acetate solution to a warm concentrated solution of the hydrochloride, the *amino-arsinic acid* separates as a gum which rapidly crystallises, on rubbing, in long, narrow plates with sloping ends. It is moderately soluble in cold water. The maximum tolerated dose is 0.5 mg.

*3'-Aminobenzenesulphonyl-4-aminoarsenobenzene*.—This was prepared from the corresponding acid by means of hypophosphorous acid at 45–50° in the usual way (Found: As, 23.6.  $C_{24}H_{22}O_4N_4S_2As_2$  requires As, 23.3%). It is a white or creamy-white, amorphous powder when dry, soluble in sodium hydroxide, and slowly soluble in sodium carbonate solution. It dissolves in molten phenol, but the solution soon becomes turbid and finally fills with a finely-divided precipitate.

*3:3'-Dinitrobenzenesulphonyl-4-aminophenylarsinic Acid* (V; *R* = H).—*3'-Nitrobenzenesulphonyl-4-aminophenylarsinic acid* (10.0 g.) in 30 c.c. of sulphuric acid was slowly treated at 0° with nitric acid (1.75 c.c.; *d* 1.42) dissolved in a little sulphuric acid (5 c.c.). After 30 minutes, the solution was poured on to ice. The yield was 93%. This *dinitro-acid* crystallises well from boiling water, in which it is sparingly soluble, in short needles and similarly

from boiling 90% formic acid, in which it is readily soluble (Found : S, 7.2.  $C_{12}H_{10}O_9N_3SAs$  requires S, 7.2%). On boiling with 32% hydrochloric acid for 8 hours, it was only partly hydrolysed, giving an 83% yield of 3-nitro-4-aminophenylarsinic acid. No 4-aminophenylarsinic acid could be detected in the mother-liquors. The maximum tolerated dose is 0.1 mg.

3 : 3' - *Diaminobenzenesulphonyl-4-aminophenylarsinic Acid*.—Reduction of the corresponding dinitro-acid by ferrous chloride and alkali at 0° gave this *diamino-acid* in 70% yield. It was isolated through the magnesium salt in ammoniacal solution (Found : As, 19.5.  $C_{12}H_{14}O_5N_3SAs$  requires As, 19.4%). When liberated from acid solution by addition of sodium acetate, it crystallises in slightly distorted, diamond-shaped plates. The maximum tolerated dose is 1.5 mg.

3' - *Nitrobenzenesulphonyl-3-amino-4-hydroxyphenylarsinic Acid*.—3-Amino-4-hydroxyphenylarsinic acid (11.6 g.) was dissolved in water (60 c.c.) with the aid of 3.85 g. of anhydrous sodium carbonate. Nitrobenzenesulphonyl chloride (2 mols.; 22 g.) was added at once and a few drops of ether. The mixture was shaken for 30 minutes, and three successive portions of *N*-sodium carbonate (1 mol.) at 30-minute intervals were then added with intermediate shaking. The solution, on being made definitely acid to Congo-paper, deposited a pale-coloured gum immediately and, after 12 hours in the cold room, a crystalline powder. These were collected and stirred with 75 c.c. of *N*-hydrochloric acid in the boiling water-bath until the non-soluble portion had crystallised. This treatment was essential to remove aminohydroxyphenylarsinic acid carried down from acid solution with the gum. The crystalline, chalky solid obtained on cooling was a complex mixture probably containing *O*- and di-*N*-sulphonylated derivatives (Found : S, 9.0. A disulphonamide requires S, 10.6%). It was dissolved in 20 volumes of 0.5*N*-sodium hydroxide, boiled for 30 minutes, and while still hot treated with concentrated hydrochloric acid so long as an oily turbidity was produced. After brief stirring, the hot solution was freed from oil by filtration through a fluted paper. The filtrate showed no further tendency to deposit oil, but deposited the required nitro-acid in a crystalline state. The original mother-liquors on concentration under reduced pressure gave a succession of crops of the required nitro-acid and unchanged aminohydroxyphenylarsinic acid separable by extraction with *N*-hydrochloric acid. The total yield was 33%. If one molecular proportion of sulphonyl chloride was originally used instead of two, the same difficulties were encountered and the yield was 28%. For analysis, the *acid* was recrystallised from 20 volumes of boiling water, from which it crystallised extremely well

as a *dihydrate* in large, straw-coloured prisms or rhombs (Found : Loss at  $95^{\circ}$ , 8.4.  $C_{12}H_{11}O_8N_2SAs \cdot 2H_2O$  requires  $H_2O$ , 7.9%. Found on anhydrous material : S, 8.0.  $C_{12}H_{11}O_8N_2SAs$  requires S, 7.7%). When dissolved in sodium hydrogen carbonate solution and treated with a drop of dilute ferric chloride, it gives an intense purple solution which on addition of caustic alkali becomes redder ; the colour is discharged by excess of caustic alkali with separation of ferric hydroxide. On addition of acid, however, to neutrality to litmus, the colour is also discharged with precipitation of a grey, amorphous precipitate which, after separation, redissolves in sodium hydrogen carbonate solution with the same purple colour. In a similar way, cobalt nitrate gives a rose-coloured solution with an absorption band in the yellowish-green part of the spectrum. The reaction is more intense in sodium carbonate solution, but is discharged by excess of acid or caustic alkali. A nickel salt gives a clear yellowish-brown solution, whilst a copper salt gives an intense deep brown solution. The maximum tolerated dose is 0.5 mg.

*3'-Aminobenzenesulphonyl-3-amino-4-hydroxyphenylarsinic Acid.*—The reduction of the foregoing nitro-acid was carried out with ferrous chloride and alkali. The isolation of the pure amino-acid was effected as follows. The filtrate from the ferric hydroxide together with the alkaline extracts (0.2*N*-sodium hydroxide) of the ferric hydroxide was of a deep purple colour, and on being made neutral to Congo-paper deposited, after standing for 12 hours, the required amino-acid mixed with an amorphous, grey complex of ferric hydroxide and the amino-acid. These were collected, dissolved in 2*N*-sodium hydroxide, and filtered from the ferric hydroxide, which separated in part. The filtrate, on being made neutral to litmus, deposited the remainder of the bound iron as the complex, which could be removed, and thereafter the pure amino-acid was obtained on making the filtrate neutral to Congo-paper. The iron complex could be re-submitted to the same treatment with caustic alkali, when ferric hydroxide was again precipitated, but not quite completely, and the filtrate gave a further small crop of iron complex and the pure amino-acid on being made neutral to litmus and Congo-paper, respectively. The original mother-liquors, on concentration under reduced pressure, yielded further crops of pure amino-acid. For physiological testing and analysis, the combined crops of amino-acid were dissolved in *N*-hydrochloric acid and precipitated with saturated sodium acetate solution. The yield was 76% (Found : Loss at  $95^{\circ}$ , 7.5 ; S, 7.5.  $C_{12}H_{13}O_6N_2SAs \cdot 2H_2O$  requires  $H_2O$ , 8.1 ; S, 7.6%). It crystallises from boiling water, in which it is fairly readily soluble, in glistening prisms. It is readily soluble in *N*-hydro-

chloric, nitric, or sulphuric acid. The *hydrochloride* crystallises in rectangular tablets, the *sulphate* in short needles, and the *nitrate* in prisms. In sodium hydrogen carbonate solution, the amino-acid gives a purple colour with ferric chloride and on neutralisation to litmus a complex containing iron is precipitated as a dove-grey powder. Some preparations, however, are almost black. This is free from chloride and dissolves in sodium hydrogen carbonate with restoration of the purple colour (Found on air-dried material: Fe, 10.4; S, 6.5, whence  $\text{Fe} : \text{S} = 1 : 1.08$ ). The rose-pink colour developed on similar addition of cobalt nitrate is very marked. There is an absorption band in the yellowish-green. A soluble nickel complex is similarly formed with a yellowish-brown colour, and with copper salts a very intense brownish-red solution is obtained showing considerable stability to caustic alkali. The maximum tolerated dose is 0.5 mg.

*3'-Nitrobenzenesulphonyl-4-amino-2-hydroxyphenylarsinic Acid.*—4-Amino-2-hydroxyphenylarsinic acid (11.6 g.) was converted into the sulphonamide by the Fischer-Bergell process, nitrobenzenesulphonyl chloride (2 mols.) being used. The solution, on being made acid to Congo-paper, deposited a gum and, on standing some hours, a crop of crystals. The total precipitate was collected and warmed on the water-bath with *N*-hydrochloric acid; it then became wholly crystalline. It was dissolved in 10 volumes of *N*-sodium hydroxide and heated on the water-bath for 30 minutes. The *nitro-acid* was obtained on acidification in colourless needles rapidly transforming to plates; yield 9.1 g. The original mother-liquors contained additional acid, which was isolated by concentration. This acid is a dihydrate (Found: Loss at  $95^\circ$ , 8.4.  $\text{C}_{12}\text{H}_{11}\text{O}_8\text{N}_2\text{SAs} \cdot 2\text{H}_2\text{O}$  requires  $\text{H}_2\text{O}$ , 8.2%. Found on anhydrous material: S, 8.0, 7.6.  $\text{C}_{12}\text{H}_{11}\text{O}_8\text{N}_2\text{SAs}$  requires S, 7.7%). It is soluble in 32 parts of boiling water and separates in very pale buff-coloured rhombs or prisms. (For its colour reactions, see next paragraph.) The maximum tolerated dose is 0.2 mg.

*3'-Aminobenzenesulphonyl-4-amino-2-hydroxyphenylarsinic Acid.*—This acid was prepared from the nitro-acid in 63% yield by means of ferrous chloride and alkali. It tends to form an iron complex in the alkaline extracts of the ferric hydroxide precipitate just as does its isomeride described above. It can be isolated, however, in exactly the same way (Found: S, 8.1.  $\text{C}_{12}\text{H}_{13}\text{O}_6\text{N}_2\text{SAs}$  requires S, 8.3%). It is readily soluble in boiling water and crystallises in tufts of fine needles. In *N*-mineral acids it is very readily soluble. When dissolved in sodium hydrogen carbonate solution, it gives a clear deep yellowish-brown colour with ferric chloride and a bright emerald-green colour with copper sulphate. Under comparable

conditions, the parent nitro-acid gives with ferric chloride a clear reddish-brown solution and with copper salts an olive-green solution. The parent acid of this group, 4-amino-2-hydroxyphenylarsinic acid, gives a reddish-brown solution with ferric salts and an emerald-green solution with copper sulphate. The maximum tolerated dose is 0.025 mg.

*N-p-Toluenesulphonyl-o-aminophenol* (VIII;  $R = H$ ).—When prepared by the process described by Reverdin and de Luc (*Ber.*, 1914, 47, 1538) for the isomeric derivative of *m*-aminophenol, this sulphonamide was obtained in very good yield and agreed in properties with the description given by Tröger and Ullmann (*J. pr. Chem.*, 1895, 51, 441). It dissolves on warming with dilute aqueous sodium carbonate; the solution becomes turbid on cooling and gives a bright purple colour on addition of ferric chloride. With cobalt nitrate, it gives a pink colour with an absorption band in the yellow-green.

*N-p-Toluenesulphonyl-o-methylaminophenol* (IX) was prepared by extending Reverdin and de Luc's method to *o*-methylaminophenol. *o*-Methylaminophenol sulphate ("Ortol," 4.3 g.) and sodium acetate (6.8 g.; hydrated) were dissolved in 50% alcohol (100 c.c.) and heated for 30 minutes on the water-bath, *p*-toluenesulphonyl chloride (4.75 g.) being added in several portions from time to time. On cooling, *N-p-toluenesulphonyl-o-methylaminophenol* (4.6 g.) separated in white needles. It was recrystallised from glacial acetic acid and showed m. p. 127—128° (Found: S, 11.3.  $C_{14}H_{15}O_3NS$  requires S, 11.6%). It is readily soluble in caustic alkali but insoluble in dilute acids. It is unchanged by nitrous acid. Its solution in boiling dilute aqueous sodium carbonate becomes turbid on cooling, but gives no purple colour with ferric chloride and no pink colour with cobalt nitrate.

*N-4-Toluenesulphonyl-3-amino-4-hydroxybenzoic Acid* (VIII;  $R = CO_2H$ ).—Aminohydroxybenzoic acid (1.5 g.) was dissolved in 10 c.c. of pyridine and treated with 2.37 g. of toluenesulphonyl chloride. After 12 hours, the mixture was poured into *N*-hydrochloric acid, the solid collected, and boiled for 30 minutes with *N*-sodium hydroxide. On acidification the sulphonamide separated straightway almost pure in 77% yield. For analysis it (2.3 g.) was recrystallised from the minimum volume (50 c.c.) of 50% (by vol.) acetic acid and separated in glistening, pale straw-coloured, wedge-shaped prisms, m. p. 250° (decomp.) (Found: S, 10.7.  $C_{14}H_{13}O_5NS$  requires S, 10.4%). In sodium hydrogen carbonate solution it gives an intense purple colour with ferric chloride and a bright pink colour with cobalt nitrate, the solution showing an absorption band in the yellowish-green part of the spectrum.

*N-p-Toluenesulphonyl-p-methylaminophenol* was prepared following Reverdin's directions for his so-called *O-toluenesulphonyl-N-p-monomethylaminophenol*. It melts at 136–137° (Reverdin gives 135°) and crystallises in needles from dilute alcohol or benzene. It is insoluble in dilute acids and unchanged by nitrous acid, but is readily soluble in sodium hydroxide and in sodium carbonate solution on warming. When dissolved in sodium carbonate solution, it does not give a coloration with ferric chloride.

*p-Xanthylphenylarsinic Acid* (XII).—Sodium *p*-aminophenylarsinate pentahydrate (32.9 g.) was diazotised at 0° in 200 c.c. of water and 30 g. of concentrated hydrochloric acid, and the product run slowly into a rapidly stirred solution of 20 g. of potassium xanthate in 420 c.c. of a 10% solution of hydrated sodium carbonate, kept at 80°. After being stirred for 1 hour, the solution was cooled and acidified. The precipitated resin solidified after a few hours and was submitted to a partial purification by dissolution in sodium carbonate solution, filtration from insoluble by-products, and reprecipitation by acids. The yield of crude xanthate was 62% (Found: S, 18.8.  $C_9H_{11}O_4S_2As$  requires S, 19.9%). The acid could not be obtained crystalline nor of a higher sulphur content, but it behaved normally on oxidation.

*Oxidation of p-Xanthylphenylarsinic Acid*.—Five g. of crude *p*-xanthylphenylarsinic acid were heated on the water-bath for 2 hours with 100 c.c. of 3*N*-nitric acid and finally to boiling for  $\frac{1}{2}$  hour. When cold, the crystalline acid was collected (yield 82%). *Diphenyl disulphide pp'-diarsinic acid* (XIII) dissolves in 900 parts of boiling water, from which it crystallises in narrow plates or needles. It crystallises much more readily from 200 parts of 2*N*-nitric acid (Found: As, 32.2; S, 13.9.  $C_{12}H_{12}O_6S_2As_2$  requires As, 32.2; S, 13.8%). A 1% solution in 0.2*N*-ammonia treated with 5% barium chloride solution gave, on heating, a *barium* salt crystallising in needles. On cooling, the barium salt rapidly re-dissolved, but was again precipitated on heating. The acid has a maximum tolerated dose of 0.002 mg.

The nitric acid mother-liquors of the above oxidation were evaporated to a syrup with repeated additions of water to remove the excess of nitric acid. They were then diluted and treated with sufficient baryta to precipitate the sulphuric acid present. On evaporation the solution set to a crystalline magma of *p-sulphophenylarsinic acid* (XIV). This was redissolved in water, and the solution evaporated until a crust formed. On keeping, the acid separated in long prisms. These are extremely soluble in water, but can be freed from the mother-liquors by washing with glacial acetic acid. The whole of the *p*-xanthylphenylarsinic acid unaccounted

for as disulphide appears to be present as sulpho-acid. The sulpho-acid was, however, more readily obtained as follows. The disulphide (5 g.) was boiled with 50 c.c. of 6*N*-nitric acid for 4 hours. The clear solution was evaporated dry and left 6.0 g. of crude sulpho-arsinic acid. This was crystallised once from water and washed with glacial acetic acid (Found: Loss at 95°, 5.8.  $C_6H_7O_6SAs.H_2O$  requires  $H_2O$ , 6.0%. Found on anhydrous material: S, 11.6.  $C_6H_7O_6SAs$  requires S, 11.4%). This acid also crystallises occasionally in hexagonal plates, possibly an anhydrous form, as it frequently appears as a crust on the surface of hot saturated solutions. The maximum tolerated dose is 0.5 mg.

The disulphide is reduced by hypophosphorous acid in the presence of a trace of iodide to an insoluble, yellow arseno-compound, probably *thiolarsenobenzene*, because it is insoluble in sodium hydrogen carbonate but soluble in caustic alkali. Under similar conditions, at 50–55° *p*-sulphophenylarsinic acid is reduced to *p*-sulphophenylarsenobenzene, which is very soluble in water and can be isolated in a crude condition as a yellow, gelatinous product by evaporation of the reduction liquors in a vacuum over sulphuric acid.

HAMPSTEAD, N.W. 3.

[Received, February 24th, 1926.]

## CLXXVII.—*The Action of Phosphorus on Salts of Silver and Other Metals.*

By OSWALD JAMES WALKER.

It has long been known that yellow phosphorus is able to precipitate many heavy metals from solutions of their salts, and attempts have been made to obtain quantitative information about the phenomenon by determining the ratio of metal deposited to phosphorus which had reacted. Using solutions of copper sulphate, Straub (*Z. anorg. Chem.*, 1903, **35**, 460) investigated the ratio of the amount of copper deposited to the total amount of phosphorus which had reacted (*i.e.*, phosphorus as phosphide and phosphoric acid), but he did not obtain any definite value. He concluded that the action proceeded in stages, and that when it was incomplete or when atmospheric oxygen was rigorously excluded 1 atom of phosphorus precipitated 2 atoms of copper. Tauchert (*Z. anorg. Chem.*, 1913, **79**, 350) obtained similar results, but stated that hypophosphoric acid was one of the products. Bird and Diggs (*J. Amer. Chem. Soc.*, 1914, **36**, 1382) also investigated the action of phosphorus on copper sulphate and concluded that the main

action consisted in the transfer of positive charges from the copper ions to the phosphorus, as follows :

the positive phosphorus ions reacting immediately with water to form phosphoric acid. In support of their theory, Bird and Diggs found that the ratio of atoms of copper precipitated to phosphorus oxidised to phosphoric acid was approximately 5 : 2. In obtaining this ratio, however, they did not include the amount of phosphorus present as lower acids and as phosphide. They ascribed these products to secondary reactions.

#### EXPERIMENTAL.

In order to determine to what extent phosphorus reacts with solutions of salts of the heavy metals and to decide which metal would be most suitable for a more detailed investigation, sticks of phosphorus were kept in contact with solutions of salts of a large number of different metals. Deposits of metallic appearance were found on the surface of the phosphorus after varying intervals with neutral or slightly acid solutions of salts of the following metals—gold, platinum, palladium, silver, mercury, and copper. No action was observed, even after several weeks, with salts of metals below copper in the electrochemical series, provided that the solution was not alkaline. In ammoniacal solution, however, salts of the following metals also gave deposits on the surface of the phosphorus—lead, nickel, thallium, and, not quite so readily, tin, cobalt, cadmium, and zinc. An interesting point of considerable importance is revealed by comparing these results with the data which are available for the action of phosphine on metallic salt solutions in papers by Kulisch (*Annalen*, 1885, **231**, 327), Moser and Brukl (*Z. anorg. Chem.*, 1922, **121**, 73), and Brukl (*ibid.*, 1922, **125**, 252). An examination of their results shows that those solutions which react with phosphine are exactly those which give deposits on phosphorus, and the metals may be divided into the same two groups mentioned above with respect to the action of phosphine on their salt solutions. Reference to this point will be made at a later stage.

From the above experiments, the most suitable salts for a more detailed investigation seemed to be those of silver and copper. As silver salts had not been used previously in any quantitative study, it was decided to examine more closely the action of phosphorus on them and especially on the nitrate. There is no possibility in this case of the metal being reduced to a lower stage of valency, and, as will be shown below, the complications due to the

formation of phosphide are not so great as with copper salts. In order to minimise any oxidising effect due to the free nitric acid formed, concentrations not greater than  $N/10$  were used as a rule.

*Action of Yellow Phosphorus on Silver Salts.*

The phosphorus used throughout the course of this work was purified by warming with caustic soda solution, then with potassium dichromate and sulphuric acid, followed by thorough washing. It was cast into thin sticks and kept under water in the dark.

When a stick of phosphorus was placed in a  $N/10$ -solution of silver nitrate, a black, shiny deposit was formed almost immediately on the surface of the phosphorus; bright crystalline silver was then slowly deposited which finally became grey and spongy when it was all out of solution. After complete deposition of the silver, the solution contained phosphoric, phosphorous, and nitric acids, and traces of nitrous acid. No hypophosphorous acid, hypophosphoric acid, or ammonia was detected. The deposit consisted almost entirely of metallic silver, but contained a small amount of phosphorus, due to a thin, darker layer next to the surface of the phosphorus stick. This thin layer appeared to be a phosphide of silver and was probably the same as the black deposit first formed when the phosphorus was placed in the silver nitrate solution. The amount of phosphorus present in the deposit was small compared with that in the solution as oxy-acids. The question of phosphide formation will be considered later.

With solutions of silver sulphate and of silver acetate the reaction proceeded in a similar way. When phosphorus was placed in an ammoniacal solution of silver nitrate, a black deposit was formed which was converted, after some time, into white, crystalline silver. With a solution of silver cyanide in potassium cyanide a black deposit was very slowly formed on the surface of the phosphorus.

*Quantitative Experiments with Silver Salts.*—Experiments were made in the first place to determine whether any definite relationship existed between the amount of silver deposited and the total amount of phosphorus oxidised. Preliminary determinations showed that the ratio of the number of atoms of silver precipitated to the number of atoms of phosphorus oxidised, denoted hereafter as  $Ag : P$ , varied with the length of time during which the phosphorus had remained in contact with the solution. Accordingly, the ratio  $Ag : P$  was determined before complete precipitation of the silver had taken place.

Sticks of phosphorus were placed in solutions of silver nitrate, and portions withdrawn at intervals for the determination of the

amounts of silver salt and of phosphorus acids in the solution. The silver was determined in one portion by Volhard's method. A second portion was evaporated to dryness with aqua regia in order to ensure complete oxidation of the phosphorous acid, and the phosphoric acid was determined gravimetrically as magnesium pyrophosphate. In later experiments, this method was replaced by the more convenient volumetric method of Wilkie (*J. Soc. Chem. Ind.*, 1910, **29**, 794), in which the phosphoric acid was precipitated under given conditions as silver phosphate by means of standard silver nitrate solution, the excess of silver nitrate being titrated with thiocyanate solution after filtering.

The results of several experiments with solutions of silver nitrate are in Table I, all concentrations being given in g.-atoms or g.-mols. per litre. The general conclusions may be summarised as follows :

1. The ratio Ag : P varied during the deposition of the silver from a value of more than 5 : 1 near the beginning of the reaction to about 3.6 : 1 at the point corresponding to complete deposition of the silver.

2. No appreciable oxidation of the phosphorus by the oxy-acid set free from the metallic salt took place. Experiments in which solutions of the sulphate were used, in order to avoid the formation of nitric acid, gave results similar to those obtained with the nitrate solutions.

3. The phosphorus was not appreciably oxidised by atmospheric oxygen. Similar results were obtained whether air was bubbled through the solution (Expt. 3) or completely excluded (Expt. 4) during the deposition of the silver.

4. The oxygen necessary for the oxidation of the phosphorus must therefore come from the decomposition of the water.

A further slow oxidation of the phosphorus took place even after complete precipitation of the silver. This is shown by the results in Table II. In these experiments equal quantities of a standard silver nitrate solution were sealed up with phosphorus sticks in small bulbs. After sufficient time had elapsed to allow all the silver to be deposited, the bulbs were opened at varying intervals and the total phosphorus acids were determined in the solution. It will be seen that the quantity of phosphorus oxidised increases with the time, and that the values of the ratio Ag : P are much lower than those obtained before complete precipitation of the silver.

TABLE II.

Expt.	Time (days).	Ag pptd.	P oxid.	Ag : P.
1	6	0.00250	0.000717	3.49
	9		0.000807	3.10
	14		0.000865	2.89
2	7	0.00277	0.000857	3.23
	17		0.00120	2.31

The points obtained by plotting against one another the values of silver precipitated and phosphorus oxidised before complete precipitation of the silver lie approximately on a straight line which corresponds to a constant ratio of Ag : P of 4 : 1 but which does not pass through the origin. The ratio Ag : P calculated from the actual values of silver precipitated and phosphorus oxidised has, on the other hand, been shown to decrease with time. If, however, the ratio Ag : P is calculated by taking, not the values of total silver precipitated and total phosphorus oxidised from the beginning of the reaction, but the differences between subsequent values and the first value ( $a_0$  or  $b_0$ ) in each experiment, a much more constant ratio Ag : P is obtained, as shown in the last column of Table I. The average value is 4.0 : 1, if the two values shown in brackets, which are obtained from small differences, are neglected.

It would appear, therefore, that whilst at the beginning of the reaction the ratio Ag : P is higher than 4 : 1, after a certain time the main reaction taking place corresponds approximately to the precipitation of 4 atoms of silver for every atom of phosphorus oxidised.

*Formation of Phosphorous Acid.*—It was thought desirable to examine whether any definite relationship existed between the amounts of silver deposited and of phosphorous acid formed. Bird and Diggs supposed that the formation of phosphorous acid was due to the reduction of the phosphoric acid by the excess of

phosphorus, but this is most improbable. The further reaction between the phosphorous acid formed and the silver nitrate still in solution would, of course, introduce a complication, but experiments made to test this reaction showed that it was negligible in the concentrations used.

Phosphorus sticks were placed in solutions of silver nitrate and the amounts of phosphorous acid and of silver salt in the solution were determined at intervals. Phosphorous acid was estimated by the iodimetric method of Boyer and Bauzil (*J. Pharm. Chim.*, 1918, 18, 321), after the excess of silver salt had been precipitated with potassium iodide. The results of several experiments are in Table III.

		0.0910	18.4	0.00922	10.0	6.3

With *N*/10-solutions, the ratio of silver precipitated to phosphorous acid formed (Ag : H<sub>3</sub>PO<sub>3</sub>) is fairly constant, with the exception of one determination which was made near the beginning of the reaction. In Expts. 3 and 4, *N*/2-silver nitrate was used and determinations of the ratio Ag : H<sub>3</sub>PO<sub>3</sub> were made before 25% of the total silver had been precipitated. The results are higher and not constant. If, however, the values of silver precipitated and phosphorous acid formed are plotted against one another, the points lie on straight lines having a slope corresponding to a constant ratio of Ag : H<sub>3</sub>PO<sub>3</sub> of 6.3 : 1. By subtracting in each experiment the first values of silver deposited (*a*<sub>0</sub>) and of phosphorous acid formed (*b*<sub>0</sub>) from the subsequent values, and by using these differences to calculate the ratio Ag : H<sub>3</sub>PO<sub>3</sub>, fairly constant figures are obtained, as is shown in the last column of Table III.

From the quantitative experiments already mentioned, it would appear that phosphorous and phosphoric acids are produced simultaneously in constant proportion during the action of phosphorus

on silver nitrate, if we neglect the first stages of the reaction. In the following table are the results of an experiment in which the phosphorous acid and the total oxidised phosphorus ( $\text{H}_3\text{PO}_3 + \text{H}_3\text{PO}_4$ ) were determined in a solution of silver nitrate in contact with phosphorus, at varying intervals before the silver was completely precipitated.

TABLE IV.

$\text{H}_3\text{PO}_3 (= a).$	$\text{H}_3\text{PO}_3 + \text{H}_3\text{PO}_4$ ( $= b$ ).	$a/b.$	$\frac{a-a_0}{b-b_0}.$
0.00318 ( $= a_0$ )	0.00367 ( $= b_0$ )	0.87	—

0.0129	0.0197	0.65	0.60
0.0150	0.0236	0.63	0.59

The figures in the third column show, however, that near the beginning of the reaction phosphorous acid is the chief product formed.

*Electrochemical Nature of the Reaction between Phosphorus and Metallic Salt Solutions.*

Wöhler (*Annalen*, 1851, **79**, 126) found that when phosphorus was placed in a solution of copper sulphate, copper was deposited on a copper wire in contact with the phosphorus. Wicke (*ibid.*, 1852, **82**, 145) likewise noticed that silver was deposited on the surface of a silver wire in contact with phosphorus placed in silver nitrate solution; and Bird and Diggs (*loc. cit.*) described similar experiments which they regarded as evidence strongly in favour of their electrochemical theory.

Experiments were made to determine whether deposition of metal would take place on any conducting surface in contact with the phosphorus. Platinum, gold, silver, and carbon were kept in contact with phosphorus sticks immersed in solutions of silver nitrate or of copper sulphate. In every case silver or copper was deposited on the conducting surface at points far removed from the phosphorus. No metal was deposited on non-conducting surfaces in contact with the phosphorus, such as glass, or on a conducting surface which did not touch the phosphorus.

These experiments suggest that an action of an electrochemical nature is taking place and this is shown more clearly by the following experiment. A stick of phosphorus was fused on to a platinum wire and placed in a porous pot containing *N*/10-silver nitrate and standing in a beaker filled with silver nitrate of the same concentration. The free end of the platinum wire was bent over so as to make metallic connexion between the inner and outer solutions. Silver was deposited on the phosphorus and on the platinum

wire in the inner solution, and after some time the platinum wire dipping into the outer solution was covered with a bright deposit of crystalline silver. Silver was also deposited on the outer wall of the porous diaphragm at points which had apparently no metallic connexion with the platinum wire or with one another. In experiments in which no platinum wire was used, a stick of phosphorus alone being placed in the inner solution, deposition of silver again took place on the outer wall of the porous cell. This was found to be due to silver being deposited in the pores of the diaphragm, thus establishing metallic connexion between the inner and outer solutions. Deposition of silver on the outer wall of the diaphragm took place only when the inner wall was in metallic connexion with the phosphorus. Similar results were obtained by using solutions of silver sulphate or silver acetate.

In all these experiments metal ions were discharged and metal deposited—in some cases at a considerable distance from the surface of the phosphorus—only at such points as were in metallic connexion with the phosphorus surface, the contact being established either by the metal already deposited or by another conductor. The physical state of the silver and copper deposited by means of phosphorus in these experiments strongly resembled the state in which these metals are deposited from their salt solutions by an electric current. These facts favour the view that an action of an electrochemical nature takes place, *i.e.*, a direct discharge of ions to the metallic state.

#### *Formation of a Phosphide.*

The quantitative results show that owing to the formation of a phosphide in the early stages of the reaction the precipitation of the silver is not accompanied by the oxidation of an exactly equivalent amount of phosphorus. It was not found possible to ascertain the constitution of the phosphide formed, but indirect evidence indicates the probability that it is the compound  $\text{Ag}_3\text{P}$ . Moser and Brukl (*Z. anorg. Chem.*, 1922, **121**, 80) obtained this compound by the action of phosphine on silver nitrate solution and showed that it was an unstable substance capable of reacting with an excess of silver salt to give metallic silver and acids of phosphorus. The phosphide obtained by the action of phosphorus on silver nitrate was likewise decomposed by excess of silver salt. The deposit obtained by keeping a stick of phosphorus in silver nitrate solution for a short time was separated from the phosphorus, washed, and placed in *N*/10-silver nitrate. Ten c.c. of this solution, immediately after introduction of the silver deposit, were equivalent to 9.85 c.c. of a thiocyanate solution. After a few days,

10 c.c. required only 9.05 c.c. of the thiocyanate, and the solution gave a precipitate with ammonium molybdate, thus showing that silver had been precipitated and phosphorus oxidised.

The work of Christomanos (*Z. anorg. Chem.*, 1904, **41**, 309) on the action of phosphorus dissolved in ether or in benzene on solutions of copper salts pointed to the formation of a phosphide having the formula  $\text{Cu}_3\text{P}_2$ . In the case of silver salts, a black phosphide was formed, but no definite compound was isolated. Experiments were made to determine the constitution of the phosphide obtained by shaking a solution of silver nitrate with solutions of phosphorus in ether, benzene, and carbon disulphide. The black precipitate so obtained became greyer in colour after standing in contact with excess of silver salt, and it gradually assumed the appearance of metallic silver. The proportion of silver to phosphorus in the black precipitate first formed varied considerably owing to the difficulty in washing it free from excess of phosphorus without causing decomposition. The values obtained for the ratio Ag : P in the washed, but damp, precipitate varied between 2.5 : 1 and 3.9 : 1. It seems probable that, in this case also,  $\text{Ag}_3\text{P}$  is formed.

After a solution of silver nitrate had been shaken with a solution of phosphorus, the aqueous layer always contained phosphorous and phosphoric acids. The ratio of silver precipitated to phosphorus oxidised was determined. In the early stages, when the precipitate was quite black and consisted almost entirely of phosphide, high values of the order of 10 : 1 were obtained for the ratio Ag : P. When the mixture had stood for several days until the precipitate appeared to consist wholly of metallic silver, the ratio Ag : P lay between 5 : 1 and 3 : 1, i.e., the values were of the same order as those obtained in the experiments with phosphorus sticks. The presence of phosphorous acid in the above experiments was due to the first reaction, viz., the formation of phosphide. Silver phosphide, prepared by the action of phosphine or of solutions of phosphorus in various solvents, was washed and placed in a fresh quantity of silver nitrate solution. The phosphide was slowly oxidised to silver and phosphoric acid, no phosphorous acid being produced.

#### *Action of Phosphorus on Solutions of Copper Salts.*

The amount of phosphide formed in the case of copper salts was quite appreciable. Experiments with *N*/10-copper sulphate showed that, at the point corresponding to complete precipitation of the copper, about 13% of the total phosphorus which had reacted was present as phosphide, the remainder being in the solution as phosphorous and phosphoric acids. In the case of silver

salts, practically all the phosphorus which had reacted was present in the solution as oxy-acids.

If, however, the stick of phosphorus covered with the deposit of phosphide and copper was kept in contact with the solution for a long period, more phosphorus was oxidised, even if atmospheric oxygen was excluded, and eventually no phosphide was left in the deposit. This disposes of the suggestion of Bird and Diggs, who stated that the bright deposit of copper on remaining in contact with the phosphorus was gradually converted, as a secondary reaction, into the black phosphide. In the case of copper precipitated from a solution of the sulphate, the deposit was certainly found to turn black on standing, but it then contained no phosphorus. The deposit obtained from copper nitrate solutions retained its bright coppery colour for months. The experimental evidence shows that the phosphide formation takes place between phosphorus and metal ions, and not between phosphorus and the metal.

A determination was made of the ratio between the amounts of copper precipitated and of phosphorus oxidised before complete precipitation of the metal, the procedure being the same as in the case of silver nitrate. *N*/10- and *N*/2-Solutions of copper sulphate and copper nitrate were used. Copper was estimated in the solution volumetrically by means of thiosulphate solution. The values of copper precipitated and of phosphorus oxidised, expressed in g.-atoms per litre, are in Table V, the concentrations of copper salts being expressed in g.-mols. per litre.

TABLE V.

Expt.	Cu salt.	Time (hrs.).	Cu pptd. (= <i>a</i> ).	P oxid. (= <i>b</i> ).	Cu : P (= $2a/b$ ).	$\frac{a-a_0}{b-b_0} \times 2$ .
1	0.05	39	0.0351	0.0145	4.8	—
	CuSO <sub>4</sub>	47	0.0394	0.0170	4.6	3.8

	Cu(NO <sub>3</sub> ) <sub>2</sub>	47	0.0361	0.0156	4.6	4.1
		69	0.0445	0.0199	4.5	3.9
3	0.25	48	0.1523	0.0622	4.9	—
	CuSO <sub>4</sub>	88	0.2407	0.1051	4.6	4.1
4	0.25	40	0.1437	0.0549	5.2	—
	Cu(NO <sub>3</sub> ) <sub>2</sub>	88	0.2483	0.1115	4.5	3.7

The values of the ratio Cu : P have all been multiplied by 2 in order to make them comparable with the values of Ag : P. It will be seen that the value of Cu : P depends on the extent to which the reaction has proceeded. If, however, this ratio is calculated as shown in the last column, the disturbing effect of phosphide formation near the beginning is avoided and more constant values are obtained. As in the case of silver nitrate, after the reaction

between phosphorus and the metallic salt has proceeded for some time, 1 atom of phosphorus is oxidised for every 4 equivalents of the metal deposited.

### *Discussion and Summary.*

From the experiments with silver and copper salts it appears that when a stick of phosphorus is placed in a solution of the metallic salt solution a reaction proceeds in two distinct stages. The first process is the formation of a black phosphide on the surface of the phosphorus; at the same time, the solution is found to contain phosphorous acid. After a layer of the phosphide has been formed, metal begins to be deposited in a bright crystalline state, and phosphorus is oxidised to phosphorous and phosphoric acids. During this stage, approximately 4 equivalents of the metal are deposited for every atom of phosphorus oxidised.

With regard to the formation of a phosphide, there can be little doubt that it is due to the prior production of phosphine by the action of phosphorus on water, another portion of the phosphorus being simultaneously oxidised to phosphorous acid. Strong evidence for this view is obtained from the exact parallelism which exists between the actions of phosphorus and phosphine on salt solutions of the heavy metals; only those metallic salt solutions which give phosphides by the action of phosphine are able to react with phosphorus. Cross and Higgins (J., 1879, 35, 255) found that boiling water was decomposed by phosphorus, which was partly reduced to phosphine and partly oxidised to oxy-acids, and that, in the absence of oxygen, decomposition of the water took place only in the presence of certain metallic salts.

It is suggested, therefore, that the first stage in the action of phosphorus on the metallic salt takes place as follows (M and X representing an equivalent of the positive and negative radicals, respectively) :

The appearance of a deposit of the metal evidently depends on the preliminary formation of the phosphide. It has already been shown that the phosphides of silver and of other metals are capable of reacting with excess of the metallic salt to give the metal and phosphoric acid. The second stage, therefore, appears to be

According to these equations, 4 equivalents of the metal should be deposited for every atom of phosphorus oxidised, and this was the ratio actually obtained with silver and copper salts. The

amount of phosphorous acid, however, was somewhat greater than that required by these equations. It is quite possible that this may be due to the following reaction proceeding to a small extent along with reaction (2) :

As regards the phenomena which have been described as electro-chemical, it must be assumed that reaction (2) is responsible for their appearance. This reaction consists essentially in the discharge of positive metal ions while phosphorus becomes oxidised, *i.e.*, loses electrons. The ionic process may be represented as  $\text{M}_3\text{P} + 5\text{M}' = 8\text{M} + \text{P}^{\text{*****}}$ , the positive phosphorus ions reacting immediately with water to form phosphoric acid. According to this view, the  $\text{P}^{\text{*****}}$  ions constitute an intermediate stage in the transition from phosphide to phosphoric acid. The discharge of  $\text{M}'$  ions and the formation of  $\text{P}^{\text{*****}}$  ions may occur at points widely separated from one another, provided that a metallic conducting path be available for the passage of the necessary electrons.

In conclusion, I wish to thank Professor Sir James Walker, F.R.S., for his interest and helpful advice during the course of this work.

UNIVERSITY OF EDINBURGH.

[Received, March 10th, 1926.]

## CLXXVIII.—*Experiments on the Formation of Mother-of-Pearl.*

By PHANI BHUSAN GANGULY.

It is known that mother-of-pearl, like the substance of the pearl, consists of calcium carbonate associated with water and an organic substance (conchiolin). The following is a typical analysis of mother-of-pearl (G. and H. Harley, *Proc. Roy. Soc.*, 1888, **43**, 461): Calcium carbonate, 66.0; organic matter, 2.5; water, 31.0%; total 99.5%.

As early as 1814, Brewster (*Phil. Trans.*, 1814, **104**, 397) explained the iridescent colours of mother-of-pearl as being due to two factors—a grating effect on the surface, and an interference effect caused by a thin film of calcium carbonate. The grating effect on mother-of-pearl can be easily transferred to a film of gelatin dried on its surface, and the distance between the lines can be measured. In a recent paper, Lord Rayleigh (*Proc. Roy. Soc.*, 1923, *A*, **102**, 674) has shown that the second effect is not due to a single film, but is caused by alternate layers of calcium carbonate and conchiolin, forming a series of equally spaced thin parallel plates. He ascribes the surface effect to the edges of the closely packed alternate layers

of inorganic and organic matter. This alternating structure is suggestive of the periodic precipitations which occur in the well-known Liesegang phenomenon, and as a matter of fact both Liesegang (*Kolloid Z.*, 1913, **12**, 181) and Clément and Rivière (*Compt. rend.*, 1922, **174**, 1353) have tried to produce structures similar to mother-of-pearl by the periodic precipitation of calcium phosphate in gelatin. Thus Liesegang allowed sodium phosphate to diffuse from an aqueous solution into a gelatin jelly containing calcium nitrate. The periodic structures obtained in this way exhibit some iridescence, but after a time they lose their lustre and become dull and "chalky." In order to avoid effects due to foreign electrolytes, it was decided to study the precipitation of calcium carbonate from an aqueous solution of calcium bicarbonate containing a gelatinising organic colloid.

#### EXPERIMENTAL.

The solution of calcium bicarbonate was prepared by passing carbon dioxide into a saturated solution of lime water. In this way a stock solution could be prepared at room temperature containing 0.0134 g.-mol. of calcium carbonate per litre.

With organic colloids such as gum arabic, gum tragacanth, and fish glue, no iridescent structures could be obtained by the method employed in these experiments. The best results were obtained with commercial leaf gelatin (containing 10% of moisture and 1.924% of ash). Iridescent deposits could not be obtained with a sample of highly purified and almost ash-free gelatin prepared in this laboratory. Liesegang (*Z. physikal. Chem.*, 1914, **88**, 1) has found that the best rings of silver chromate are produced when the gelatin contains small quantities of "gelatose" (a hydrolytic product of gelatin) as well as acid. All samples of commercial gelatin contain "gelatose" and therefore are most suitable for the production of Liesegang periodic layers.

The method of procedure was as follows. Varying amounts of gelatin were weighed into a series of test-tubes, to which measured volumes of water were added. The tubes were then stoppered and the gelatin was allowed to swell, after which it was dissolved by immersing the tubes in hot water. When the solutions had cooled to about 40°, measured volumes of the calcium bicarbonate solution were run in, the contents of each tube thoroughly mixed, and drops from each placed on clean glass plates. The thin layers of gelatin-bicarbonate solution thus produced were allowed to evaporate slowly at room temperature. More rapid evaporation either at higher temperatures (*e.g.*, 50°) or in desiccators containing drying agents (or alkalis to absorb carbon dioxide) failed to give iridescent deposits of calcium carbonate. Another factor of importance in the

production of iridescence is the initial thickness of the layer of solution on the glass plate. The best results are obtained when this thickness lies between 1 and 3 mm.

An examination of the dried layers showed that for a given initial concentration of calcium carbonate the result depended on the concentration of gelatin. With any given initial calcium carbonate concentration and increasing gelatin concentrations, four types of product, corresponding to four fairly well demarcated regions, were in general obtained :

*Region 1.*—If the gelatin concentration lies below a certain value, there is produced an irregular crystalline deposit, with a thicker aggregation of calcium carbonate crystals at the centre, but no iridescence.

FIG. 1.

*Region 2.*—If the gelatin concentration is somewhat higher, iridescent specks appear, generally in the centre, together with a visible deposit of calcium carbonate crystals all over the area. In this case the calcium carbonate usually formed a series of coarse irregular rings.

*Region 3.*—With a still higher gelatin concentration there is no visible deposit of calcium carbonate, and the whole area, now quite translucent, shows a beautiful mother-of-pearl-like iridescent colour, varying with the angle of observation.

*Region 4.*—Finally, if the gelatin concentration exceeds a certain value, the layer remains clear and translucent, but exhibits no colour.

The general nature of the results obtained is well shown in the accompanying figure. The lines AB, AC, AD, together with the axes, divide the diagram into the four regions or zones already

described, although it must be understood that the positions of these lines are not fixed with any great degree of precision.

Microscopic examination of the thin iridescent plates of gelatin-calcium carbonate corresponding to the zone AB—AC shows that the slowly decomposing calcium bicarbonate has deposited the calcium carbonate in a series of more or less regular and parallel layers or sheets resembling those of a Liesegang structure. Various photomicrographs were taken and the spacing of the layers was determined by means of a Hilger travelling microscope. There were present 4000—6000 layers per cm. The accompanying photograph shows the type of structure obtained.

#### *Discussion of Results.*

These experiments show that it is possible to prepare a clear, translucent, thin plate or sheet of dried gelatin containing a very fine spatially periodic precipitation of calcium carbonate and exhibiting the iridescent colour effects characteristic of mother-of-pearl. The colours shown by the preparations described in this paper are in all probability due to a grating effect caused by the closely-spaced layers of calcium carbonate, although it has not been found possible to determine by means of sections the exact orientation of these layers with respect to the surface of the thin plate of gelatin. Nevertheless, the photomicrographs show clearly enough that the layers of calcium carbonate do not lie parallel to the surface of the gelatin plane, but must be oriented at an angle to it which probably does not differ much from  $90^\circ$ . Each drop of solution produces a thin, more or less circular, lens-shaped disc on the glass plate. It is probable that the precipitation of calcium carbonate begins at the surface of the outer rim, and proceeds rhythmically in a series of closely-spaced concentric rings towards the central part of the surface of the evaporating disc of solution. As evaporation of water and carbon dioxide proceeds, this rhythmic precipitation is carried more or less vertically downwards, *i.e.*, at right angles to the main surface of the disc. The result of such a periodic precipitation would be to yield a grating surface capable of producing colours in reflected light, provided the spacing be fine enough. Although this is the most probable explanation of the colour effects described in this paper, the possibility of colour production by interference of light reflected from a series of parallel plates cannot be excluded. Taken in conjunction with the work of Brewster and of Lord Rayleigh, the synthetic chemical experiments described leave little doubt as to the origin of the colours exhibited by mother-of-pearl. The thin sheets of gelatin-calcium carbonate which have been obtained approach very closely in their nature and structure

*Microphotograph of gelatin-calcium carbonate. ×560.  
(Corresponding to x in the figure.)*

*[To face p. 188i.]*

to natural mother-of-pearl, and may indeed be described as "elements" of mother-of-pearl, although, of course, the organic colloid used is different from the "conchiolin" of the natural material.

*Summary.*

1. The deposition of calcium carbonate from a thin layer of an aqueous solution of calcium bicarbonate in the presence of gelatin has been studied.

2. The nature of the deposit depends upon the initial concentration of calcium bicarbonate and the ratio of gelatin to calcium bicarbonate.

3. For any given initial concentration of calcium bicarbonate there is a range of gelatin concentrations which yield translucent layers showing the iridescent colours characteristic of mother-of-pearl.

4. The structure of mother-of-pearl has been discussed in the light of these experiments and the physical work of Brewster and of Lord Rayleigh.

In conclusion, the author wishes to express his thanks to Professor Donnan for suggesting this problem to him and for his kind interest and guidance in the work.

[Received, March 16th, 1926.]

CLXXIX.—*Aminobenzthiazoles. Part III. The Tautomerism and Unsaturation of the Aminothiazole System.*

By ROBERT FERGUS HUNTER.

As one of the three objects\* of this investigation (see Part I, J., 1925, 127, 2023), the mobility of the symmetrical triad system

\* A fourth object, viz., the study of the relation between unsaturation and mobility in tautomeric triad systems of the aminothiazole type, is of particular interest in connexion with the whole philosophical aspect of tautomerism involving a mobile hydrogen atom (compare Thorpe, J., 1923, 123, 1361; Kon, Stevenson, and Thorpe, J., 1922, 121, 650), and will be fully dealt with in a later paper. In the 5-bromo-1-alkylaminobenzthiazoles, the increasing molecular volume of the alkyl group in the ethyl, *n*-propyl, *n*-butyl, *isobutyl* series tends to enhance the aminothiazole phase of the system, and consequently to increase the stability of the dibromo-addition compounds. Indeed, in the ethyl series Mr. Soyka and myself were able

in 1-amino- and substituted 1-aminobenzthiazoles has been examined, with the result that the tautomerism of the 1-aminobenzthiazole system (I) with the corresponding 1-imino-1:2-dihydrobenzthiazole complex (II) has been established.

There are three tests for the mobility of symmetrical triad systems (Ingold and Piggott, J., 1922, **121**, 2381; 1923, **123**, 1470): (A) The symmetry test, (B) the fission test, and (C) the substitution test (compare also Farrow and Ingold, J., 1924, **125**, 2543). Only the first and third of these tests are applicable to the system under discussion. There exists already in the literature of 1-aminobenzthiazole evidence of the symmetry type. Thus, whilst the classical synthesis of this compound from 1-chlorobenzthiazole (Hofmann, *Ber.*, 1879, **12**, 1126) is usually regarded as a proof of the constitution (I), its synthesis from phenylthiosemicarbazide (Fischer and Besthorn, *Annalen*, 1882, **212**, 326) \* can be formulated only in terms of the iminodihydro-structure (II).

The symmetry test, however, was more definitely established by the synthesis of 1-acetylaminobenzthiazole (VII) and 1-imino-2-acetyl-1:2-dihydrobenzthiazole (VIII) from the bromides (V) and (VI), respectively, which were obtained by bromination of the stable and labile forms of acetylphenylthiocarbamide (Hugershoff, *Ber.*, 1899, **32**, 3649; Wheeler, *Amer. Chem. J.*, 1902, **27**, 270; Hunter, *loc. cit.*). On hydrolysis, the two isomeric acetyl derivatives

to isolate both forms of the dibromide, which must be regarded as being of the type  $[H]NBr_2 \cdot C \cdot N \cdot Et$  and  $NBr_2 \cdot C \cdot N[H]Et$ , respectively. These forms were strikingly different in physical properties and in their reducibility by hydriodic acid (compare West, J., 1924, **125**, 710 and other papers). Both gave the same ethylamino-base on reduction with sulphurous acid and, moreover, the labile form was converted into the more stable form by boiling for some time with a mixture of bromine and chloroform. This conversion shows that it is at least probable that at some stage an equilibrium  $[H]NBr_2 \cdot C \cdot N \cdot Et \rightleftharpoons NBr_2 \cdot C \cdot N[H]Et$ , which is apparently a case of retarded mobility (Kon and Linstead, J., 1925, **127**, 815) involving quinquevalent nitrogen, may occur. In view of this, it has seemed desirable to institute a series of experiments on the bromination both of mobile and of "nascently" mobile (compare Goss and Ingold, J., 1925, **127**, 2776) systems of the amidine type.

In the bromination of *s*-di- $\beta$ -naphthylthiocarbamide in chloroform (J., 1925, **127**, 2270) two forms of the hexabromide of 2- $\beta$ -naphthylamino- $\alpha$ -naphthathiazole were accidentally isolated, and only one of these was obtained by bromination of the naphthathiazole base itself.

\* Fischer and Besthorn's "phenylthiocarbazine," obtained by the action of 20% hydrochloric acid on phenylthiosemicarbazide at 125–130°, was shown by Hugershoff (*Ber.*, 1903, **36**, 3134) to be 1-aminobenzthiazole.

(VII and VIII) yielded the same 1-aminobenzthiazole (or 1-imino-1:2-dihydrobenzthiazole).

With regard to the third test (C), it was found that 1-aminobenzthiazole methylates almost exclusively in the imino-form (II), yielding 1-imino-2-methyl-1:2-dihydrobenzthiazole (XI), whose constitution was established by rational synthesis from *as*-methylphenylthiocarbamide (IX) by way of the *dibromide* (X). During the methylation a more soluble isomeride was also produced. This, owing to experimental difficulties, could not be obtained pure, but it was undoubtedly 1-methylaminobenzthiazole (XIV), which was also synthesised from *s*-methylphenylthiocarbamide (XII) by way of the *tetrabromide* (XIII). [Formulae IX, X, and XI are IV, VI, and VIII, respectively, and XII, XIII, and XIV are III, V, and VII, respectively, all with Me in place of Ac.]

The ethylation of 1-aminobenzthiazole proved more troublesome than the methylation. The bulk of the product was, however, finally identified as 1-imino-2-ethyl-1:2-dihydrobenzthiazole, whose constitution was established by its synthesis from *as*-ethylphenylthiocarbamide by way of the *tetrabromo*-addition compound as in the case of the corresponding methyl derivative.

The acetylation of 1-aminobenzthiazole was studied in the hope of isolating both acetyl derivatives (VII and VIII). The base acetylated almost completely in the amino-form (I), giving 1-acetylaminobenzthiazole, and although on several occasions the presence of a small amount of a low-melting acetyl derivative was observed, the second isomeride could not be isolated pure.

The substitution test (C), therefore, supports the symmetry test (A), since with a reagent favouring the imino-form, the triad system reacts almost completely in this form, the methyl group attaching itself almost exclusively to the less basic nitrogen atom (Marckwald, *Annalen*, 1895, **286**, 343; von Pechmann, *Ber.*, 1895, **28**, 869, 2362; 1897, **30**, 1779; Cohen and Marshall, *J.*, 1910, **97**, 328), whilst with

acetic anhydride, which favours the amino-form, the amidine system reacts almost completely in the latter form, yielding the 1-acetyl-amino-derivative.

Although experimental difficulties prevented the isolation in a pure condition of two methyl or ethyl derivatives, there can be no doubt that in both cases both alkyl derivatives were actually present, for Pyman has shown (J., 1923, 121, 367, 3359) that, on alkylation, an amidine whose two nitrogen atoms differ in basicity invariably yields two alkyl derivatives, a very small quantity of the isomeride corresponding to the more basic form of the amidine accompanying a large quantity of the more readily formed alkyl derivative. The two nitrogen atoms in the aminothiazole system differ considerably in basicity, this being shown by the base acetylating almost completely in the more basic form.

Mobility in 1-aminobenzthiazole having thus been established, the general chemistry of the substance was studied. The base was readily converted into an unstable diazonium chloride, which coupled with  $\beta$ -naphthol in the usual way. Attempts to convert the diazonium chloride into 1-hydroxybenzthiazole, however, invariably yielded 1-aminoazobenzthiazole hydrochloride,

(compare Hantzsch and Popp, *Annalen*, 1889, 250, 257).

The aminothiazole appeared to react in the normal way with formaldehyde and acetaldehyde, but pure condensation products could not be isolated. Attempts to condense the base with benzaldehyde failed. This is readily understood, however, since the formation of the benzyldene derivative would involve the removal of both the mobile hydrogen atom and the potentially mobile hydrogen atom of the triad system.

The base benzoylated normally, giving 1-benzoylamino benzthiazole, which on treatment with an excess of bromine yielded a tetrabromide (formula as V). Under the influence of dilute alcohol this yielded 5-bromo-1-benzoylamino benzthiazole. The fact that the presence of a benzoyl group only allows the formation of a tetrabromide in circumstances in which 1-acetylamino benzthiazole readily passes into a hexabromide is probably to be attributed to the steric effect of the phenyl group in the benzoylamino-residue.

1-Aminobenzthiazole reacts very readily with sodium hypochlorite, yielding a deep purple dye of the rosaniline type.

On treating 1-aminobenzthiazole hydrochloride with alcoholic ethyl nitrite, neither the expected 1-imino-2-nitroso-1:2-dihydrobenzthiazole nor benzthiazole itself was produced, but the hydrochloride of a new base, isomeric with 1-aminobenzthiazole, which

crystallised in beautiful ruby-red prisms. The base itself was very pale yellow. A similar reaction was observed in the cases of 1-amino-3-methyl- and 1-amino-5-methyl-benzthiazole. Possibly the intensely coloured hydrochloride and the base may have formulæ (XV) and (XVI), respectively (compare Kehrman, *Ber.*, 1906, **39**, 914; Smiles and Hilditch, *J.*, 1908, **93**, 145, 1687; Battegay and Vechot, *Bull. Soc. chim.*, 1925, **37**, 1271).

The tautomerism of 5-bromo-1-aminobenzthiazole and 5-bromo-1-imino-1:2-dihydrobenzthiazole was established by means of the symmetry test (A). The hexabromide of 1-acetylaminobenzthiazole,  $C_6H_4 \begin{smallmatrix} SBr_4 \\ NBr_2 \end{smallmatrix} > C \cdot NHAc$ , was converted into 5-bromo-1-acetylaminobenzthiazole, and the dibromide of 1-imino-2-acetyl-1:2-dihydrobenzthiazole (VI) into the isomeric 5-bromo-1-imino-2-acetyl-1:2-dihydrobenzthiazole, by treatment with dilute alcohol (compare Hunter, *J.*, 1925, **127**, 2026). On hydrolysis both these 5-bromo-acetyl derivatives yielded the same 5-bromo-1-aminobenzthiazole (formula as I or II). The fission test (B) is inapplicable in this case, and the substitution test (C) was not investigated in view of the difficulties encountered in the previous case.

In view of the curious observations made regarding the bromides of the *o*-, *m*-, and *p*-toluidinomethylbenzthiazoles (*loc. cit.*), the bromo-addition compounds of 1-amino-3-methyl-, 1-amino-4-methyl- and 1-amino-5-methyl-benzthiazole were examined. Whereas *o*-tolylthiocarbamide readily passed into the dibromide of the first, *m*-tolylthiocarbamide gave the labile tetrabromide of the second,  $C_6H_3Me \begin{smallmatrix} SBr_2 \\ NBr_2 \end{smallmatrix} > C \cdot NH_2$ , whilst *p*-tolylthiocarbamide yielded a more stable tribromo-addition compound of the last, which is doubtless the hydrobromide of the dibromide. This tribromide was on one occasion isolated in two forms (compare the case of 2-β-naphthylamino-α-naphthathiazole hexabromide, *J.*, 1925, **127**, 2274).

Bromination of *m*-xylylthiocarbamide gave the tetrabromide of 1-amino-3:5-dimethylbenzthiazole, which is the most labile aminothiazole bromide so far isolated. The instability is clearly to be attributed to the methyl groups in positions 3 and 5, there being no possibility either of *o*- or of *p*-migration of bromine into the aromatic nucleus (compare Fries, *Annalen*, 1906, **346**, 128).

Lastly, the bromides of 2-amino- $\beta$ -naphththiazole (XVII) and 2-amino- $\alpha$ -naphththiazole (XVIII) were examined. Both  $\alpha$ - and  $\beta$ -naphthylthiocarbamide on bromination readily yielded the *tetrabromides* of (XVII) and (XVIII), respectively. These are compounds of the usual type, but are more stable than the bromides of the aminobenzthiazole series, no doubt owing to the presence of the naphthalene nucleus, since the bromo-addition compounds of 2- $\beta$ -naphthylamino- $\alpha$ -naphththiazole (*loc. cit.*) are remarkably stable under ordinary laboratory conditions.

1-Imino-2-methyl-1 : 2-dihydrobenzthiazole (XI) on bromination yielded a stable orange-yellow *tribromide* of the type obtained by exposing the higher bromides of the 1-tolylaminodimethylbenzthiazole series (*loc. cit.*) to moist air.

The dibromide of 1-aminobenzthiazole (XIX) (Hugershoff, *Ber.*, 1901, **34**, 3130; 1903, **36**, 3121) obtained by brominating phenylthiocarbamide in chloroform, on treatment with warm water, is instantly converted into 5-bromo-1-imino-1 : 2-dihydrobenzthiazole hydrobromide (XX).

This transformation is clearly a *para*-migration, analogous in some respects to the *N*-bromoacetanilide  $\rightarrow$  *p*-bromoacetanilide isomerisation (Chattaway and Orton, *J.*, 1899, **75**, 1046; 1900, **77**, 134, 152, 789, 797), but differing from it in that the nitrogen atom is in the quinquivalent state. The passage of the dibromide into the bromo-hydrobromide can be explained by means of a bridged form of the benzthiazole nucleus (XXI) (compare Ingold, *J.*, 1922, **121**, 1133, 1143) analogous to the formula which Shearer (*Proc. Phys. Soc.*, 1923, **35**, ii, 81) has assigned to naphthalene on the basis of *X*-ray analysis.\*

\* The parachors (*J.*, 1925, **127**, 1525 and later papers) of 1-aminobenzthiazole and of certain other benzthiazole derivatives are being determined by Dr. Sugden in the hope that they may give some indication of the intramolecular exchanges which take place in the benzthiazole system. Unfortunately, the difference between the calculated values of the parachor for the ordinary form of 1-aminobenzthiazole (I or II) ( $[P] = 311.9$ ) and for the bridged form suggested in this paper as a phase of the benzthiazole system ( $[P] = 308.9$ ) is very small (Sugden, private communication) and may not be capable of definite experimental detection.

The bridged formula (XXI) represents only *one* of the intra-annular phases of benzthiazole, in tautomeric equilibrium with the

normal phase (XXII), which is the usually accepted structure for the substance. The bridged form involves a hypothetical form of the thiazole nucleus, analogous to the bridged formula of thiophen (Farmer, Ingold, and Thorpe, J., 1922, **121**, 134) and the intra-annular five-carbon nucleus (*idem*, *loc. cit.*; Ingold, Seeley, and Thorpe, J., 1923, **123**, 863; Grimwood, Ingold, and Thorpe, *ibid.*, p. 3303). The strikingly aromatic properties of the thiazole nucleus (Hantzsch and collaborators, *loc. cit.*) suggest that the thiazole ring must, if the views of Ingold and his collaborators (J., 1922, **121**, 1133, 1143; 1923, **123**, 2066, 2081) regarding aromatic nuclei are correct, be a tautomeric system, although in view of the difficulties which heterocyclic nuclei present in this connexion from the experimental point of view (Ingold and Piggott, J., 1922, **121**, 2749; Ingold, J., 1924, **125**, 87), the problem of obtaining direct evidence of a bridged form of the thiazole nucleus appears at the present time to be insoluble. Evidence of a bridged form of the benzthiazole system must, however, be taken as *indirect* evidence on this point, and a series of experiments has been instituted in the hope of proving that the bridged formula (XXI) represents *one* phase of the benzthiazole system. With regard to the 1-amino-benzthiazole dibromide  $\rightarrow$  5-bromo-1-imino-1:2-dihydrobenzthiazole hydrobromide change, it is suggested, not that this transformation is a proof of the bridged structure of the benzthiazole nucleus, but merely that it is best explained on the basis of the latter. The exceedingly beautiful fluorescence of certain benzthiazole derivatives (Hunter, *Chemical News*, 1923, **127**, 385) is noteworthy in connexion with the problem of the bridged phase (compare Kaufmann, *Ahrens Vorträge*, 1908, **12**, 35; Ingold, J., 1922, **121**, 1134).

#### EXPERIMENTAL.

(Substances exhibiting amino-iminodihydro-tautomerism are named on the basis of their amino-formula).

##### *The Mobility of 1-Aminobenzthiazole.*

*Methylation.*—1-Aminobenzthiazole (2 g.) was heated with methyl iodide (1.6 c.c.) at 100° for 5 hours. The product, after being treated with alkali and with hot water to remove any unchanged amino-base, crystallised from alcohol in plates, m. p. 115°. After

recrystallisation from benzene it melted at  $122^{\circ}$  and did not depress the m. p. of an authentic specimen of 1-imino-2-methyl-1:2-dihydrobenzthiazole (XI). It was further characterised by the formation of the stable, yellow-orange tribromo-addition compound (page 1393).

In an experiment similar to the above, the methylation product was extracted with cold ether and alcohol. The extract on evaporation yielded a clear pale yellow gum, which could not be crystallised, consisting of the more soluble methyl derivative. After the gum had solidified, it melted at about  $114^{\circ}$ . Mixed with a specimen of 1-methylaminobenzthiazole, it melted at  $120^{\circ}$  after softening at about  $100^{\circ}$ .

*Ethylation.*—1-Aminobenzthiazole (2 g.) and ethyl iodide (1.5 c.c.) were heated at  $100^{\circ}$  for 5–6 hours. The product, after treatment with alkali and warm water, was usually obtained as a tenacious gum, which sometimes solidified on standing for some weeks. On trituration with ether the product sometimes crystallised. It had m. p.  $85^{\circ}$  and was identified as 1-imino-2-ethyl-1:2-dihydrobenzthiazole (mixed melting point determination).

*Acetylation.*—A solution of 8 g. of 1-aminobenzthiazole in acetic anhydride (30 c.c.) was heated under reflux and cooled and the crystalline acetyl derivative was collected. The filtrate was mixed with alcohol and evaporated; small needles, m. p.  $115^{\circ}$ , were thus obtained. The acetyl derivative (7 g.) was extracted with boiling alcohol; the residue of small prisms had the same m. p.,  $186^{\circ}$ , as the lustrous plates of 1-acetylaminobenzthiazole deposited from the extract. The remaining liquors were fractionally crystallised, but although low-melting substances (m. p.  $120^{\circ}$ ) were frequently obtained, 1-imino-2-acetyl-1:2-dihydrobenzthiazole could not be isolated pure. The yield of pure 1-acetylaminobenzthiazole was almost quantitative. The crude acetylation product had no action on sodium hypobromite, showing the absence of unchanged base.

*1-Imino-2-methyl-1:2-dihydrobenzthiazole Dibromide (X).*—*as-Methylphenylthiocarbamide* (1 g.) in chloroform (10 c.c.) was gradually treated with a solution of bromine (0.8 c.c.) in chloroform (3 c.c.); a bulky orange precipitate separated which redissolved with evolution of heat and hydrogen bromide. The mixture was refluxed for 2 minutes and cooled; the bulk of the product then separated in tile-red crystals. The filtrate gradually deposited the *dibromide* in glistening, orange-red needles which, after drying in a vacuum over potassium hydroxide, sintered and softened at  $125^{\circ}$  (Found: Br, 49.8.  $C_8H_8N_2Br_2S$  requires Br, 49.4%). The *dibromide* had the usual properties of these compounds, and slowly became yellow in the air with loss of bromine.

1-*Imino-2-methyl-1 : 2-dihydrobenzthiazole* (XI).—The dibromide, suspended in sulphurous acid, was treated with sulphur dioxide until a colourless solution was obtained. This, on being made alkaline with ammonia, deposited the free methyl base in small prisms, m. p. 123° (Found : S, 18.9.  $C_8H_8N_2S$  requires S, 19.5%).

1-*Imino-2-methyl-1 : 2-dihydrobenzthiazole Tribromide*.—The methyl derivative (0.2 g.) dissolved in chloroform (7 c.c.) was slowly treated with an excess of a 20% solution of bromine in the same solvent; an orange precipitate of the bromo-addition compound was obtained. The mixture was warmed and then cooled in ice. The *tribromide*, after being dried in a vacuum, was obtained in minute, orange prisms which lightened at 230–240° and became white without melting at 245° [Found : Br, 59.8.  $(C_8H_8N_2Br_3S)_2$  requires Br, 59.4%].

1-*Methylaminobenzthiazole Tetrabromide* (XIII).—A solution of *s*-methylphenylthiocarbamide (4 g.) in chloroform (25 c.c.) was gradually treated with bromine (3.2 c.c.) and heated under reflux for a few minutes. On cooling, the *tetrabromide* crystallised in rosettes of shining, scarlet needles, m. p. 65–67° (decomp.), which were dried in a vacuum over potassium hydroxide (Found : Br, 66.1.  $C_8H_8N_2Br_4S$  requires Br, 66.1%).

The tetrabromide was exposed to the air for 20 hours (compare 1-anilinobenzthiazole tetrabromide → tribromide transformation; J., 1925, 127, 2026), losing bromine with the formation of a yellow-orange *dibromide*. This was extracted with chloroform, and separated on scratching in small, orange-yellow prisms which, after drying in a vacuum, sintered at 136° and charred at 191° (Found : Br, 48.8.  $C_8H_8N_2Br_2S$  requires Br, 49.4%). The dibromide, however, differed from the tribromides of the 1-arylaminobenzthiazoles (*loc. cit.*) in losing more bromine on prolonged exposure to air.

*Bromo-substitution Derivatives*.—The tetrabromide dissolved readily in hot absolute alcohol, and on diluting the solution with water and concentrating it, a crystalline mass of the hydrobromides of the bromo-substitution products was obtained. This was treated with ammonia and the liberated bases were crystallised from ethyl acetate-alcohol, from which silky, lustrous plates of a mixture of monobromo- and dibromo-substitution derivatives were obtained, m. p. 203°; these could not be separated (Found : Br, 46.8.  $C_8H_7N_2BrS$  requires Br, 37.0%.  $C_8H_6N_2Br_2S$  requires Br, 49.9%). This behaviour is curious, for in all previous experiments on the bromination of substituted benzthiazoles it was possible to introduce only one bromine atom into the benzene nucleus (Hunter, this vol., p. 540).

1-*Methylaminobenzthiazole* (XIV).—The tetrabromide was suspended in sulphurous acid and treated with sulphur dioxide. The crystalline paste of salts obtained was slowly added to a strong solution of ammonia, in which it dissolved. The base crystallised on cooling, and a further small quantity was obtained by extracting the filtrate with ether. The base was obtained from dilute alcohol in tufts of silky needles, m. p. 135°, and finally from absolute alcohol in prisms, m. p. 138° (Found: S, 19.8.  $C_8H_8N_2S$  requires S, 19.5%).

1-*Imino-2-ethyl-1 : 2-dihydrobenzthiazole tetrabromide* was obtained from *as*-ethylphenylthiocarbamide (3 g.) and bromine (2.2 c.c.) in chloroform by the method for preparing the dibromide (X). After drying in a vacuum over potassium hydroxide, the tetrabromide was obtained in glistening, vermilion-orange prisms, m. p. 160—161° (decomp., with previous sintering) (Found: Br, 62.6.  $C_9H_{10}N_2Br_4S$  requires Br, 64.3%).

1-*Imino-2-ethyl-1 : 2-dihydrobenzthiazole*, prepared by reducing the preceding tetrabromide (10 g.) in the usual way, was obtained as a gum which solidified; it crystallised from alcohol in pale yellow prisms, m. p. 86° (Found: S, 18.1.  $C_9H_{10}N_2S$  requires S, 17.9%).

*Labile Acetylphenylthiocarbamide*.—Phenylthiocarbamide (16 g.) was heated with acetic anhydride (14 c.c.) at 80° (Hugershoff, *loc. cit.*). The product crystallised from ethyl acetate in prisms, m. p. 136°; after recrystallisation it melted at 138°.

1-*Imino-2-acetyl-1 : 2-dihydrobenzthiazole Dibromide* (VI).—(A) The labile acetylphenylthiocarbamide (2 g.) dissolved in chloroform (25 c.c.) was gradually treated with bromine (1.2 c.c.). Heat and hydrogen bromide were evolved in the usual way and crystallisation took place in the hot solution towards the end of the bromination. The mixture was refluxed for a short time, cooled, and the *dibromide* collected and dried in a vacuum; it was then obtained in glistening orange prisms, m. p. 130—132° (decomp.) (Found: Br, 45.6.  $C_9H_8ON_2Br_2S$  requires Br, 45.5%).

(B) The acetylphenylthiocarbamide (2 g.) dissolved in 12 c.c. of chloroform was gradually treated with 1.6 c.c. of bromine; hydrogen bromide was evolved and a dark red tar produced. The solvent was decanted off and the tar boiled for 1 minute with 20 c.c. of absolute alcohol, being thereby changed into fine purplish-red prisms, which were dried in a vacuum. This *dibromide* sintered at about 160° and melted at 173° (decomp.) (Found: Br, 42.3%).

This dibromide showed the most striking stability to air, and appreciably lost bromine only over a period of some weeks. It was also more slowly reduced by sulphurous acid than the other bromides of 1-imino-2-acetyl-1 : 2-dihydrobenzthiazole.

*1-Imino-2-acetyl-1 : 2-dihydrobenzthiazole Dibromide Hydrobromide.*—The labile acetylphenylthiocarbamide (4 g.) dissolved in chloroform (30 c.c.) was gradually treated with bromine (3 c.c.), and the mixture boiled. The product consisted of small, shining, dark chocolate-coloured prisms which were dried in the usual way. They became suddenly orange at 178° and melted at 180° (decomp.) (Found: Br, 55.6.  $C_9H_8ON_2Br_2S \cdot HBr$  requires Br, 55.7%). This bromide had the usual properties, being reduced by sulphurous acid and converted into the substitution derivative by treatment with diluted alcohol, and was strikingly similar to the dibromide of 4'-amino-1-phenyl-5-methylbenzthiazole (J., 1925, 127, 1318) in appearance and stability in air.

*1-Imino-2-acetyl-1 : 2-dihydrobenzthiazole (VIII).*—This was obtained from the dibromide by means of sulphurous acid and ammonia in the usual way. It separated from 20% alcohol in minute crystals, m. p. 118—120° (Found: S, 17.2.  $C_9H_8ON_2S$  requires S, 16.7%).

*Hydrolysis.* A part of the product was hydrolysed with 60% sulphuric acid, the solution neutralised at 0°, and the product recrystallised from hot water. Lustrous plates of 1-aminobenzthiazole were thus obtained which, alone or mixed with a genuine specimen, melted at 126°. The base was further characterised by the formation of the dibromide and of benzthiazole-1-azo- $\beta$ -naphthol.

Specimens of the acetyl derivative have sometimes been obtained from alcohol-ethyl acetate in pale yellow prisms, m. p. 140° (or higher); these also yield 1-aminobenzthiazole on hydrolysis with 60% sulphuric acid, but have not yet been fully investigated.

*Stable Acetylphenylthiocarbamide.*—The labile acetyl derivative (18 g.) was kept at 150—160° for 10 minutes and then at 170—180° for an equal time. The product crystallised from alcohol-ethyl acetate in prisms, m. p. 170—171°, as recorded (*loc. cit.*).

*1-Acetylaminobenzthiazole Tetrabromide (V).*—When stable acetylphenylthiocarbamide (1 g.) in chloroform (7 c.c.) was slowly treated with bromine (0.9 c.c.), hydrogen bromide was evolved and a clear red gum separated. The mixture was boiled and cooled. On being rubbed, the gum solidified to a mass of orange-red prisms which were dried in the usual way; m. p. 137—139° (Found: Br, 61.8.  $C_9H_8ON_2Br_4S$  requires Br, 62.5%).

*1-Acetylaminobenzthiazole (VII)* was obtained from the tetrabromide (1 g.) in the usual way. It crystallised from alcohol in prisms, m. p. 186°, and was identical with the acetyl derivative obtained by the direct acetylation of 1-aminobenzthiazole.

*1-Benzoylaminobenzthiazole*, obtained from 1-aminobenzthiazole

(1 g.) by the Schotten-Baumann method, crystallised from alcohol in prisms, m. p.  $186^{\circ}$  (Hugershoff, *loc. cit.*).

*1-Benzoylamino benzthiazole Tetrabromide*.—The benzoyl derivative (0.4 g.) dissolved in 5 c.c. of chloroform was treated with bromine (0.3 c.c.), and the solution boiled. On cooling, the *tetrabromide* crystallised in silky, orange-yellow plates which, after drying in a vacuum, lightened in colour at about  $170^{\circ}$  and became colourless and lost bromine at about  $185^{\circ}$  (Found: Br, 56.8.  $C_{14}H_{10}ON_2Br_4S$  requires Br, 55.8%).

*5-Bromo-1-benzoylamino benzthiazole*.—A solution of the tetrabromide in alcohol was boiled, diluted, and evaporated, the white, crystalline product was treated with ammonia, and the *bromo-derivative* was dried and recrystallised from ethyl acetate, separating in small prisms, m. p.  $226^{\circ}$  (Found: Br, 25.2.  $C_{14}H_9ON_2BrS$  requires Br, 24.0%).

*Benzthiazole-1-azo- $\beta$ -naphthol*.—A solution of aminobenzthiazole (1.5 g.) in 20 c.c. of dilute hydrochloric acid was diazotised in the usual way, and the product coupled with 1.4 g. of  $\beta$ -naphthol dissolved in 8 c.c. of 5% sodium hydroxide solution. The orange-brown azo-compound was collected and extracted with ether; the extract, on evaporation in a vacuum at room temperature, left the azo-compound in deep purple-red prisms, m. p.  $146^{\circ}$  after sintering at  $140^{\circ}$  (Found: S, 10.3.  $C_{17}H_{11}ON_3S$  requires S, 10.5%). The product dyed cotton a fugitive shade of yellow. On reduction with tin and hydrochloric acid it gave 1-aminobenzthiazole, which was identified by its m. p. and by the m. p. of its mixture with a genuine specimen.

*1-Aminoazobenzthiazole*.—A solution of diazotised 1-aminobenzthiazole (prepared from 4 g. of the base in 50 c.c. of water and 10 c.c. of concentrated hydrochloric acid) was boiled for an hour, filtered from tar [which did not yield any trace of 1-hydroxybenzthiazole (Jacobson, *Ber.*, 1886, 19, 1811) on extraction with alkali] and concentrated. The red crystals of the *hydrochloride* obtained separated from alcohol (animal charcoal) in yellow prisms, m. p.  $232^{\circ}$  (decomp.) after softening at  $224^{\circ}$ . The *base* was obtained by treating it with ammonia and was crystallised from ether and from boiling water, separating in small, cream-white, lustrous plates, m. p.  $135^{\circ}$  (Found: S, 21.6.  $C_{14}H_9N_5S_2$  requires S, 20.7%). On reduction with tin and hydrochloric acid, 1-aminobenzthiazole was isolated and identified (m. p. and mixed m. p. determination).

*Reaction of 1-Aminobenzthiazole with Sodium Hypochlorite*.—The base (1 g.) in 30 c.c. of water was gradually treated with 50 c.c. of 0.3*N*-sodium hypochlorite. The purple precipitate produced, after being washed with a little ether, separated from chloroform—

light petroleum at 20° in dark purple crystals, which softened at 156—158°. The compound had dyeing properties of the usual type.

*ψ-Aminobenzthiazole Hydrochloride (XV).*—The hydrochloride from 5 g. of 1-aminobenzthiazole was suspended in 80 c.c. of alcohol at 5° and slowly treated with 16.5 c.c. of a 15% alcoholic solution of ethyl nitrite. The mixture became yellow on addition to 50 c.c. of boiling alcohol and thereafter bright orange on refluxing for a short time. On spontaneous evaporation, clusters of hard, shining, ruby-red prisms were obtained, which were washed with ether and recrystallised from alcohol. The *hydrochloride* was thus obtained in deep orange needles, m. p. 239—240° (Found: Cl, 19.6.  $C_7H_6N_2S \cdot HCl$  requires Cl, 19.1%).

*ψ-Aminobenzthiazole (XVI).*—The bright yellow base obtained by treating the red hydrochloride with ammonia (*d* 0.880) was dried and recrystallised from "sodium-dried" benzene at 20°, separating in slender, pale yellow needles which sintered and softened at 129° and melted to a clear purple-red liquid at 131° (Found: N, 18.4; S, 21.6.  $C_7H_6N_2S$  requires N, 18.7; S, 21.3%). Its mixture with 1-aminobenzthiazole commenced to soften at 120° and melted indefinitely at about 127°. On treating the base with hydrochloric acid the red hydrochloride was at once regenerated.

*ψ-Amino-3-toluthiazole Hydrochloride.*—The hydrochloride from 1 g. of 1-amino-3-methylbenzthiazole (p. 1398) was suspended in 25 c.c. of alcohol and treated with 3 c.c. of ethyl nitrite solution. A *hydrochloride* was obtained as in the previous case in ruby-red prisms which sintered at 140° and showed colour change at 145° (Found: Cl, 18.0.  $C_7H_8N_2ClS$  requires Cl, 18.7%). On treatment with ammonia a base similar to the previous one was obtained.

*ψ-Amino-5-toluthiazole hydrochloride* was obtained from 1-amino-5-methylbenzthiazole in red prisms which sintered at 130°, darkened at 140° and softened at about 150°.

#### *The Mobility of 5-Bromo-1-aminobenzthiazole.*

*5-Bromo-1-aminobenzthiazole dibromide*, prepared from *p*-bromophenylthiocarbamide (1 g.) and bromine (0.8 c.c.) in chloroform (10 c.c.) in the usual way, separated, on cooling, as a red gum which solidified in orange-red needles, softening at 80—82° (Found: Br, 63.5.  $C_7H_5N_2Br_2S$  requires Br, 61.7%). By successive treatment with sulphurous acid and ammonia it was converted into 5-bromo-1-aminobenzthiazole, m. p. 211°, identical with the bromo-substitution product obtained by dissolving 1-aminobenzthiazole dibromide in hot water (Hugershoff, *loc. cit.*).

*1-Acetylaminobenzthiazole Hexabromide.*—1-Acetylaminobenzthiazole (0.5 g.) in chloroform (6 c.c.) was slowly treated with

bromine (0.4 c.c.), and the solution boiled after some time. The *hexabromide* crystallised from the warm liquid, on scratching, in small, orange-red prisms which, after being dried, turned yellow at 130°, lost bromine at about 140°, and became colourless at about 160° (Found: Br, 71.6.  $C_9H_5ON_2Br_6S$  requires Br, 71.4%).

*5-Bromo-1-acetylaminobenzthiazole*.—A solution of the preceding hexabromide in alcohol was diluted with a little water and concentrated. The white, crystalline product, after treatment with dilute ammonia, crystallised from ethyl acetate in prisms, m. p. 223° (Found: Br, 30.0.  $C_9H_7ON_2BrS$  requires Br, 29.5%). On hydrolysis with 50% sulphuric acid, impure 5-bromo-1-aminobenzthiazole (m. p. 184°) was obtained which melted at 198° when mixed with an authentic specimen.

*5-Bromo-1-imino-2-acetyl-1:2-dihydrobenzthiazole*.—A solution of the dibromo-addition compound of 1-imino-2-acetyl-1:2-dihydrobenzthiazole in alcohol was diluted with water, concentrated on a steam-bath, decanted from a small purple residue, and evaporated. The resin thus obtained became hard on treatment with ammonia and thereafter crystallised from alcohol-ethyl acetate in small plates, m. p. 199–200° (Found: Br, 30.0.  $C_9H_7ON_2BrS$  requires Br, 29.5%).

On hydrolysis with 40% sulphuric acid and neutralisation, 5-bromo-1-aminobenzthiazole (m. p. 204°) was obtained; this crystallised from alcohol in prisms which, alone or mixed with 5-bromo-1-aminobenzthiazole prepared from 1-aminobenzthiazole dibromide, melted at 210°.

#### *Homologues of 1-Aminobenzthiazole.*

*1-Amino-3-methylbenzthiazole Dibromide*.—The solution obtained by treating 2 g. of *o*-tolylthiocarbamide in 20 c.c. of chloroform with bromine (1.5 c.c.) was refluxed and concentrated; on cooling, lustrous orange plates of the *dibromide* crystallised, m. p. 110° (effervescence) (Found: Br, 49.6.  $C_8H_5N_2Br_2S$  requires Br, 49.4%). The dibromide was unstable and decomposed with loss of bromine on exposure to air. It dissolved in alcohol, and from the solution, diluted with water and thereafter concentrated, white needles of the *hydrobromide* of bromo-1-amino-3-methylbenzthiazole were obtained which became yellow at 260° and charred at about 290° (Found: Br, 49.8.  $C_8H_7N_2BrS \cdot HBr$  requires Br, 49.7%). The *base* obtained by treating the hydrobromide with ammonia separated from alcohol-ethyl acetate in tufts of silky needles, m. p. 212° (Found: Br, 33.1.  $C_8H_7N_2BrS$  requires Br, 32.9%).

*1-Amino-3-methylbenzthiazole* was obtained from the dibromide by reduction with sulphurous acid and sulphur dioxide in the usual

way. It crystallised from 50% alcohol in small, lustrous plates, m. p.  $136^{\circ}$ , and resembled 1-aminobenzthiazole in odour (Found: S, 19.8.  $C_8H_8N_2S$  requires S, 19.5%). The diazotised base gave a red azo-dye on coupling with alkaline  $\beta$ -naphthol.

*1-Amino-5-methylbenzthiazole Dibromide Hydrobromide.*—*p*-Tolylthiocarbamide (2 g.) was brominated in chloroform as in the previous case. The bromo-addition compound was obtained in small, glistening orange-red prisms, m. p.  $134^{\circ}$  (decomp.) after sintering at  $128^{\circ}$  (Found: Br, 59.0.  $C_8H_8N_2Br_2S \cdot HBr$  requires Br, 59.2%). The tribromide was very unstable in air. Treatment of its alcoholic solution with water produced the hydrobromide of the bromo-substitution derivative, which crystallised in silky needles. The base obtained by treatment with ammonia crystallised from alcohol (80%) in small prisms, m. p.  $210^{\circ}$  (Found: Br, 33.0.  $C_8H_7N_2BrS$  requires Br, 32.9%).

By brominating *p*-tolylthiocarbamide (1 g.) in chloroform under similar conditions to the above, the tribromide was on one occasion obtained in bright red prisms, m. p.  $106^{\circ}$  (decomp.) (Found: Br, 59.5%).

*1-Amino-5-methylbenzthiazole*, obtained by reduction of the tribromide, crystallised from 50% alcohol in small, glistening prisms, m. p.  $142^{\circ}$ , having the usual faint odour of these bases (Found: S, 19.1.  $C_8H_8N_2S$  requires S, 19.5%). The base yielded an unstable diazonium chloride which coupled with alkaline  $\beta$ -naphthol, giving a red azo-dye of the usual type.

*1-Amino-4-methylbenzthiazole Tetrabromide.*—Prepared from *m*-tolylthiocarbamide (0.3 g.) and bromine (0.4 c.c.) in chloroform (5 c.c.) in the usual way, the *tetrabromide* was obtained, either spontaneously or by cooling the solution and scratching, in slender, orange-red needles which, after being dried, became yellow at  $140^{\circ}$ , soft at  $160^{\circ}$ , white at  $180^{\circ}$ , brown at  $210^{\circ}$ , and melted and decomposed at about  $250^{\circ}$  (Found: Br, 66.8.  $C_8H_8N_2Br_4S$  requires Br, 66.1%). It had the usual properties of these bromides.

*1-Amino-4-methylbenzthiazole.*—The *tetrabromide* was reduced in the usual way. The base was precipitated by making the sulphurous acid solution alkaline and a further small quantity was obtained by extracting the filtrate with ether. The base crystallised from 50% alcohol in pearly plates, m. p.  $145^{\circ}$  (sintering at  $135^{\circ}$ ), having the faint characteristic odour of these compounds (Found: S, 19.2.  $C_8H_8N_2S$  requires S, 19.5%).

*1-Amino-3 : 5-dimethylbenzthiazole Tetrabromide.*—Prepared from 1 g. of *m*-xylylthiocarbamide and bromine (0.8 c.c.) in chloroform (10 c.c.), the *tetrabromide* separated from the cooled solution in red flakes which, after being dried in a vacuum, became colourless at

80—90° and were unmelted at 250° (Found: Br, 63.8.  $C_9H_{10}N_2Br_4S$  requires Br, 64.3%). It is very unstable, losing bromine and becoming colourless on exposure to air for  $\frac{1}{2}$  hour.

1-Amino-3:5-dimethylbenzthiazole, obtained from it in the usual way, crystallised from ether in needles and thereafter from dilute alcohol in silvery plates, m. p. 116° (softening at about 100°), having the usual faint odour of these compounds (Found: S, 16.8.  $C_9H_{10}N_2S$  requires S, 17.9%).

2-Amino- $\beta$ -naphthathiazole Tetrabromide.—Prepared from  $\alpha$ -naphthylthiocarbamide (0.5 g.) and bromine (0.5 c.c.) in chloroform, the tetrabromide was obtained as an orange, microcrystalline powder which, after drying in a vacuum, began to lighten in colour at 130° and was unmelted at 260° (Found: Br, 60.9.  $C_{11}H_8N_2Br_4S$  requires Br, 61.6%).

2-Amino- $\beta$ -naphthathiazole, obtained by reducing the tetrabromide, crystallised from alcohol-ethyl acetate in small, odourless crystals, m. p. 235—237° after sintering at about 220° (Found: S, 16.1.  $C_{11}H_8N_2S$  requires S, 16.0%).

2-Amino- $\alpha$ -naphthathiazole Tetrabromide.— $\beta$ -Naphthylthiocarbamide (0.5 g.) was brominated as in the case of the  $\alpha$ -compound. The tetrabromide was obtained as a yellow, microcrystalline powder, m. p. 165° (decomp.) (Found: Br, 60.8%).

2-Amino- $\alpha$ -naphthathiazole crystallised from alcohol-ethyl acetate in small prisms, m. p. 249—251°, after sintering at about 230° (Found: S, 16.2.  $C_{11}H_8N_2S$  requires S, 16.0%).

*The 1-Aminobenzthiazole Dibromide  $\rightarrow$  5-Bromo-1-aminobenzthiazole Hydrobromide Transformation.*

1-Aminobenzthiazole dibromide (obtained by Hugershoff's method, *loc. cit.*; after being dried in the usual way, it turned red at 105—110°, melted at 112—114°, and charred at 206°) (36 g.) was added to 200 c.c. of nearly boiling water. A colourless solution was at once produced which on evaporation on the steam-bath left 32 g. of crude 5-bromo-1-aminobenzthiazole hydrobromide (a certain amount of the dibromide undergoes decomposition, giving the hydrobromide of 1-aminobenzthiazole). Thirty g. of the product, after treatment with ammonia and recrystallisation from alcohol, yielded 15—16 g. of 5-bromo-1-aminobenzthiazole.

In view of the curious physiological action of certain benzthiazole derivatives (J., 1925, 127, 911), the "alleged immunity to certain swamp fevers conferred by "thiazole dermatitis" (private communication from Dr. G. M. Dyson), and the clinical use of substances such as *o*-aminophenyl sulphide in syphilis, a series of

experiments has been commenced in collaboration with Dr. Dyson on the trypanocidal effect of water-soluble aminobenzthiazoles.

The author desires to express his gratitude to Professor J. F. Thorpe, F.R.S., for his kind interest in these experiments, and to the Trustees of the Dixon Fund of the University of London for a grant which has defrayed the cost of some of the materials.

### CLXXX.—*Aminobenzthiazoles. Part IV. The Stability of the Bromides of the 1-Xylidinodimethylbenzthiazoles.*

By ROBERT FERGUS HUNTER.

THE remarkable instability of 1-amino-3 : 5-dimethylbenzthiazole tetrabromide (this vol., p. 1389) must be attributed to the combined effects of the *o*- and *p*-methyl groups, since the stability of the bromo-addition compounds of 1-amino-5-methylbenzthiazole, 1-amino-3-methylbenzthiazole, and 1-amino-3 : 5-dimethylbenzthiazole decreases in the order given. The *o*-methyl group is mainly responsible for the instability, a fact which is further exemplified by the relative stabilities of the bromides of 1-*o*-toluidino-3-methylbenzthiazole and 1-*p*-toluidino-5-methylbenzthiazole (Hunter, J., 1925, 127, 2023).

It was therefore of interest to examine the effect of replacing the amino-group in 1-amino-3 : 5-dimethylbenzthiazole by an arylamino-group. In the first place, it might be expected on *a priori* grounds that the residual affinity of the aromatic nucleus of the arylamino-group would exert a stabilising influence on the bromo-addition compound of such a base, and secondly, on the basis of Ingold's modified strain theory (J., 1921, 119, 305 and later papers),\* the bulky substituent might be expected to enhance the arylamino-

\* The theoretical basis of this theory will be discussed in a paper dealing with the mobility of the 5-bromo-1-alkylaminobenzthiazole system and the addition of bromine to tautomeric systems of this type. The unsaturation of the ring nitrogen atom of the mobile triad system  $N:C-N[H] \rightleftharpoons N[H]:C-NX$  is profoundly affected by the mobility or potential mobility of the tautomeric hydrogen atom. For instance, there is a striking increase in the stability of the 5-bromo-1-alkylaminobenzthiazole 2 : 2-dibromide towards hydriodic acid as the alkyl group is in turn ethyl, *n*-propyl, *n*-butyl, and *isobutyl*. In this connexion it is hoped to obtain some information on the deflexion of the carbon tetrahedral angle (Deshapande and Thorpe, J., 1922, 121, 1430, and later papers) produced by the hitherto unstudied butyl, amyl, and hexyl groups.

phase of the mobile aminothiazole system (this vol., p. 1385) the ring nitrogen atom in which is more unsaturated than that in the 1-imino-1:2-dihydrothiazole form. The second effect also, owing to the nitrogen atom being the centre of unsaturation in a thiazole ring (this vol., p. 538), would increase considerably the stability of the bromo-addition compound.

The bromides of the 1-xylidinodimethylbenzthiazoles (I and II) were therefore studied and it was found that the 1-xylidino-group had a most striking stabilising effect on the aminobenzthiazole bromide complex.

Under the usual conditions of bromination in chloroform (*loc. cit.*), *s*-di-*m*-xylylthiocarbamide readily passed into the *tetrabromide* of 1-*m*-xylidino-3:5-dimethylbenzthiazole (III), which is one of the most stable compounds of this type so far isolated, its stability in air being of the same order as that of the 2-β-naphthylamino-α-naphthathiazole bromides (J., 1925, 127, 2270). The formation, in the presence of an excess of halogen, of a labile *heptabromo*-addition compound of the dimethylbenzthiazole was also observed, this compound being doubtless the hydrobromide of the hexabromo-addition compound, which was on one occasion isolated in an impure condition. These compounds were all reduced in the usual manner by sulphurous acid, yielding the xyloidinodimethylbenzthiazole (I).

While these experiments were in progress, a paper by Levi (*Atti Cong. Naz. Chim. Ind.*, 1924, 400) appeared, in which 1-*m*-xylidino-3:5-dimethylbenzthiazole (I) was described as being formed by the thionation of a mixture of *m*-xylidine and phenyl-*m*-xylylthiocarbamide. Levi's product, however, although it gave the pure acetyl derivative, must have been very impure, because the melting point recorded is nearly 20° too low. This is not so surprising in view of the difficulties involved in such preparations (Hunter, *J. Soc. Chem. Ind.*, 1923, 42, 302T).

Under the usual conditions of bromination, *s*-di-*p*-xylylthiocarbamide readily passed into the *tetrabromide* of 1-*p*-xylidino-3:6-dimethylbenzthiazole (IV), a bright red compound resembling the *m*-xylidino-isomeride in stability and other properties.

None of the 1-xylidinodimethylbenzthiazole bromides gave any evidence whatsoever of the existence of stable yellow tribromides (*loc. cit.*). Therefore, with regard to stability in the air, the 1-arylaminobenzthiazole bromides fall into two groups, the first of which includes the labile red bromo-addition compounds, such as those derived from 1-anilinobenzthiazole and its tolyl and  $\alpha$ -naphthyl homologues, which on exposure to air evolve bromine and pass into stable yellow tribromides; and the second of which includes the stable red bromides of 2- $\beta$ -naphthylamino- $\alpha$ -naphthathiazole and of the 1-xylidinodimethylbenzthiazoles described in this paper, which lose bromine appreciably only on prolonged exposure to moist air and do not appear to be capable of yielding yellow tribromides.

#### EXPERIMENTAL.

**1-m-Xylidino-3 : 5-dimethylbenzthiazole Hexabromide Hydrobromide.**—A solution of 1 g. of *s*-di-*m*-xylylthiocarbamide in chloroform (10 c.c.) was gradually treated with a solution of bromine (1 c.c., in chloroform, 3 c.c.) and then heated under reflux for 2 minutes, cooled, and a part of the solvent evaporated off in a vacuum at 15°. The red gum produced, which solidified, was triturated with an ethereal solution of bromine; the *heptabromide* was then obtained in small, red prisms which, after drying in a vacuum over potassium hydroxide, sintered at 153° and melted at 158° (decomp.) (Found: Br, 66·7.  $C_{17}H_{18}N_2Br_6S \cdot HBr$  requires Br, 66·7%).

**1-m-Xylidino-3 : 5-dimethylbenzthiazole Tetrabromide (III).**—The dixylylthiocarbamide (5 g. in chloroform, 10 c.c.) was treated as above (bromine, 4·8 c.c., in chloroform, 10 c.c.) and the cooled solution allowed to crystallise in a vacuum; the *tetrabromide* was then obtained in small, orange-red crystals which, after being washed with bromine in ether and dried in a vacuum, melted at 130° (decomp.) (Found: Br, 52·7.  $C_{17}H_{18}N_2Br_4S$  requires Br, 53·3%). The tetrabromide had the usual properties of these compounds, being reduced by hydriodic acid with liberation of iodine, and evolving acetaldehyde on boiling with dilute alcohol.

Bromination in similar circumstances of 5 g. of the thiocarbamide with 5 c.c. of bromine produced on one occasion a red gum which, on trituration with bromine in ether, solidified to a mass of small, red crystals, m. p. 126° after drying in a vacuum (Found: Br, 61·3.  $C_{17}H_{18}N_2Br_6S$  requires Br, 62·9%).

1-m-Xylidino-3 : 5-dimethylbenzthiazole obtained in the usual way by reducing any of the bromides with sulphurous acid and sulphur dioxide (*loc. cit.*) and liberating the base with ammonia, crystallised from alcohol-ethyl acetate (1 : 1) in large flakes and thereafter

from light petroleum (b. p. 40—60°) in small prisms, both forms melting at 175° (Found : S, 11.4. Calc. : S, 11.4%).

The acetyl derivative, obtained by heating a solution of the base in acetic anhydride for a few minutes and pouring it into alcohol, slowly crystallised in large prisms, m. p. 131—132° after recrystallisation from alcohol (Levi, *loc. cit.*, gives m. p. 131°).

*s-Di-p-xylylthiocarbamide*.—A mixture of technical *p*-xylydine (18 g.), alcohol (27 c.c.), carbon disulphide (33 c.c.), and potassium hydroxide (4 g.) was heated for 2—3 hours, and the product worked up in the usual way; on recrystallisation from alcohol the thiocarbamide was obtained in needles, m. p. 146—147° (Dyson and George, J., 1924, 125, 1705, give the m. p. as 148.5°). The yield was about 50%.

*1-p-Xylidino-3 : 6-dimethylbenzthiazole Tetrabromide* (IV).—*Di-p-xylylthiocarbamide* (1.25 g.) in chloroform was treated with bromine (1.2 c.c.) in chloroform (2.5 c.c.) in the usual way, the solution concentrated in a vacuum, and the product triturated with an ethereal solution of bromine. The red oil obtained, on partial evaporation of the ether, solidified to a mass of small, red crystals of the *tetrabromide* which were washed with chloroform and dried in a vacuum in the usual way. They had the usual properties and charred above 200° (Found : Br, 53.6.  $C_{17}H_{18}N_2Br_4S$  requires Br, 53.2%).

*1-p-Xylidino-3 : 6-dimethylbenzthiazole*, obtained by the reduction of the *tetrabromide* in the usual way, crystallised from ethyl acetate in small prisms, m. p. 200° (Found : S, 11.6.  $C_{17}H_{18}N_2S$  requires S, 11.4%).

In conclusion, the author desires to express his gratitude to Professor J. F. Thorpe, F.R.S., for his kind interest in this work, and to Mr. G. G. Alford for carrying out some of the experiments. A part of the expense of the materials was defrayed by a grant for which the author is indebted to the Trustees of the Dixon Fund of the University of London.

[Received, February 9th, 1926.]

## CLXXXI.—*The Direct Synthesis of Nitrous Oxide.*

By DAVID LEONARD CHAPMAN, RICHARD ALLEN GOODMAN, and  
RODNEY THOMAS SHEPHERD.

HITHERTO it has not been found possible to effect a direct synthesis of nitrous oxide. We shall show that this compound is slowly formed when an electric discharge is passed through nitrogen at low

pressure in a quartz tube into the walls of which oxygen has previously been driven by means of the discharge, and can be isolated as it is formed by condensing it in a U-tube surrounded by liquid air. When completely decomposed by heating a platinum wire in it, the volume increases in the ratio 2 to 3, the proportion of nitrogen to oxygen in the decomposition products being 2 to 1.

The quartz tube, A (*vide* diagram), in which the discharge took place was approximately 1 m. in length and 1180 c.c. in volume. The rest of the apparatus was of glass, and was connected to the quartz tube by a ground glass joint, B, which was lubricated with glacial phosphoric acid and sealed by mercury. The long U-tube,  $t_1$ , could be immersed in liquid air when desired, and served the

double purpose of keeping back mercury vapour and of condensing the nitrous oxide. A T-piece, C, led to the McLeod gauge used to measure the pressures. The discharge tube, with gauge and liquid-air trap, could be shut off from the rest of the apparatus by the mercury seals  $s_1$  and  $s_2$ . The seal,  $s_2$ , served to put the quartz tube into communication with a U-tube,  $t_2$ , and a bulb, D, which contained a spiral of fine platinum wire welded to thick platinum leads, which passed to the outside through a lead-glass seal.  $t_3$  was another U-tube which could be surrounded by liquid air. Beyond the mercury seal,  $s_3$ , was a mercury vapour pump and an auxiliary Sprengel pump. The remainder of the apparatus was for the purpose of generating and storing the gases required.

*Hydrogen.*—The hydrogen required for the analysis was admitted to the apparatus by diffusion through the walls of a platinum tube, E, sealed into the end of a glass tube. The platinum tube was heated

to redness in an atmosphere of hydrogen, prepared in the ordinary way in a small Kipp's apparatus from zinc and dilute sulphuric acid. The gas, after bubbling through a solution of caustic soda, was passed through a quartz tube which surrounded the platinum tube. To admit hydrogen to the apparatus the quartz tube was heated strongly.

*Nitrogen.*—The nitrogen was prepared by the decomposition of pure anhydrous barium azide contained in a vertical tube, F. This was connected to a reservoir, G, of capacity about 400 c.c., in which the gas was stored. One limb of the seal  $s_4$  was blown out into a bulb, of volume about 4 c.c., the upper end being connected by millimetre capillary tubing to another seal,  $s_5$ . This arrangement was employed to withdraw small amounts of gas from the reservoir, in which the pressure was about 1 cm., in the following way. The mercury in the seal  $s_4$  was lowered, and when raised again, shut off a small amount of gas in the bulb. The seal  $s_5$  was then lowered until the T-piece was just cleared. The mercury in  $s_4$  was then raised, and the gas enclosed in the bulb driven past the seal  $s_5$  into the apparatus. By subsequently lowering the mercury in the seal  $s_4$ , the bulb could be again evacuated. The tube, F, containing the barium azide, was heated in a small bath of glycerol. The nitrogen was evolved at a convenient rate at  $152^\circ$ .

*Oxygen.*—The oxygen was prepared by the thermal decomposition of recrystallised potassium permanganate contained in the tube K. The gas passed up a tower, L, containing solid caustic potash to absorb any carbon dioxide. L was connected to a reservoir, H, and two seals,  $s_6$  and  $s_7$ , by means of which small quantities of gas could be removed as described above in the case of nitrogen.

The gases were not admitted to the discharge tube until they had remained in that portion of the apparatus between the seals  $s_1$ ,  $s_3$ ,  $s_5$ ,  $s_7$ , for at least  $\frac{1}{2}$  hour with liquid air surrounding the U-tube  $t_3$ . The gases did not come into contact with any grease taps whatever.

*The Discharge.*—For the purpose of exciting the discharge, two pieces of aluminium foil about 6 cm. wide were fastened by copper wire round the tube at equal distances from each end and from each other. The aluminium electrodes were connected by means of copper wire with the secondary of a 10-inch induction coil, which was run from the 100-volt mains, a resistance keeping the primary current constant at about  $2\frac{1}{4}$  amp. Interruption of the primary was effected by a mercury break of the simple dipper type. The dipper was oscillated by means of an eccentric coupled directly to the shaft of an electric motor. By this means constant interruption was obtained. There was an external spark-gap of 1 cm.

To conduct an experiment, the whole apparatus was first

thoroughly evacuated, all the tubing, including the McLeod gauge, being heated twice with a blow-pipe flame, in order to drive off gases retained by the surface of the glass. The quartz tube was thoroughly heated to redness, section by section, to expel any gas that might be absorbed. The required amount of oxygen was then withdrawn from the reservoir, and admitted to the quartz tube in the manner already described. The initial pressure of oxygen was about 0.08 mm. The pressures recorded below have been reduced to the temperature of 18°, allowance being made for the cooling effect of the liquid air on the small proportion of gas contained in the U-tube  $t_1$ . After the discharge had been started, the progress of the absorption was followed by measuring the pressure at convenient intervals of time. The discharge was stopped when the pressure-time curve had become very flat. The liquid air was then removed, and the tube evacuated. Nitrogen was then admitted to a pressure of about 0.08 mm., the liquid air replaced round  $t_1$ , and the discharge again started. From time to time the discharge was stopped, and the pressure measured both with and without liquid air surrounding the U-tube  $t_1$ . The difference between these two pressures gave the amount of condensable gas formed. It was, of course, produced at a gradually decreasing rate. The results of four experiments are in Table I.

TABLE I.

Oxygen absorbed.	Nitrogen absorbed.	Condensable gas.	Duration.
0.01669 mm.	0.03777 mm.	0.01688 mm.	6½ hrs.
0.02168	0.04282	0.02321	9½
0.01576	0.04725	0.02999	11½
0.01479	0.04869	0.02185	17½

When a convenient amount of gas had been obtained, the tube was evacuated, the liquid air remaining round the U-tube. A small amount of the condensable gas was always lost during this operation, showing that the liquid had an appreciable vapour pressure at the temperature of liquid air. Some experiments were made with a view to determining the properties of the gas. It was quite stable, and could be kept for any length of time. It was very rapidly destroyed by the discharge, decomposition being complete in about 5 seconds. The observed expansion was dependent on the length of time during which the discharge passed, a maximum being reached in a few seconds. The contraction which followed the expansion was probably mainly due to combination of the oxygen produced in the decomposition with mercury vapour, in the presence of which this experiment had to be performed. The gas was not condensed when the U-tube was surrounded by solid carbon dioxide and ether. It did not react with oxygen when left to stand with this

gas, showing that it could not be nitric oxide. This conclusion was confirmed by the circumstance that the gas did not attack the mercury in the McLeod gauge either before or after it had been mixed with oxygen.

*Analysis.*—The gas was analysed in the following way. The mercury seal  $s_2$  was opened, and the pressure of the gas in the whole of the apparatus to the right of the seal  $s_1$  measured. Liquid air was then placed round the U-tube  $t_2$ , and when all the gas had condensed,  $s_2$  was closed. The liquid air was then removed, and replaced by solid carbon dioxide and ether, in order that the decomposition might be carried out in the presence of as little mercury vapour as possible. The platinum spiral was then heated to bright redness. After some hours the heating was stopped and the bulb allowed to cool. The flask containing the solid carbon dioxide and ether was removed, the seal  $s_2$  opened, and the pressure measured both with and without liquid air surrounding the U-tube  $t_1$ . The difference between these two measurements gave the amount of condensable gas undecomposed. The difference between this and the amount originally present represented the gas decomposed. The results are in Table II.

TABLE II.

	Mm.
Pressure after decomposition, with liquid air .....	0.03746
Pressure after decomposition, without liquid air .....	0.03948
Condensable gas undecomposed .....	0.00202
Initial amount of condensable gas .....	0.02661
Condensable gas decomposed .....	0.02459
Expansion on decomposition .....	0.01287

It will be seen that, within the limits of experimental error, the expansion is equal to half the amount of condensable gas decomposed.

The next analysis was made in such a way as to enable the amount of oxygen produced by the decomposition to be determined. When this was known, the relative proportions of oxygen and nitrogen in the condensable gas could be calculated.

The ratio of the volume of the quartz tube *plus* tubing up to the seals  $s_1$  and  $s_2$ , to the total volume when  $s_2$  was opened, was first determined by measuring the pressure of the same amount of gas in the two volumes. The decomposition was then carried out in the same manner as before. While this was proceeding, hydrogen was admitted to the quartz tube, and its pressure measured. From the ratio of the volumes, the pressure this gas would produce in the total volume when  $s_2$  was opened was calculated. After decomposition, the mercury in  $s_2$  was lowered, and the pressure measured, as in the former case, with and without liquid air surrounding the

U-tube  $t_1$ . The pressure of the products of decomposition was found by subtracting the pressure of the hydrogen from the total pressure measured after decomposition with liquid air surrounding the U-tube.  $t_2$  was then immersed in liquid air, and the spiral heated for several hours until no further fall in pressure occurred. From the contraction due to the formation of water, the amount of oxygen present was deduced. The nitrogen was found by difference. The results are in Table III.

Pressure of products of decomposition .....	0.03081
Expansion produced by decomposition .....	0.00991

(b) *Estimation of oxygen.*

Initial pressure (hydrogen, nitrogen, and oxygen) .....	0.05998
Final pressure (excess hydrogen and nitrogen) .....	0.02891
Contraction .....	0.03107
Amount of oxygen required for this contraction .....	0.01036

(c) *Summary.*

Condensable gas decomposed .....	0.02090
Oxygen produced .....	0.01036
Nitrogen produced .....	0.02045

The expansion produced on decomposition is again seen to be half the amount of condensable gas destroyed, and the ratio of nitrogen to oxygen in the products is 2 to 1, leaving no doubt that the gas was nitrous oxide.

In experiments not described above, a small proportion of oxygen was added to nitrogen in the discharge tube. Even when the partial pressure of the oxygen was as small as one-tenth of that of the nitrogen, nitrogen peroxide was produced.

## CLXXXII.—*Resins in Coal. Studies in the Composition of Coal.*

By WILFRID FRANCIS and RICHARD VERNON WHEELER.

WE have shown (J., 1925, 127, 112) that bituminous coal consists essentially of ulmin compounds in which morphologically organised plant-tissues, that have escaped ulmification, are dispersed. The ulmins, when first formed as the products of mouldering decay of vegetable matter, are characterised by ready solubility in alkaline solutions, but their derivatives, in the condition in which they normally exist in bituminous coal, are insoluble. Solubility in alkaline solutions can, however, be conferred on the ulmin compounds of bituminous coal by such mild oxidation as is afforded by treatment with air at low temperatures (up to 150°) or with hydrogen peroxide. The soluble ulmins so produced, which we have termed "regenerated" ulmins, are not identical in character with the insoluble ulmins in newly-won bituminous coal, for the external groupings of the molecules are modified during oxidation, the more easily detached being eliminated to form simple oxygenated compounds, with the substitution of carboxylic groupings which render the residue definitely acidic in character. The nuclear structure, however, remains unaffected. This nucleus we have shown (J., 1925, 127, 2236) to be built up of compact systems of benzenoid groupings connected together by heterocyclic structures, such as pyrrole and furan or their derivatives.

The bulk of bituminous coal consists of ulmins having molecular structures of this character. In banded bituminous coals, such as constitute the majority of British coals, the dull (durain) bands contain a proportion, usually between 20 and 30%, of morphologically organised plant entities, amongst which spore exines and cuticles predominate, that have undergone but little change from their original condition during the processes of decay suffered by the accumulations of plant material from which the coal was formed. Of the bright portions of coal, the clarain contains but small proportions, up to about 5%, of such plant entities, whilst the vitrain contains none.

In our previous papers we noted that, for the sake of simplicity, the existence in coal of natural plant substances devoid of morphological organisation, such as "resins," could be ignored, but expressed the intention of dealing with these substances separately. In order to do so, it is necessary for us to enlarge on the statement, contained in a footnote to our paper on the constitution of the coal ulmins (*loc. cit.*, p. 2236), regarding the character of vitrains; for the

× 330

× 330

FIG. 1.

× 130

FIG. 2.

× 130

FIG. 3.

× 150

existence of resins in a bituminous coal is best revealed in the vitrain portion.

The vitrain portion of a banded bituminous coal has for long been considered by British investigators to be essentially structureless, having been so qualified in Stopes's original descriptions of the banded ingredients of bituminous coal (*Proc. Roy. Soc.*, 1919, *B*, 90, 470), based largely on an examination of transparent sections. Partly through the use of a new method of examining, by reflected light, coal surfaces that have been polished and etched, and partly as the result of the remarkably fine technique for the preparation of transparent sections of coal developed by Dr. R. Thiessen, of the United States Bureau of Mines, who has been good enough to prepare for us sections of a number of specimens of vitrain from British coals, it is now realised that a completely structureless vitrain, if it exists at all, is a rarity.

A description of the structures to be observed in most vitrains is reserved for another communication. It will suffice here to state that, in all of the many examples of vitrain that we have examined, the appearance of plant cells, usually derived from cortical tissues, can be disclosed. We purposely refer to the "appearance" of plant cells, because these structures cannot be separated from the coal mass intact and preserved, as can the cuticles and spore exines, and it is clear that, being ulmins, they are pseudomorphs of the original structures.

For the work described in this paper, vitrain from the Hamstead coal, which we have used for much of our previous work, was chosen because its oxidation by hydrogen peroxide could readily be controlled. During a carefully regulated oxidation of Hamstead vitrain, the soluble "regenerated" ulmins being removed from time to time by means of dilute sodium hydroxide solution, it was found that, when but little residue remained, the particles began to assume distinctive shapes. Some of the particles had the appearance of fibre cells, whilst in a few the shapes of tracheids, showing bordered pits, could be observed. All such shapes were, however, transient, disappearing as the ulmins dissolved. Nevertheless we were able to secure examples and retain them long enough to photograph them under the microscope. Some are reproduced in Fig. 1.

The fragments to which, from the point of view of the present paper, the greater interest attaches, were dark-coloured and elongated. They were usually ribbed along their major axes and had clean-cut ends. On persisting with the action of hydrogen peroxide, followed by treatment with sodium hydroxide solution, these fragments became gradually lighter in colour and finally, when all the ulmins had been removed, appeared as yellow rods varying in length

up to 0.02 inch. Their diameter was about one-tenth of their length.

From their general character and from the cellular appearance of the ulmin material surrounding them, there seems little doubt but that these rods were resin inclusions. A number of them were collected and extracted in a Soxhlet fat-extraction apparatus with chloroform, in which they were almost completely soluble, when a dark yellow semi-solid extract was obtained. The analytical results (Found: C, 80.6; H, 10.3%) are consistent with the assumption that the material was a resin.

Confirmation of the suggestion that the resin rods existed in this sample of Hamstead vitrain in the position that they had occupied in the woody tissues from which the vitrain was formed is obtainable from photomicrographs of portions of the same sample of vitrain as was used for the oxidation experiments, polished and etched with chromic and sulphuric acids. Two such photographs are reproduced in Figs. 2 and 3, the magnification in each instance being 130 diameters. In Fig. 2, the surface is at right angles to, and in Fig. 3 it is parallel with, the cell-walls. The resin inclusions appear as circular patches in Fig. 2 and as rods in Fig. 3.

The cellular structure that abounds in vitrain—in the present example it is of xylem—can be clearly seen in the photographs, and it may well be asked how such structures could have escaped notice. Although they are readily rendered visible by polishing and etching a vitrain surface, a method of examination that has but recently come into use, the structures are difficult to detect in a transparent section viewed by transmitted light, because they are not outlined on the transparent reddish-brown background by a contrasting colour, but are faintly visible (and then only when the section is exceedingly thin and well illuminated) by reason of slight differences in shade. For example, a photograph of a section ( $\times 150$ ) of the same sample of vitrain as was used for Fig. 2 is reproduced in Fig. 4. The circular patches so noticeable in Fig. 2 can be recognised, but no organised structures can be detected.

We are indebted to Miss M. M. Evans, of the Fuel Research Board's staff, for the preparations illustrated in Figs. 2 and 3, and to Dr. R. Thiessen for that illustrated in Fig. 4. Our thanks are also due to the Safety in Mines Research Board for permission to publish this paper.

SAFETY IN MINES RESEARCH BOARD,  
SHEFFIELD.

[Received, April 22nd, 1926.]

CLXXXIII.—*A Study of the Rule of the Conservation of the Type of Substitution in Aromatic Substances.*  
*Part I. Chlorination of 2-Chloro-4-nitrotoluene.*

By WILLIAM DAVIES and GEOFFREY WINTHROP LEEPER.

MORGAN and DREW (J., 1920, 117, 793) have shown that the main product (more than 85%) of nitration of 2-chloro-4-nitrotoluene (I) is the 5-nitro-derivative (II). It was shown by one of us (J., 1922, 121, 806) that, when (I) was chlorinated in the presence of certain catalysts, not the 5- but the 6-chloro-derivative (III) was produced in a yield of more than 30%, and no other isomeride was isolated in a pure condition. It was accordingly stated (p. 806) that "it is very probable that the separation of (III) in such large amount indicates that this is the chief product." Holleman (*Chemical Reviews*, 1924, 217) quite rightly points out that (III) had not been proved to be the principal product of the reaction, and considers it possible that (IV) may occur in the residual non-crystallisable oil in such large amount as actually to be the chief product of the reaction. As changes in substitution type are of great importance both from the synthetical and the theoretical point of view, an attempt has been made to determine more accurately the proportion of (III) formed.

The more obvious lines of attack have already been investigated (Davies, *loc. cit.*, p. 810) without success. As the monochlorination product of (I) is clearly an extremely complicated mixture, the method of estimation suggested by Holleman (*loc. cit.*, p. 217) was not adopted, but instead attempts were made to convert (III) into a derivative which could be separated from the mixture by chemical means. It is to be expected that (III) would be rather more easily substituted than (IV), and the behaviour of certain reagents on (III) was accordingly examined. It was not readily sulphonated, but was quantitatively converted into the nitro-derivative (V) by

nitration under mild conditions. This could not be smoothly converted into a nitrophenol by the action of alkali under various conditions, but it was readily transformed by the action of alcoholic ammonia into (VI) (the yield of pure substance being 77%), and insufficient of the isomeric 2:6-dichloro-3-nitro-*p*-toluidine was formed to admit of its being isolated. This change is incidentally still another instance of replacement in agreement with the rule of Kenner and Parkin (J., 1920, 117, 852. See also J., 1925, 127, 2344).

2:6-Dichloro-4-nitro-*m*-toluidine (VI) has very slight basic properties and accordingly attempts were made to convert it into an acidic substance. It does not react with *p*-toluenesulphonyl chloride, and although good yields of the benzoyl and acetyl derivatives of the amine may be obtained, these compounds do not dissolve very readily in cold dilute alkali. The *chloroacetyl* derivative (VII), however, is quantitatively obtained, and easily dissolves in cold aqueous sodium hydroxide solutions, from which it is precipitated unchanged on acidification. It was hoped to be able to separate in this way (V) from (IV) or its nitro-derivative (VIII) (compare Cohen and Dakin, J., 1901, 79, 1131).

The chlorination product from (I) was therefore nitrated under the gentle conditions which were sufficient to give (V), and after the removal of the catalyst the whole product was treated with alcoholic ammonia, but it was then found that some portion of the nitration product other than (V) gave amines with ammonia with the formation of large quantities of ammonium chloride. It is possible that the 5-chlorine atom in (VIII) had, despite the steric hindrance due to the two adjacent nitro-groups, reacted with the ammonia. As the *chloroacetyl* derivatives of the amines produced were themselves soluble in alkali, this method of separation by chemical means was abandoned.

Finally, crystallisation from methylated spirit of the nitration product of the chlorination mixture was resorted to, and 2:6-dichloro-3:4-dinitrotoluene (V) was isolated in a yield corresponding to 47.9% of 2:6-dichloro-4-nitrotoluene (III) in the chlorination product. This physical method of separation, although far from being an ideal one, makes it certain, when considered in connexion with the following facts, that (III) is the chief dichloronitrotoluene formed. First, it is impossible to separate by fractional crystallisation all the (V) produced, owing to the formation of liquid and low-melting solid mixtures of a complex nature. Secondly, it has been shown (Davies, *loc. cit.*, p. 810) that the monochlorination of (I) with the calculated amount of chlorine left some unchanged substance, and therefore that one or more trichloro-*p*-nitrotoluene derivatives were formed. In fact, a larger amount of (V) can be isolated

when the chlorine absorbed is about 1% greater than the quantity theoretically required to produce dichloro-*p*-nitrotoluenes (see p. 1417). Hence the monochlorination product of (I) contains considerable quantities of substances other than dichloro-*p*-nitrotoluenes.\* Moreover, there is reason to believe that a portion of the chlorine goes into the side chain. On monochlorination of (III) in presence of either antimony trichloride or ferric chloride, a very complex mixture is formed from which nothing pure can be isolated by distillation or crystallisation, although mono-substitution could lead only to 2:5:6-trichloro-4-nitrotoluene. Nitration and reduction followed by condensation with phenanthraquinone gives only a small quantity of a phenanthrazine (m. p. 343°), which is possibly derived from 2:5:6-trichloro-4-nitrotoluene. It is certain from this experiment that the expected nuclear substitution of (III) has not occurred smoothly, and no doubt this anomalous reaction, whatever it may really be, occurs to some extent in the chlorination of the simpler 2-chloro-4-nitrotoluene. Side-chain substitution in presence of a catalyst is not so rare as is usually considered. One such instance, with 2-chloro-4-nitrotoluene, has already been pointed out (J., 1922, 121, 812), with iodine as the catalyst. The present authors find that the action of bromine on *p*-nitrotoluene at 95–120° (this relatively high temperature being necessary to bring about a reaction) gives a 46% yield of pure *p*-nitrobenzyl bromide (m. p. 99°), and a similar result with toluene in presence of antimony tribromide and bromine is recorded by van der Laan (*Rec. trav. chim.*, 1907, 26, 1).

It is difficult to advance a logical and satisfactory explanation which will account for a change of substitution type such as the one here established. As has been already pointed out (Davies, *loc. cit.*, p. 809), steric conceptions based on the atomic volumes of the groups whose positions of substitution are compared lead to contradictory conclusions, though Holleman (*loc. cit.*, p. 220) apparently considers the application of such ideas helpful as far as some rather simpler molecules are concerned. A more satisfactory, although far from convincing explanation may be found in a consideration of the difference in chemical nature of the two groups under comparison, and also in the experimental conditions of the

\* In the actual experiments herein described, *p*-nitrotoluene was dichlorinated and 2-chloro-4-nitrotoluene was not first isolated and monochlorinated (see Davies, *loc. cit.*, p. 810, for the justification of this). In any case, the other possible isomeride, 3-chloro-4-nitrotoluene, could on further chlorination give no 2:6-dichloro-*p*-nitrotoluene, and therefore the dichlorination of *p*-nitrotoluene could not, when compared with the monochlorination of 2-chloro-4-nitrotoluene, favourably affect the proportion of 2:6-dichloro-3:4-dinitrotoluene (V) actually isolated.

reactions. Investigations are being carried out with special reference to these points of view.

#### EXPERIMENTAL.

**2 : 6-Dichloro-3 : 4-dinitrotoluene (V).**—A solution of dry 2 : 6-dichloro-4-nitrotoluene (III) (6.7016 g.) in concentrated sulphuric acid (33 c.c.) at 65° is treated with a mixture of nitric acid (3.3 c.c.; *d* 1.52) and concentrated sulphuric acid (17 c.c.). The temperature is kept at 80—85° for 8 minutes. The oil that has separated then solidifies and, after drying over phosphorus pentoxide in a cathode-ray vacuum, weighs 8.1517 g. (yield 99.8%). Its m. p., 129—130°, is raised only 1° by repeated crystallisation. Further exposure to a cathode-ray vacuum causes a steady loss in weight due, as shown by a blank experiment with pure dry material, to the volatility of the substance.

The oxidisable *o*-diamine obtained by reducing 2 : 6-dichloro-3 : 4-dinitrotoluene with zinc dust in dilute alcohol containing a trace of ammonium chloride was characterised as 1 : 3-dichloro-2-methylbenzophenanthrazine, yellowish-brown plates from anisole, m. p. 279—286° (corr.), by condensation with phenanthraquinone in glacial acetic acid. The azine is sparingly soluble in cold organic solvents and develops a cerise coloration in cold concentrated sulphuric acid (Found : Cl, 19.3.  $C_{21}H_{12}N_2Cl_2$  requires Cl, 19.5%). The conversion of (V) into this compound is, however, not a quantitative process and, moreover, does not lend itself to the rough estimation of (V) in the presence of other *o*-dinitro-compounds of toluene.

**2 : 6-Dichloro-4-nitro-*m*-toluidine (VI).**—A mixture of 2 : 6-dichloro-3 : 4-dinitrotoluene (50 g.) and 200 c.c. of alcoholic ammonia (5%) is heated for  $\frac{1}{2}$  hour at 90—98° (10 atm.). The pressure is then released, 50 c.c. of alcoholic ammonia (10%) are added, and the mixture is heated for 2 hours at 127° and 7.3 atm. The product is allowed to crystallise, and after recrystallisation from alcohol 34 g. (77% yield) of the pure amine are obtained, only a small amount of low-melting material and a mere trace of ammonium chloride being produced. 2 : 6-Dichloro-4-nitro-*m*-toluidine, m. p. 136°, forms thin, deep yellow plates from benzene and brown prisms from alcohol and is soluble in mineral acids only if very concentrated (Found : Cl, 31.75.  $C_7H_6O_2N_2Cl_2$  requires Cl, 32.1%). It is different from the only other possible isomeride, 2 : 6-dichloro-3-nitro-*p*-toluidine (m. p. 130—131°; Davies, *loc. cit.*, p. 814), and is converted through its diazonium sulphate into 2 : 6-dichloro-4-nitrotoluene in good yield. Its constitution is thus established.

**2 : 6-Dichloro-4-nitroaceto-*m*-toluidide**, obtained by boiling the base

and excess of acetyl chloride in benzene for 9 hours, separates from alcohol or benzene in colourless plates, m. p.  $185^{\circ}$ . The *benzoyl* compound, similarly prepared, forms colourless, feathery crystals, m. p.  $215^{\circ}$  (Found: N, 8.7.  $C_{14}H_{10}O_3N_2Cl_2$  requires N, 8.6%). 2 : 6-Dichloro-4-nitrochloroaceto-*m*-toluidide (VII), also similarly prepared, separates from alcohol in colourless plates, m. p.  $170^{\circ}$  (Found: N, 9.4.  $C_9H_7O_3N_2Cl_3$  requires N, 9.4%).

The mixture formed by dichlorinating *p*-nitrotoluene is nitrated under the conditions described on p. 1416, the product thoroughly washed with water and heated with alcoholic ammonia under the conditions described on p. 1416. The final product, containing much ammonium chloride, and amines formed by elimination of chlorine and a nitro-group, is treated with excess of benzene, the benzene-alcohol constant-boiling mixture removed on the water-bath, the dry amine chloroacetylated in benzene, the benzene and excess of chloroacetyl chloride are removed, ultimately in a vacuum, and the chloroacetylated amines extracted with cold sodium hydroxide solution and reprecipitated with cold hydrochloric acid. The product, however, melts below  $158^{\circ}$ , and is a mixture of chloroacetylated amines, from which, after three recrystallisations from alcohol, (VII) is isolated in a quantity corresponding to a yield of less than 40% of (III).

*Estimation of 2 : 6-Dichloro-4-nitrotoluene (III) as 2 : 6-Dichloro-3 : 4-dinitrotoluene (V).*—In the preliminary experiments 1 g.-mol. (137 g.) of *p*-nitrotoluene was chlorinated in the presence of antimony trichloride until, after the removal of chlorine and hydrogen chloride, the increase in weight (69 g.) corresponded closely (within 0.2 g.) to the entry of 2 gram-atoms of chlorine. After nitration, and separation of (V) by repeated crystallisation from methylated spirit, the oily residue was distilled in steam, and the least volatile portion fractionally crystallised from alcohol. The product (2 g., m. p.  $85.5^{\circ}$ ) was shown by a mixed melting-point determination to be 2-chloro-4 : 5-dinitrotoluene (II). The yield of (V) corresponded to a yield of 43% of (III), and it was found advantageous to have a slight excess of chlorine over the 2 gram-atoms theoretically required, because the trichloronitrotoluene derivatives did not appear to interfere in the separation of (V) to the same extent as did (II).

One g.-mol. of *p*-nitrotoluene (137 g.) mixed with 4.5 g. of antimony trichloride is chlorinated at  $65$ – $75^{\circ}$  until the weight is 212.7 g. A current of dry air is blown through the liquid at  $100^{\circ}$  until all the chlorine and hydrogen chloride are removed. The increase in weight is now 0.7 g. in excess of the 69 g. theoretically required. A solution of exactly half the product (105.6 g.) in concentrated sulphuric acid (350 c.c.) is treated at  $65^{\circ}$  with a

mixture of nitric acid (20 c.c.;  $d$  1.52) and concentrated sulphuric acid (50 c.c.). Having been kept at 80–85° for 8 minutes, the mixture is poured on to ice, and kept for 48 hours at 0°. The solid product is then washed with cold water and boiled with methylated spirit (300 c.c.), the solution (A) poured off, and the residue dissolved in a further 300 c.c. of alcohol (Solution B). After 5 hours, (B) deposits almost pure (V), and the filtrate is used to dissolve the less pure crystals from (A). The deposit from (B) is recrystallised from methylated spirit, pure (V) being produced (m. p. 130–131°), and the filtrate is used to crystallise the much less pure portions; when the m. p. of these has been raised to 125–128°, they are crystallised from spirit. The process is expedited by pouring off the mother-liquor from the first crop of crystals, which contains the largest amount of (V), while the solution is hot. (V) is the least soluble substance present. In this way more than 50 g. of a pure product (m. p. 130–131°) are obtained in a very short time; further small quantities are obtained from the intermediate fractions. The large volume of solution containing the most soluble portion, when concentrated and kept for several months, deposits a solid from which a very small quantity of (V) can be isolated. In the first experiment, which lasted a week, 56.8 g. of (V) were isolated, corresponding to a yield of 45.2% of (III). In the second estimation, which, owing to the more thorough examination of the oily portions, was more prolonged, 60.1 g. [corresponding to a yield of 47.9% of (III)] were obtained and there were indications that a small quantity of (V) still remained in the oily mixture.

The semi-solid final product was recrystallised from alcohol and, apart from a large quantity of oil, two crystalline fractions, m. p. 85–97° and 100–115°, were obtained. The second substance softened at 100–101°, which is the m. p. of (VIII), but this compound could not be obtained pure. It (4 g.) was reduced as described on p. 1416, and the amine obtained was condensed with phenanthraquinone (2 g.) in boiling acetic acid. The product formed yellowish-brown needles (0.85 g.), m. p. 307–309° (decomp.; corr.), from anisole and gave a cerise coloration with cold concentrated sulphuric acid (Found: Cl, 23.6%). Whatever this compound may be, its formation shows that almost all (V) has been removed from the 100–115° fraction (about 9 g.). The high percentage of chlorine, much greater than that required for the phenanthrazines from (II) and (V), shows that probably a trichloro-nitrotoluene derivative is present.

*Chlorination of 2 : 6-Dichloro-4-nitrotoluene (III).*—This compound (41.2 g.), mixed with ferric chloride (1.8 g.), is chlorinated at 65–80°

for 24 hours, the increase in weight being 7.8 g. (calc. for monochlorination, 6.9 g.). The high temperature of 80° is ultimately required, not only to expedite the process, but also to melt the solid which crystallises out towards the end of the reaction. The product after removal of inorganic matter distils at 135—155°/5 mm. The colourless distillate is crystallised from spirit, and the portion (7 g.) which melts over the lowest range (60—78°) is nitrated with mixed sulphuric and nitric acids, the product reduced as described on p. 1416, and the base produced condensed with an excess of phenanthraquinone in glacial acetic acid. The compound (1.3 g.) produced separates from anisole, in which it is very slightly soluble in the cold, in deep yellow prisms, m. p. 343° (corr.) (Found: Cl, 26.6.  $C_{21}H_{11}N_2Cl_3$  requires Cl, 26.8%), and may be 1 : 3 : 4-trichloro-2-methylbenzophenanthrazine, which would be the expected product if nuclear substitution had taken place in the chlorination. It is not easy, however, to understand why such a small quantity of it is formed, and why the chlorination does not proceed, as would be expected, to give 2 : 5 : 6-trichloro-4-nitrotoluene as the chief product. A pure substance could be obtained neither from the chlorination product nor from the nitration product of this by repeated crystallisation.

This phenanthrazine is different from that obtained from the highest-melting substance [after the removal of (V)] formed in the nitration of the dichlorination product of *p*-nitrotoluene. The lower-melting portions of this product, which almost certainly contains several 3 : 4-dinitrotoluene derivatives, were not examined from the point of view of the formation of phenanthrazine derivatives.

#### *Summary.*

The product of monochlorination of 2-chloro-4-nitrotoluene in presence of antimony trichloride, from which more than 30% of 2 : 6-dichloro-4-nitrotoluene had previously been isolated (J., 1922, 121, 806), has now been shown to contain, in addition to considerable quantities of substances other than nuclear-substituted dichloro-4-nitrotoluenes, 47.9% of that compound, estimated as 2 : 6-dichloro-3 : 4-dinitrotoluene. This result, when compared with the nitration of 2-chloro-4-nitrotoluene (Morgan and Drew, J., 1920, 117, 793), in which more than 85% of the product is 2-chloro-4 : 5-dinitrotoluene, shows that a change of substitution type has occurred.

The authors are indebted to the Victorian Government Research Grant Committee for a grant towards the cost of chemicals.

### CLXXXIV.—*The Boiling Points of Some Higher Aliphatic n-Hydrocarbons.*

By FRANCIS FRANCIS and NORMAN EDWARD WOOD.

THE long-continued fractionation of Scotch paraffin wax led to the isolation of seven fractions of constant boiling point (J., 1922, 121, 1529), and later (*loc. cit.*, p. 2804), evidence was advanced for the belief that these fractions were pure hydrocarbons. Piper and his students (J., 1925, 127, 2194) submitted these hydrocarbons to X-ray analysis, and finding that the spacings coincided with those obtained by Müller and Saville for synthetic hydrocarbons (*loc. cit.*, p. 600), concluded that "the hydrocarbons obtained from paraffin wax are identical in constitution with the synthetic *n*-hydrocarbons."

Certainly, then, as regards the material obtained from shale in Scotland fusing between 55° and 56°, and most probably paraffin from all sources, the view that has been held since Krafft's work in 1888 has been proved finally to be correct. The number of hydrocarbons present in different paraffins is still an open question, but if Scotch wax is at all typical, the number is not so large as Krafft stated, and is much nearer 10 to 12 than the 35 (18 of which were considered to be pure) that he believed to be present in the specimen he investigated (*Ber.*, 1907, 40, 4779).

In Piper's communication, the question was raised of the untrustworthiness of the molecular magnitudes of some of the hydrocarbons from paraffin wax as determined by the ordinary ebullioscopic methods.

We thought it most probable that a direct comparison of the boiling points of synthetic *n*-docosane,  $C_{22}H_{46}$ , with fraction B over a range of pressures would show either that these two substances were identical, which Piper states to be the case, or that B was  $C_{23}H_{48}$ , the deduction from a series of very concordant molecular-weight determinations by the ebullioscopic method. *n*-Docosane was synthesised by the electrolysis of a solution of potassium laurate "Kahlbaum" (Petersen, *Z. Elektrochem.*, 1906, 12, 141) and purified by three crystallisations from benzene; it fused at 44.5° and the specimen used for this work boiled at a constant temperature.

A boiling-point graph drawn from the data (Table I) for this synthetic material showed that all the boiling points at different pressures of the hydrocarbon B isolated from paraffin fell on that curve. There can therefore be no doubt that the two substances are identical, that one of the constituents of paraffin is

*n*-docosane, and that the molecular-weight determination of this hydrocarbon from that source was too high by about 4%.

TABLE I.

Synthetic Hydrocarbons.

$C_{16}H_{34}$ .		$C_{22}H_{46}$ .		$C_{30}H_{62}$ .		$C_{34}H_{70}$ .	
19.5 mm.	161.5°	24.7 mm.	233.5°	30.5 mm.	311.5°	30 mm.	337.5°
13.8	156	18.3	226	20.5	300	19.5	325
9.0	145	11.2	215	14.5	291	15.0	319
5.3	137	5.0	198	6.2	268	4.6	297.5
				1.7	241.5	2.4	285

The synthetic hydrocarbons ( $C_{24}$ ,  $C_{25}$ ,  $C_{26}$ ,  $C_{28}$ ,  $C_{29}$ ,  $C_{31}$ ) required to make a similar direct comparison between the other six hydrocarbons isolated from paraffin were not available.

Consequently we synthesised *n*-hexadecane, *n*-triacontane, and *n*-tetratriacontane in order to obtain the relationship between the boiling points at 15 mm. of these hydrocarbons and their respective carbon contents. This would enable a comparison to be made with the boiling points under the same pressure of the hydrocarbons isolated from paraffin.

Hexadecane was prepared by the reduction of cetyl iodide and purified by treatment with concentrated sulphuric acid; it showed a constant boiling point of 156°/13.8 mm. Triacontane and tetratriacontane were synthesised by the electrolysis of the potassium salts of palmitic and stearic acids, respectively, these acids being the purest obtainable from Kahlbaum. Each hydrocarbon was purified by three crystallisations from benzene and the specimens used in this investigation had constant boiling points.

From the data for the synthetic hydrocarbons in Table I, the boiling points at 15 mm. can be obtained by interpolation, and when these were plotted against their respective carbon contents a smooth curve resulted.

On this curve, within an experimental error of between  $1^{\circ}$  and  $2^{\circ}$ , lay the boiling points at 15 mm. of the following hydrocarbons isolated from paraffin:  $C_{24}H_{50}$ ,  $C_{26}H_{54}$ ,  $C_{28}H_{58}$ ,  $C_{29}H_{60}$ . We had insufficient amounts of the hydrocarbons  $C_{25}H_{52}$  and  $C_{31}H_{64}$  from paraffin to determine the boiling points with any degree of accuracy.

As these results are in entire agreement both with the molecular weights of these paraffin hydrocarbons as determined by the Menzies and Wright apparatus (J., 1925, 127, 2194) and with those obtained by X-ray analysis, there can be no doubt that the paraffin wax investigated in these laboratories contains in addition to *n*-docosane, the *n*-hydrocarbons tetracosane, hexacosane, octacosane, and nonacosane. The two (pentacosane and hentriacontane) whose boiling points at 15 mm. have not been determined had been analysed by X-rays and can clearly be added to this list.

It has been shown (J., 1922, 121, 2808) that on the oxidation of the seven hydrocarbons obtained from paraffin, in each case the small amounts which escaped this process were identical with the hydrocarbon used, and this fact was taken as a criterion that pure specimens had been isolated. Sufficient amounts of the unchanged hydrocarbons from the oxidation of tetracosane and octacosane (from paraffin) were available for the purpose of determining their boiling points at different pressures; in both cases these lay on the graphs for the parent hydrocarbons (see Table I, Fractions C.O. and F.O.). This constitutes a further proof of their identity and an additional support for the view that the two hydrocarbons are pure materials.

All the boiling points given in Table I were determined in an apparatus similar to that used for the fractionation of wax (J., 1922, 121, 1529), but the data obtained were not corrected for the exposed stem of the thermometer.

Krafft prepared a large number of synthetic *n*-hydrocarbons in 1882 and 1886 (*Ber.*, 15, 1687, 1711; 19, 2218), and we found that the boiling points at 15 mm. recorded by him for the ten hydrocarbons  $C_{15}H_{32}$  to  $C_{24}H_{50}$  fell on the graph (connecting b. p. and carbon content) constructed from our more limited data. Even in the case of  $C_{27}H_{56}$ ,  $C_{31}H_{64}$ ,  $C_{32}H_{66}$ , and  $C_{35}H_{72}$ , the difference was only  $+2^{\circ}$ .

This correspondence with our uncorrected data was so striking that we concluded that Krafft's boiling points at 15 mm. could not have been corrected for the exposed stem of the thermometer. It appeared to us that the corrections, certainly necessary for our own data, were equally applicable to his.

On the thermometer used in this work and with the same appa-

ratus the boiling point of naphthalene at 744.2 mm. was 211.1°, and of benzophenone 293.5° at 749 mm. Dimmer's formula for the correction (Landolt-Bornstein, ii, 1212) being applied, these data become 216.9° and 305.9° at 760 mm., which are in agreement with the recorded boiling points of these substances, *viz.*, 217.2° and 305.9°. The correction amounts to 1.7° at 150°, 4.5° at 200°, 8.3° at 250°, and 12.3° at 300°.

In Table II are the most probable corrected boiling points at 15 mm. of Krafft's hydrocarbons and those described in this communication; the error, we believe, does not exceed  $\pm 1.5^\circ$ .

K = Krafft.

F = present communication.

The observed b. p. of our specimen of hexadecane on the thermometer used in this investigation was 278° at 764.8 mm.; correction for exposed stem raises this to 288.6°. Within the experimental error, this agrees with Krafft's determination, *viz.*, 287.5° at 760 mm.

Since the boiling point at 760 mm. recorded by Krafft for this hydrocarbon, and also those of C<sub>17</sub>H<sub>36</sub>, C<sub>18</sub>H<sub>38</sub>, and C<sub>19</sub>H<sub>40</sub>, all lie on a smooth curve connecting boiling points and carbon content, there can be no doubt that, as far as these hydrocarbons are concerned, Krafft's data at normal pressure were corrected for the exposed stem of the thermometer.

Our warmest thanks are due to Professor Sydney Young of Trinity College, Dublin, for the great assistance he has given us in considering and comparing our results with those of Krafft. In Krafft's communications to the *Berichte* there are many cases in which it is not possible to be certain whether the data recorded have or have not been corrected in the manner discussed in this communication.

CLXXXV.—*The Monochloro-derivatives of m-Cresol.*

By GEORGE PHILIP GIBSON.

EXCEPT in the case of 6-chloro-*m*-cresol (Kalle and Co., D.R.-PP. 90,847 and 93,694; Friedländer's "Fortschritte," Vol. IV, 94) and 6-chloro-*m*-methoxybenzoic acid (Peratoner and Condorelli, *Gazzetta*, 1898, 28, i, 214), little information is given in the literature regarding the monochloro-derivatives of *m*-cresol (Mazzura, *Gazzetta*, 1899, 29, i, 380; 1900, 30, ii, 84; Friedländer and Schenk, *Ber.*, 1914, 47, 3040; Raschig, D.R.-P. 232,071, 1909; Biechele, *Annalen*, 1869, 151, 115).

The author has studied the monochlorination of *m*-cresol, isolated the 2-, 4-, and 6-chloro-*m*-cresols (the first with difficulty), and converted them into the corresponding chloro-*m*-methoxybenzoic acids. The constitutions of these were determined by preparing the respective compounds from the corresponding 2-, 4-, and 6-nitro-*m*-cresols (Gibson, J., 1923, 123, 1267) by successive methylation, reduction, substitution of chlorine for the amino-group, and oxidation of the resulting chloro-*m*-tolyl methyl ethers.

The reduction of 2-nitro-*m*-tolyl methyl ether by tin and hydrochloric acid produces an oily mixture of bases instead of the pure 3-methoxy-*o*-toluidine which is formed when iron and dilute acetic acid are used (Gibson, *loc. cit.*). The least volatile constituent of this mixture is a chloro-base, m. p. 47°. This is probably 5-chloro-3-methoxy-*o*-toluidine, since an isomeric base, m. p. 50°, was obtained by reducing 6-chloro-2-nitro-*m*-tolyl methyl ether.

## EXPERIMENTAL.

*Chlorination of m-Cresol.*—A saturated solution of chlorine (1.1 mols.) in carbon tetrachloride (7.5 g. in 100 c.c.) was added gradually to a mechanically stirred solution of *m*-cresol in carbon tetrachloride. The solvent was then evaporated and the residue fractionally distilled. After five operations, 37% of the product boiled at 196–197° and 47% at 231–233°.

The fraction, b. p. 196–197°, was seeded at 0° with a crystal of 4-chloro-*m*-cresol obtained by the hydrolysis of 4-chloro-*m*-tolyl toluene-*p*-sulphonate. The crystals thus produced were separated from the residual oil, washed quickly with ice-cold light petroleum, and recrystallised from that solvent. The crystals obtained by seeding the residual oil, diluted with an equal volume of light petroleum (b. p. 50–60°), at –15° were similarly treated.

4-Chloro-*m*-cresol was thus obtained (29% of the fraction) in large, colourless prisms, m. p. 46°, b. p. 196° (Found: Cl, 24.8.

$C_7H_7OCl$  requires Cl, 24.8%). The *methyl ether* is a colourless, pleasant-smelling liquid, b. p. 212.5°. The *acetate* has b. p. 122—123°/11 mm. The *benzoate* separates from alcohol in massive tablets containing alcohol, m. p. 31°, and from light petroleum in crystals, m. p. 40°. The *toluene-p-sulphonate*,

crystallises from alcohol or acetone in large, six-sided prisms, m. p. 96°. It is sparingly soluble in alcohol or light petroleum.

The mixture of chloro-*m*-cresols obtained from the final petroleum mother-liquor (p. 1424) was converted almost quantitatively by treatment with sodium hydroxide solution and methyl sulphate into a mixture of ethers, b. p. 218—219°, which on oxidation with boiling dilute permanganate solution gave a theoretical yield of a mixture, m. p. 185—196°, of chloromethoxybenzoic acids. This mixture, systematically crystallised from chloroform, gave 42% of 4-chloro-*m*-methoxybenzoic acid, m. p. 211°. The final mother-liquors yielded a glue-like mass, which was dissolved in ether and fractionally extracted with 1% aqueous sodium hydroxide; the ethereal solution of the acid from each of these fractions was again extracted with an aqueous solution of the sodium salt of the next fraction. By repeated treatment of this kind, the mixture was completely separated into 2-chloro- and 4-chloro-*m*-methoxybenzoic acids.

2-Chloro-*m*-cresol, the presence of which in the crude chlorination product was thus established, was obtained by boiling its methyl ether (below) with hydriodic acid for 6 hours. The product was freed from the unchanged methyl ether with the aid of sodium hydroxide and distilled (b. p. about 194°); it then crystallised from light petroleum in massive, ill-defined, transparent crystals, m. p. 55—56°, having a pronounced phenolic odour and being very sparingly soluble in cold water. The *methyl ether*, prepared from 2-nitro-*m*-tolyl methyl ether (p. 1426), crystallised from light petroleum in massive prisms, m. p. 24.2°, b. p. 218.5° (Found : Cl, 22.7.  $C_8H_9OCl$  requires Cl, 22.7%).

6-Chloro-*m*-cresol.—A portion (49%) of the fraction of the crude chlorination product, b. p. 231—233°, solidified, and recrystallisation from light petroleum gave pure 6-chloro-*m*-cresol, m. p. 57° (Kalle and Co., *loc. cit.*, give 66°), b. p. 234° (Found : Cl, 24.9. Calc. : Cl, 24.8%).

The *methyl ether* boils at 213.5° and the *acetate* at 123—124°/11 mm. The *benzoate*, m. p. 86°, crystallises in thin, rectangular plates from alcohol, carbon tetrachloride, or light petroleum, and is not freely soluble in the latter two (Found : C, 68.1; H, 4.5.  $C_{14}H_{11}O_2Cl$  requires C, 68.2; H, 4.4%). The *toluene-p-sulphonate*,

m. p. 98°, crystallises from alcohol and light petroleum, in both of which it is only slightly soluble, in plates and needles respectively.

The mother-liquors from the 6-chloro-*m*-cresol (p. 1425) gave, on evaporation, a solid of low melting point, which was treated with methyl sulphate and alkali; the resulting mixture of methyl ethers\* gave, after repeated fractional distillation, 35% of 6-chloro-*m*-tolyl methyl ether (b. p. 213.5°) and about 21% of a liquid, b. p. 248–249°, which was probably a mixture of 2:6- and 4:6-dichloro-*m*-tolyl methyl ethers.

*Reduction of 2-Nitro-m-tolyl Methyl Ether* (compare Gibson, J., 1923, 123, 1267; Hodgson and Beard, J., 1925, 127, 498).—By the action of tin and hydrochloric acid on this ether a mixture (m. p. 27°) of 3-methoxy-*o*-toluidine and 5-chloro-3-methoxy-*o*-toluidine (about 10% of the product) is produced. The former is removed by fractional distillation in steam, and the residue, after being freed from a red impurity by distillation in a vacuum, separates from light petroleum in slender needles of 5-chloro-3-methoxy-*o*-toluidine, m. p. 47°, b. p. 140–142°/11.5 mm., which are slightly soluble in light petroleum (Found: N, 8.1.  $C_8H_{10}ONCl$  requires N, 8.2%).

The *acetyl* derivative, obtained by means of acetic anhydride containing a trace of sulphuric acid (Smith and Orton, J., 1908, 93, 1250), crystallises from alcohol, acetone, or benzene in colourless needles, m. p. 170°. It is sparingly soluble in water, light petroleum, carbon tetrachloride, or benzene (Found: N, 6.5.  $C_{10}H_{12}O_2NCl$  requires N, 6.6%).

*2-Chloro-m-tolyl Methyl Ether*.—The more volatile portion of the steam distillate (see above), consisting of 3-methoxy-*o*-toluidine with a small proportion of the chloro-base just described, is transformed into a mixture of chloro- and dichloro-*m*-tolyl methyl ethers by the Sandmeyer method. This product is distilled in steam, extracted from the distillate with ether, freed from any phenolic compounds by shaking with dilute aqueous alkali hydroxide, and repeatedly fractionally distilled. 2-Chloro-*m*-tolyl methyl ether (p. 1425) is thus obtained in a pure state (yield 54%, calculated on the nitro-compound used). The fractions of high boiling point, after distillation in a vacuum and recrystallisation from light petroleum, give 2:5-dichloro-*m*-tolyl methyl ether (yield 8.7%), which crystallises from light petroleum in slender

\* Methylation in this type of compound overcomes the lowering of the boiling point due to the ortho Cl:OH grouping and the effect of a second chlorine atom in the molecule is then appreciable: 6-chloro-*m*-tolyl methyl ether boils at 213.5° and 4:6-dichloro-*m*-tolyl methyl ether at 249°, whereas the corresponding cresols boil at 234° and 232°, respectively.

prisms, m. p. 52°, b. p. 119—120°/12.5 mm., having the pleasant odour characteristic of these chloro-ethers (Found : OMe, 16.2; Cl, 37.0.  $C_8H_8OCl_2$  requires OMe, 16.2; Cl, 37.1%).

6-Chloro-2-nitro-*m*-tolyl methyl ether is formed when 2-nitro-*m*-tolyl methyl ether is treated with chlorine at 160—170° until the gain in weight corresponds to 1 g.-atom. The dark reddish-brown product is repeatedly distilled (10 mm.) to free it from unchanged 2-nitro-ether (b. p. 120—130°), and the larger fraction (b. p. 140—145°), which solidifies, is fractionally crystallised from alcohol in order to remove some impurity, probably 4-chloro-2-nitro-*m*-tolyl methyl ether, which crystallises from the mother-liquors in tufts of very slender needles.

The 6-chloro-derivative (yield 55%) crystallises readily from alcohol, light petroleum, or carbon tetrachloride in large, pale yellow prisms, m. p. 112°. It is sparingly soluble in hot or cold water, alcohol, light petroleum, or carbon tetrachloride, but is fairly easily soluble in acetone, benzene, or chloroform (Found : Cl, 17.9.  $C_8H_8O_3NCl$  requires Cl, 17.65%).

6-Chloro-3-methoxy-*o*-toluidine, prepared by reducing the preceding compound with iron borings and dilute acetic acid (compare p. 1424), crystallises from light petroleum, in which it is fairly easily soluble, in long needles, m. p. 50°, b. p. 145—146°/12 mm. (Found : N, 8.2.  $C_8H_{10}ONCl$  requires N, 8.2%).

The acetyl derivative, m. p. 154°, crystallises readily from organic solvents, and is sparingly soluble in light petroleum, carbon tetrachloride, or benzene (Found : N, 6.3.  $C_{10}H_{12}O_2NCl$  requires N, 6.6%).

When diazotised 6-chloro-3-methoxy-*o*-toluidine is treated with an alkaline solution of sodium stannite, and the resulting 6-chloro-*m*-tolyl methyl ether (b. p. 213—214°) oxidised with boiling dilute permanganate solution, 6-chloro-*m*-methoxybenzoic acid, m. p. 173.5°, is obtained (p. 1428).

*Orientation of the 2-, 4-, and 6-Chloro-m-cresols.*—The orientation of 2-chloro-*m*-cresol, by the preparation of its methyl ether from 2-nitro-*m*-cresol, has already been described (p. 1426). From the isomeric 4- and 6-nitro-*m*-cresols, the corresponding chloro-*m*-tolyl methyl ethers were prepared in a similar manner and oxidised to the corresponding chloro-*m*-methoxybenzoic acids. These compounds were identical respectively with those prepared by methylating the 4- and 6-chloro-*m*-cresols and oxidising the methyl ethers to the corresponding chloro-acids. These results are confirmed by the observed differences in the rates of oxidation of the methyl ethers to the acids; comparative experiments showed that the times required for the oxidation of equal weights (5 g.) of the

ethers were: 2-chloro-, 7.25 hours; 4-chloro-, 2.7 hours; and 6-chloro-, 6.7 hours.

2-Chloro-*m*-methoxybenzoic acid,\* m. p. 160.5°, is almost insoluble in benzene, chloroform, carbon tetrachloride, or light petroleum (b. p. 60–80°) (Found: equiv., 186.9. Calc. for  $C_8H_7O_3Cl$ : equiv., 186.5). 4-Chloro-*m*-methoxybenzoic acid,\* m. p. 211°, crystallises from 50% aqueous alcohol in slender prisms and from chloroform in plates (Found: equiv., 186.5). 6-Chloro-*m*-methoxybenzoic acid, m. p. 173.5° (Peratoner and Condorelli, *loc. cit.*, give 171°), is only sparingly soluble in benzene, light petroleum, or carbon tetrachloride, but dissolves freely in alcohol, acetone, or chloroform (Found: equiv., 187.6).

The author desires to thank the Department of Scientific and Industrial Research for a maintenance grant, the University College Council, Nottingham, for opportunities of carrying out this work, and Professor F. S. Kipping, F.R.S., for his kindly criticism and rigorous supervision.

## CLXXXVI.—*The Action of Thionyl Chloride on Hydroxyanthraquinones. Part II. Quinizarin.*

By ALBERT GREEN.

THE action of quinizarin on boiling thionyl chloride is different from that of alizarin (J., 1924, 125, 1450). One hydroxyl group of quinizarin is replaced by a chlorine atom, which is reactive, and the product consists of deep red needles. In these and other properties the compound differs from the known monochloro-monohydroxyanthraquinones.

Slight loss of chlorine (1–2%) occurs when the compound is heated at 100°, or is boiled with acetic acid, for 1 hour. When a solution in concentrated sulphuric acid is heated on the boiling water-bath, the chlorine is eliminated as hydrogen chloride, and after 1 hour quinizarin is obtained in quantitative yield. The same product results from treatment with aqueous alkalis, and also by heating the *chloro*-compound under pressure with absolute methyl or ethyl alcohol or with acetic acid.

Oxidation with alkaline permanganate yields phthalic acid.

When a solution of the chloro-compound in absolute alcohol containing 3% of hydrogen chloride is heated, a product is obtained

\* Since this paper was written, these acids have been prepared by Hodgson (*this vol.*, p. 150).

which is isomeric with the known monoethyl ether of quinizarin (Liebermann and Jellinek, *Ber.*, 1888, **21**, 1168). This product is converted into quinizarin by heating it with concentrated sulphuric acid at 100° for an hour.

Treatment of the chloro-compound with boiling acetic anhydride, alone or with concentrated sulphuric acid, converts it into diacetyl derivatives of quinizarin. Efforts to isolate a monoacetyl derivative were fruitless, as in all cases some decomposition occurred with loss of chlorine. Similarly the products of methylation with diazomethane were not uniform and contained varying amounts of chlorine, although the analyses pointed to the presence of one methoxyl group only.

The chloro-compound condenses rapidly with boiling aniline and *p*-toluidine with loss of hydrogen chloride and production of *monoaminomonohydroxy*-compounds; longer treatment in presence of boric acid gives *diaminoanthraquinones*. These derivatives are respectively isomeric with the mono- and di-amino-compounds obtained by the condensation of quinizarin with aromatic amines, and the different colours of the solutions in concentrated sulphuric acid afford a means of distinguishing the isomerides.

While the replacement of one hydroxyl group of quinizarin by chlorine would be expected to give 1-chloro-4-hydroxyanthraquinone, it is obvious that the properties of the compound under consideration are not consonant with those of a chlorohydroxyanthraquinone in which the halogen is in one of the outer rings. 1-Chloro-4-hydroxyanthraquinone separates from alcohol in golden-yellow needles melting at 193°. It is unaffected by heating its solution in concentrated sulphuric acid for 1 hour at 100°, and is converted into quinizarin only when it is heated for several hours at 140° with sulphuric and boric acids (Eckert and Steiner, *Monatsh.*, 1914, **35**, 1145).

The replacement of a hydroxyl group by a chlorine atom by means of thionyl chloride connotes an acidic hydroxyl, and this is a well-known method of preparing the acid chlorides of carboxylic acids. Properties similar to those of an acid chloride are shown by this new derivative of quinizarin; such are its rapid condensation with amines, and the tendency of the chlorine atom to react with diazomethane. The interaction of what may be called "normal" chloroanthraquinones with amines is slow even in the presence of catalysts (compare, among others, Harrop, Norris, and Weizmann, *J.*, 1909, **95**, 1313). Meyer and Sander (*Annalen*, 1912, **396**, 145), however, have shown that halogen-substituted anthrones, in which the halogen atom is attached to a *meso*-carbon atom, react readily with amines, giving aminoanthrones.

The only structure which appears to account adequately for the properties of the new compound is that of 10-chloro-1-hydroxy-4:9-anthraquinone (I). This formula necessitates an ortho-quinonoid grouping, and in this connexion the deep red colour of the compound is noteworthy, and is not found in "normal" mono-hydroxy-9:10-anthraquinones, which are yellow.

Probably 10-chloro-1-hydroxy-4:9-anthraquinone is formed from quinizarin in one of two ways. (1) Quinizarin may exist in a reactive ortho-quinonoid state in which the two hydroxyl groups are in the 1:10 positions instead of the 1:4 as usually formulated.  $\alpha$ -Hydroxyl groups of hydroxyanthraquinones react with methylating and acylating agents much less rapidly than similar groups in  $\beta$ -positions. This fact and others have given rise to suggestions both of co-ordination between the hydrogen atoms of the  $\alpha$ -hydroxyls and the neighbouring carboxyl oxygen atoms (Dimroth and Faust, *Ber.*, 1921, **54**, 3020; Sidgwick and Callow, *J.*, 1924, **125**, 527), and also of isomeric structures in which the hydrogens of the  $\alpha$ -hydroxyl groups are attached to the *meso*-oxygen atoms (Perkin, *J.*, 1899, **75**, 453; Georgievics, *Monatsh.*, 1911, **32**, 329), to give ortho-quinonoid formulæ. There is, however, no recorded instance of a hydroxy-9:10-anthraquinone reacting in such an isomeric form.

(2) The reaction may occur in two stages. The first stage may be represented by the replacement of a carbonyl oxygen atom by two chlorine atoms—a reaction of this type occurs between benzaldehyde and thionyl chloride to give benzal chloride (Loth and Michaelis, *Ber.*, 1894, **27**, 2548). The second stage would then consist of the union of one of these chlorine atoms and the

hydrogen atom of the neighbouring hydroxyl group, giving hydrogen chloride and 10-chloro-1-hydroxy-4:9-anthraquinone. It is intended to test this theory of the mechanism of the reaction by an examination of the action of thionyl chloride on the ethers of quinizarin.

Both the above interpretations leave unexplained why only one of the carbonyl groups of quinizarin appears to take part in the reaction.

In the preparation of pure quinizarin for this investigation it was observed that the diacetyl derivative exists in two polymorphic forms with different melting points.

## EXPERIMENTAL.

*Quinizarin*.—Pure diacetylquinizarin (see p. 1435) was heated with concentrated sulphuric acid (6 parts) at 100° for 30 minutes, and the solution was then stirred into cold water. After boiling for 10 minutes, the mixture was filtered, the quinizarin washed with boiling water until free from acid, and dried at 100°. It assumed a dark metallic lustre at 183° and melted at 197–198°.

10-*Chloro-1-hydroxy-4:9-anthraquinone*.—When 30 g. of quinizarin were boiled with 120 c.c. of recently distilled thionyl chloride, solution occurred rapidly with evolution of sulphur dioxide and hydrogen chloride. After 8–30 hours, the deep red liquid was concentrated to half bulk. On cooling in a dry atmosphere, it deposited dark red, fine needles (26 g.), m. p. 225–226° (even after recrystallisation from methyl or ethyl alcohol or benzene); a further 4 g. were obtained by concentrating the filtrate. The product was washed free from thionyl chloride with dry benzene and ether and dried in a vacuum over fused calcium chloride and soda lime (Found: C, 65.0; H, 2.8; Cl, 13.7; *M*, cryoscopic in naphthalene, 265, 260.  $C_{14}H_7O_3Cl$  requires C, 65.0; H, 2.7; Cl, 13.7%; *M*, 258.5). It gave a bright red colour with alcoholic ferric chloride and when warmed with pyridine formed a dirty brown solution which slowly deposited a black, apparently amorphous powder.

A mixture of 40 c.c. of 10% aqueous potassium hydroxide, 2 g. of the quinone, and 100 c.c. of 10% potassium permanganate solution was boiled for 2 hours, and the excess of permanganate destroyed by alcohol; from the colourless acidified filtrate ether extracted 0.8 g. of impure phthalic acid (identified in the form of the anhydride, from which fluorescein was prepared).

*Conversion into quinizarin*. (1) *By sulphuric acid*. A solution (reddish-purple) of 0.86 g. of 10-chloro-1-hydroxy-4:9-anthraquinone in 20 c.c. of concentrated sulphuric acid was heated on a boiling water-bath for 1 hour and then poured into water, the suspension boiled, and the light red precipitate (0.79 g., theoretical) collected and dried (Found: C, 69.8; H, 3.3. Calc.; C, 70.0; H, 3.3%). It melted at 197° alone and when mixed with pure quinizarin, and when acetylated in pyridine gave a diacetyl derivative in prisms, m. p. 206–208°.

(2) *By acetic acid*. A mixture of 0.9 g. of the quinone and 2 c.c. of acetic acid was heated, with or without 0.3 g. of freshly-fused potassium acetate, in a sealed tube for 3 hours at 180°. The product, on recrystallisation from 20 c.c. of boiling acetic acid (bone charcoal), gave 0.3–0.4 g. of red needles which, alone or

mixed with pure quinizarin, melted at  $197^{\circ}$  (Found: C, 69.8; H, 3.4%).

(3) *By methyl alcohol.* When 0.85 g. of the quinone was heated in a sealed tube at  $200^{\circ}$  for 2 hours with 2 c.c. of absolute methyl alcohol, and the product recrystallised from methyl alcohol (bone charcoal), 0.4 g. of quinizarin, m. p.  $196-197^{\circ}$ , was obtained (Found: C, 70.0; H, 3.4%).

(4) *By ethyl alcohol.* When the experiment was repeated with absolute ethyl alcohol, 0.3 g. of quinizarin was obtained (Found: C, 69.7; H, 3.3%).

(5) *By sodium or potassium hydroxide.* A paste of the quinone (3 g.) and an excess of concentrated aqueous sodium or potassium hydroxide was boiled with water for 5 minutes and stirred into an excess of boiling dilute hydrochloric acid. The reddish-brown solid (2.5 g.) produced crystallised from acetic acid in red needles of quinizarin, m. p.  $195-197^{\circ}$  (alone and mixed) (Found: C, 69.7; H, 3.3%), which was converted into its diacetyl derivative, m. p.  $206-208^{\circ}$ .

*Acetylation.* (1) *Acetic anhydride alone.* 10-Chloro-1-hydroxy-4:9-anthraquinone (4 g.) was boiled with 40 c.c. of acetic anhydride until fumes of hydrogen chloride (due to decomposition, by atmospheric moisture at the top of the condenser, of acetyl chloride produced in the reaction) were no longer observed (4 hours). The original dark red colour became dark green, and from the filtered, cooled solution small, olive-green crystals (4.2 g.), m. p.  $204^{\circ}$ , separated. These were repeatedly crystallised from acetic anhydride (bone charcoal) and finally twice from pyridine; the characteristic yellow prisms of diacetylquinizarin were then obtained which, alone or mixed with an authentic specimen, melted at  $207-208^{\circ}$ . A quantitative experiment showed that the substance did not contain chlorine [Found: C, 66.7; H, 3.6;  $\text{CH}_3\cdot\text{CO}$ , 26.7; *M*, in freezing naphthalene, 310, 315. Calc. for  $\text{C}_{14}\text{H}_6\text{O}_4(\text{CO}\cdot\text{CH}_3)_2$ : C, 66.7; H, 3.7;  $\text{CH}_3\cdot\text{CO}$ , 26.7%; *M*, 324].

Hydrolysis of this acetyl derivative by an alcoholic solution of sulphuric acid yielded quinizarin, m. p.  $198^{\circ}$  (Found: C, 69.9; H, 3.3%).

(2) *Acetic anhydride and sulphuric acid.* When 2.2 g. of 10-chloro-1-hydroxy-4:9-anthraquinone were heated to boiling with 10 c.c. of acetic anhydride containing 2 drops of concentrated sulphuric acid, the red solution rapidly became yellow-green. The filtered solution slowly deposited 1.4 g. of very fine, pale yellow rods identical with those obtained by acetylating quinizarin under similar conditions (see under). The product of one recrystallisation from acetic anhydride containing sulphuric acid changed colour from yellow to light orange at about  $120^{\circ}$  and melted at  $200-201^{\circ}$

(Found: C, 66.5; H, 3.8;  $\text{CH}_3\text{-CO}$ , 26.6%). This diacetyl derivative separated from pyridine in small, yellow prisms, m. p. 207—208°.

Numerous experiments were carried out with a view to acetylating the single hydroxyl group. The chloro-compound was heated with acetyl chloride and potassium acetate under ordinary pressure, in benzene solution, and in sealed tubes at 90—100°. The products, however, were mixtures containing in some cases as little as 4% of chlorine. Attempted acetylations in pyridine with one molecular proportion of acetic anhydride yielded black amorphous products which would not crystallise and in which the chlorine content also varied.

*Methylation of 10-chloro-1-hydroxy-4:9-anthraquinone.* Since methylation in alkaline media was impossible, diazomethane was used. In every experiment chlorine was lost (4% in one experiment), and the products were not uniform. Nevertheless analyses clearly indicated the presence of one hydroxyl group.

In a typical experiment a suspension of 1.0 g. of the finely powdered dry compound in 30 c.c. of absolute ether at 5° was treated with an excess of diazomethane (from 2 g. of nitrosomethylurethane and 6 c.c. of 70% aqueous potassium hydroxide) in 60 c.c. of dry ether during  $\frac{1}{2}$  hour. Stirring was continued for 3 hours, and the red product (1 g.) collected after 12 hours. After darkening at about 190°, it melted to a black paste between 270° and 280° (Found: Cl, 12.1; OMe, 11.1.  $\text{C}_{14}\text{H}_6\text{O}_2\text{-OMe}$  requires Cl, 13.0; OMe, 11.4%).

*Condensations with amines.* (1) *Anilino-derivative,*

A solution of 1.5 g. of 10-chloro-1-hydroxy-4:9-anthraquinone in 8 c.c. of freshly distilled aniline was boiled for 5 minutes, the red colour changing to brown. The hot solution was stirred into an excess of dilute hydrochloric acid and boiled. The black precipitate was filtered off hot, washed free from acid and dried (1.9 g.). It separated from tetrachloroethane in black, microscopic crystals after the addition of a little ether. The product, which contained no chlorine, formed a paste at 272—274° and decomposed at 290°. It dissolved in concentrated sulphuric acid with a deep amethyst colour and in boiling sodium hydroxide to a very pale purple solution (Found: N, 4.3.  $\text{C}_{20}\text{H}_{13}\text{O}_3\text{N}$  requires N, 4.4%).

(2) *Dianilino-derivative,*  $\text{C}_{14}\text{H}_6\text{O}_2(\text{NH}\cdot\text{C}_6\text{H}_5)_2$ . A mixture of 1 g. of the chloro-compound, 0.5 g. of boric acid (dried at 120° for 4 hours), and 10 c.c. of freshly-distilled aniline was boiled for 6 hours, the purple colour becoming dark brown. It was stirred while hot into an excess of dilute hydrochloric acid, and the pre-

precipitate treated as in the previous experiment. The product consisted of black crystals (1.6 g.) which did not melt below  $310^{\circ}$ . It gave a golden-brown solution in concentrated sulphuric acid, but was insoluble in hot aqueous caustic soda (Found: N, 7.2.  $C_{26}H_{18}O_2N_2$  requires N, 7.2%).

The dianilino-derivative from quinizarin, prepared similarly, formed blue-black crystals from tetrachloroethane. These dissolved in sulphuric acid to a blue-black solution and were insoluble in boiling caustic soda solution (Found: N, 7.1%).

(3) *Mono-p-toluidino-derivative*,  $C_{14}H_7O_3 \cdot NH \cdot C_6H_4Me$ . This was prepared in a similar manner to the monoanilino-derivative. The product, which was free from chlorine (Carius), crystallised from acetic acid in microscopic, very dark brown needles which softened at  $280^{\circ}$  and showed no further change up to  $310^{\circ}$ . Its solution in sulphuric acid was amethyst and in caustic soda light purple (Found: N, 4.1.  $C_{21}H_{15}O_3N$  requires N, 4.3%).

The mono-*p*-toluidino-derivative\* from quinizarin melted at  $190-192^{\circ}$ , and dissolved in concentrated sulphuric acid with a brilliant green colour (Found: N, 4.2%).

(4) *Di-p-toluidino-derivative*,  $C_{14}H_6O_2(NH \cdot C_6H_4Me)_2$ . This was prepared similarly to (2) above, and crystallised from alcohol in bluish-black, microscopic needles which decomposed at  $305^{\circ}$  with previous sintering. The solution in sulphuric acid was dark honey-coloured (Found: N, 6.7.  $C_{28}H_{22}O_2N$  requires N, 6.7%).

The isomeric compound prepared from quinizarin gave a blue-black solution in concentrated sulphuric acid (Found: N, 6.8%).

10-*Ethoxy-1-hydroxy-4:9-anthraquinone*.—10-Chloro-1-hydroxy-4:9-anthraquinone (2.5 g.) was boiled with absolute ethyl alcohol (200 g.) containing 3% of dry hydrogen chloride for  $3\frac{1}{2}$  hours, the red solution becoming dark green and fluorescent. From the filtered, concentrated, cooled solution clusters of reddish-brown needles separated (2.1 g.), m. p.  $135^{\circ}$ , after recrystallisation from ethyl alcohol (Found: C, 71.3; H, 4.3; OEt, 16.3.  $C_{14}H_7O_3 \cdot OEt$  requires C, 71.6; H, 4.5; OEt, 16.9%).

This ether was very soluble in cold benzene and less soluble in cold ethyl alcohol. In concentrated sulphuric acid, its solution was similar to that given by quinizarin. When this solution was heated at  $100^{\circ}$  for 1 hour and then stirred into water, quinizarin (m. p.  $195-197^{\circ}$ ) was obtained in quantitative yield (Found: C, 70.0; H, 3.4%).

1-*Chloro-4-acetoxyanthraquinone*.—Commercial 1-chloro-4-hydroxyanthraquinone† was boiled with an excess of acetic anhydride

\* Kindly presented by the British Alizarine Co., Ltd., Manchester.

† Kindly presented by the Scottish Dyes, Ltd., Carlisle.

and a few drops of pyridine for  $\frac{1}{2}$  hour. The crude acetyl derivative was repeatedly crystallised from pyridine containing a little anhydride, until the melting point remained constant at 176—177°, the pure 1-chloro-4-acetoxyanthraquinone forming fine, pale primrose needles (Found: Cl, 11.8;  $\text{CH}_3\cdot\text{CO}$ , 14.4.  $\text{C}_{14}\text{H}_6\text{O}_3\text{Cl}\cdot\text{CO}\cdot\text{CH}_3$  requires Cl, 11.8;  $\text{CH}_3\cdot\text{CO}$ , 14.3%).

1-Chloro-4-hydroxyanthraquinone.—The pure acetyl derivative (2 g.) was hydrolysed by boiling for 2 hours with 140 c.c. of absolute alcohol containing 3 c.c. of concentrated sulphuric acid. On cooling, the hydroxy-compound separated in golden-yellow needles, m. p. 192—193°, unchanged by further recrystallisation (Found: Cl, 13.8. Calc. for  $\text{C}_{14}\text{H}_7\text{O}_3\text{Cl}$ : Cl, 13.7%). The alcoholic solution of 1-chloro-4-hydroxyanthraquinone gave a pale red colour with ferric chloride.

*Treatment of 1-Chloro-4-hydroxyanthraquinone with Sulphuric Acid.*—A solution of 3 g. in 50 c.c. of concentrated sulphuric acid was heated at 100° for 1 hour. The hot liquid was then stirred into 200 c.c. of cold water, the mixture boiled for 10 minutes, and the yellow product filtered off, washed with boiling water until acid-free, and dried at 100° (2.8 g.). The substance melted at 192°, alone and when mixed with an authentic specimen of 1-chloro-4-hydroxyanthraquinone (Found: Cl, 13.7%).

*Diacetylquinizarin.*—Liebermann and Giesel (*Ber.*, 1875, 8, 1648) describe diacetylquinizarin as "gelbe Saulchen" melting at 200°.

Quinizarin supplied by the British Dyestuffs Corporation, Ltd., was acetylated by boiling for 15 minutes with acetic anhydride containing a few drops of concentrated sulphuric acid. The product on purification was obtained in two polymorphic forms:

*Form A.* (1) Small, twinned, six-sided, yellow prisms from quickly chilled solutions in hot pyridine [Found: C, 66.6; H, 3.7;  $\text{CH}_3\cdot\text{CO}$ , 26.8; *M*, cryoscopic in naphthalene, 325.

$\text{C}_{14}\text{H}_6\text{O}_4(\text{CO}\cdot\text{CH}_3)_2$  requires C, 66.7; H, 3.7;  $\text{CH}_3\cdot\text{CO}$ , 26.7%; *M*, 324]. (2) Long, flat, six-sided, yellow plates by recrystallisation from acetic anhydride alone (Found: C, 66.4; H, 3.6;  $\text{CH}_3\cdot\text{CO}$ , 26.6%; *M*, 330). (3) Very thin, pale yellow needles from alcohol (Found: C, 66.7; H, 3.6;  $\text{CH}_3\cdot\text{CO}$ , 26.9%; *M*, 26.9). All three forms melted at 207—208°.

*Form B.* Sheaves of yellow needles or fine rods, which became light orange at about 120° and melted at 200—201° (Found: C, 66.6; H, 3.6;  $\text{CH}_3\cdot\text{CO}$ , 26.2%; *M*, 320). This form was converted into A by recrystallisation from pyridine, acetic anhydride, or alcohol, and hot solutions of A in acetic anhydride containing a few drops of sulphuric acid always deposited crystals of B only.

*Solubility Determinations.*—The two forms of the diacetyl derivative have identical solubilities in benzene and in chloroform at 25°. This may be accounted for by the long time required for saturation. Benzene, for example, was still unsaturated with respect to A after 15 hours' shaking at 25°.

In Table I the figures represent g. of solute per 100 g. of solution.

TABLE I.

Sub- stance.	Benzene.				Chloroform.			
	20 hrs.	30 hrs.	55 hrs.	Mean.	40 hrs.	55 hrs.	65 hrs.	Mean.
A 1	0.693	0.699	0.694	0.70	5.01	5.05	5.01	5.0
A 2	0.698	—	0.699	0.70	—	5.00	—	5.0
A 3	0.698	—	0.697	0.70	—	—	—	—
B	0.694	0.700	0.699	0.70	—	5.03	5.03	5.0
A + B	—	—	0.701	0.70	—	—	—	—

Benzene was freed from thiophen, washed, dried over calcium chloride, fractionated, and distilled from sodium before use. A uniform sample was used throughout.

"Pure" chloroform was washed with alkali, acid, and water, dried over calcium chloride, and twice distilled, and a constant boiling fraction was used.

The sealed solubility tubes were attached to a large paddle stirrer, which was rotated continuously in an electrically heated thermostat ( $25^{\circ} \pm 0.025^{\circ}$ ). Samples were taken, after settling, in 50 c.c. pipettes fitted with short removable glass tubes plugged with cotton wool.

The weighing bottles were dried to constant weight at 90°. Constant weighings ( $\pm 0.0002$  g.) were obtained by allowing the bottles, when removed from the oven, to stand in a desiccator over sulphuric acid for precisely 30 minutes, and by taking the final readings after the bottles had been on the balance for 2 minutes.

*Cryoscopic Measurements.*—In applying the test suggested by Sidgwick (J., 1915, 107, 672) for distinguishing between polymorphic, isomeric and tautomeric substances, solvents with low freezing points such as benzene and nitrobenzene could not be used, owing to the small solubilities of the acetyl derivatives in them and also to the long time required for saturation. Naphthalene was used and saturated solutions were obtained in a few minutes at a degree or two above its freezing point. Table II shows the results of these experiments.

TABLE II.

Substance.	Weight of solvent (g.).	Maximum depression.
A 1 alone .....	7.785	1.95°
After addition of B .....	"	1.90
B alone .....	7.780	1.95
After addition of A 1 .....	"	1.92

The determinations were carried out in a small Beckmann apparatus fitted with a thermometer graduated in tenths of a degree. This could be read to the nearest fortieth of a degree with ease.

The author wishes to thank the Research Fund Committee of the Chemical Society for defraying a portion of the expense of this research.

CLXXXVII.—*The Heat of Combustion of Salicylic Acid.*  
(A Reply to E. Berner.)

By PIETER EDUARD VERKADE and JAN COOPS.

DURING the last few years investigations on thermochemical standard substances, carried out in various places, have led to the adoption of benzoic acid, by international consent, as the exclusive standard substance to be used in determinations of heats of combustion. The value 6324 cal.<sub>15°</sub> per g. (air) ( $v = \text{constant}$ ), i.e., 6319 cal.<sub>15°</sub> per g. (vac.), has been accepted for the heat of combustion of this substance. At the same time, it was decided that, for scientific work, use should always be made of benzoic acid furnished for this purpose by the Bureau of Standards, Washington (*Compt. rend. de la troisième Conférence Internationale de la Chimie*, Lyons, 1922, p. 54; compare Verkade, *Chem. Weekblad*, 1922, 19, 389; 1924, 21, 13).

For some time we have tried to make it clear that this regulation is not quite sufficient. The heat capacity of a calorimetric system, found exclusively by means of this benzoic acid, is always somewhat uncertain; accidental errors, caused by contamination of the standard preparation, during packing or in the course of time, can be brought to light only with difficulty, if at all. We therefore emphasised strongly the desirability of introducing one or more further thermochemical standard substances (which, if so desired, could be considered as *secondary* standards) and, on the grounds of an extensive research, recommended salicylic acid for this purpose (Verkade and Coops, *Rec. trav. chim.*, 1924, 43, 561).

The heats of combustion of various samples of salicylic acid were determined with the following results, valid for an isothermal reaction at 19.5°, at constant volume and on the assumption that the above-mentioned heat of combustion of benzoic acid holds for the same temperature (compare Verkade, *Rec. trav. chim.*, 1925, 44, 799).

Sample.	Heat of combustion per g. (air).
Poulenc ("Standard pour calorimétrie") .....	5241.4 cal. <sub>15</sub> °
Merck ("Präparat von bestimmter Verbrennungswärme") .....	5241.7 "
Merck (crystallised from ether) .....	5241.3 "
Von Heyden ("Acid. Salicylicum recrystallis. puriss.") ..	5242.8 "
Kahlbaum ("für kalorimetrische Bestimmungen") .....	5242.6 "
Commercial ("Acid. Salicyl. praec. pulv.") (crystallised twice from water and once from chloroform) .....	5242.3 "

Thus a number of the purest samples obtainable commercially, most of them supplied especially for calorimetric purposes, furnished values for the heat of combustion which agreed within the error of observation. The heat of combustion of one of these samples remained unchanged when the substance was recrystallised from ether. A technical preparation taken from the Dutch market gave the same heat of combustion after purification. On the basis of these facts, we considered ourselves completely justified in regarding the mean of all our measurements as the heat of combustion of *pure salicylic acid*. This heat of combustion is 5241.9 cal.<sub>15</sub>° per g. (air) ( $v = \text{constant}$ ; 19.5°), *i.e.*, 5238.3 cal.<sub>15</sub>° per g. (vac.). The ratio of the heats of combustion of benzoic acid and salicylic acid is then  $6324/5241.9 = 1.2064$  (air).

Our work has recently been criticised by Berner (J., 1925, 127, 2747). Let it be said that this author shares our views regarding the desirability of introducing a second or secondary thermochemical standard substance and admits the particular suitability of salicylic acid for this purpose. However, we are said not to have taken the necessary care to ensure the greatest possible purity of our samples of salicylic acid and, on that account, to have found too high a heat of combustion; according to Berner, the heat of combustion of salicylic acid is only 5237.4 cal.<sub>15</sub>° per g. (air) ( $v = \text{constant}$ ; about 18°), *i.e.*, 5233.8 cal.<sub>15</sub>° per g. (vac.). The ratio of the heats of combustion of benzoic and salicylic acids should then be  $6324/5237.4 = 1.2075$  (air).

Berner seems to have overlooked the fact that the heat of combustion found by us was already confirmed from two sides :

1. Roth burnt salicylic acid in the micro-bomb and micro-calorimeter which he has constructed and found 5241.5 cal.<sub>15</sub>° per g. (air) for the heat of combustion, which deviates from our value by only — 0.08 part per 1000 parts (*Z. Elektrochem.*, 1924, 30, 607). Also, Roth has investigated salicylic acid in a bomb of normal dimensions and the well-known calorimetric apparatus of Stohmann-Hugershoff (*Naturwiss.*, 1924, 12, 652); it is, however, simply stated there that the heat of combustion found agreed exactly with ours. We have learned some details from a private

communication, which, by kind permission of Prof. Roth, we are able to publish. Various samples of salicylic acid from von Heyden gave concordant heats of combustion; an arbitrarily chosen commercial sample was purified by crystallisation from alcohol and after careful drying gave the same heat of combustion, which did not alter when the sample was recrystallised from alcohol and from water. The mean value of all these measurements was 5241.3 cal.<sub>15°</sub> per g. (air) ( $v = \text{constant}$ ; 18.3°); the deviation from our value amounted therefore to only  $-0.11$  part per 1000 parts.

2. Swientoslawski (*Bull. Soc. chim.*, 1925, 37, 84) found 5242.4 cal.<sub>15°</sub> per g. (air) for the heat of combustion of a commercial sample of salicylic acid, which was crystallised several times from water. This value deviates from ours only by about  $+0.10$  part per 1000 parts. Details of these measurements were not published.

These facts made it *a priori* scarcely possible for us to believe in the accuracy of Berner's results. It was improbable that the numerous preparations used by Verkade and Coops, by Roth, and by Swientoslawski—notwithstanding their different origins and different modes of purification—should all show a large surplus of exactly the same magnitude in the heat of combustion.

Nevertheless, we considered that our work ought to be controlled. In the first place, we again burnt one of the preparations which we had used previously (namely, that of Merck), making use of another bomb and of a calorimetric apparatus of considerably greater heat-capacity than that used previously. Secondly, we carefully subjected the previously used sample from von Heyden to various purification processes and measured the heat of combustion after each purification in the same apparatus. The results of these measurements are in the following table.

Material.	Heat of combustion per g. (air). ( $v = \text{constant}$ ; 19.5°).
Merck .....	5242.3
Von Heyden (crystallised twice from water, once from chloroform) .....	5241.4
Von Heyden (further crystallised from ether) .....	5241.5
„ (further crystallised from benzene) .....	5241.9

Thus we see that continued purification of von Heyden's salicylic acid brings about no change in the heat of combustion. The mean value of our 15 experiments with this acid in its various stages of purification is 5241.7 cal.<sub>15°</sub> per g. (air) ( $v = \text{constant}$ ; 19.5°). This new value for the heat of combustion of salicylic acid deviates from the one we found previously by only  $-0.04$  part per 1000 parts. For the ratio of the heats of combustion

of benzoic and salicylic acids we now obtain the value  $6324/5241 \cdot 7 = 1 \cdot 2065$  (air), which is practically identical with that found previously. We have no reason to doubt the correctness of this value, as the ratios of the heats of combustion of benzoic acid and naphthalene, and of benzoic acid and cane-sugar, obtained by us at about the same time (Verkade, Coops, and Hartman, *Rec. trav. chim.*, 1922, 41, 241; Verkade and Coops, *ibid.*, 1923, 42, 205) are in full agreement with those obtained recently in very careful work by other authors (Dickinson, *Bull. Bureau of Standards*, 1914, 11, 243; Swientoslawski and Starczewska, *Bull. Soc. chim.*, 1922, (4), 31, 654; Schläpfer and Fioroni, *Helv. Chim. Acta*, 1923, 6, 713), and at present generally accepted.

Hence we reach the conclusion that Berner found a value for the heat of combustion of salicylic acid which is too low, and that his results are subject to an error of about 0.8 part per 1000 parts. We are not able to indicate the cause of this error. At our request, Mr. Berner had the kindness to provide us with small quantities of two samples of salicylic acid which he had used in his research. These were the samples designated by Berner as 571II (Merck's acid, crystallised twice from water and once from chloroform) and 572IV (Kahlbaum D.A.B.5, subjected to sublimation in a vacuum and to several crystallisations from water, chloroform, and benzene). These samples yielded in our hands values for the heats of combustion of 5241.6 and 5241.9 cal.<sub>15</sub> per g. (air), respectively. These values are practically identical with those obtained by us for our own specimens. Berner as well as ourselves used benzoic acid from the Bureau of Standards, Washington (Standard Sample 396) in the calibration of the calorimetric apparatus.

As far as we know, Berner has not burnt standard samples of naphthalene and cane-sugar in his apparatus. The possibility therefore exists that, on burning these substances, this author may find, for the ratios mentioned above, values different from those now generally accepted as correct. In this case, the low heat of combustion of salicylic acid found by this author would be due to a slight error in the determination of the heat capacity of his apparatus.

#### EXPERIMENTAL.

The following alterations have been made in the calorimetric apparatus used for our previous measurements of the heat of combustion of salicylic acid (Verkade and Coops, *loc. cit.*) and described in detail in our first communication on heats of combustion of organic compounds (Verkade, Coops, and Hartman, *Rec. trav. chim.*, 1922, 41, 241).

We now used a silver calorimeter can of greater capacity than that used formerly, so that the quantity of water could be increased to about 2600 g., as well as a bomb of rustless V<sub>2</sub>A steel, supplied by the firm of Hugershoff, Leipzig, and especially suited, in our experience, for work of high precision.

For the method of carrying out the measurements reference may be made to the literature cited above.

*Heat Capacity of the Calorimetric Apparatus.*—This was determined by burning three samples of benzoic acid, namely, two standard preparations (Standard Samples 39a and 39b) from the Bureau of Standards, Washington, and one prepared by ourselves, which had already served for earlier work. At an oxygen pressure of 35 atms. the heat capacity was 3051.2 cal.<sub>15</sub> at a temperature of 19.5°. It seems unnecessary for us to give full details of our measurements, but we give a statement of results:

Sample.	Heat capacity.	Sample.	Heat capacity.
39a	3050.0	39b	3050.0
"	3049.6	"	3051.4
"	3051.4	"	3051.8
"	3051.6	"	3052.4
"	3051.3	Rotterdam	3050.9
"	3050.2	"	3052.3
"	3051.2	"	3051.8
		"	3052.5

For some observations regarding the heat capacity found in this way (*i.e.*, by the combustion of a standard substance), reference may be made to a paper by one of us (Verkade, *Rec. trav. chim.*, 1925, **44**, 799).

We were able to verify this heat capacity repeatedly by indirect methods, namely, by burning substances which we had already burnt before introducing the above-mentioned alterations in the calorimetric apparatus. Completely concordant results were obtained in both cases. Also (*e.g.*, in the case of *n*-butyl alcohol), we could obtain with our new apparatus complete concordance with the extremely accurate thermochemical work of Richards (compare Verkade and Coops, *Rec. trav. chim.*, 1926, in course of publication).

*Salicylic Acid Preparations.*—Von Heyden's "Acidum Salicylicum recrystallis. puriss" (used in our previous measurements) was crystallised twice from water. After drying in the air, it was very finely powdered and warmed to about 100° for 4 hours; during the heating it was again finely powdered several times. We have shown already (*Rec. trav. chim.*, 1924, **43**, 575) that salicylic acid can be heated for 20 hours at about 115° without undergoing even the slightest decomposition. This heating is necessary, since it has

been shown recently (*e.g.*, Cohen, Verkade, Saburo Miyake, Coops, and van der Hoeve, *Versl. Kon. Akad. Wetensch. Amsterdam*, 1926, **35**, 48) that on crystallisation from water, salicylic acid may occlude several parts of water per thousand, which is not removed even by very long drying in a vacuum over phosphorus pentoxide. However, this occluded water can be removed for the most part in the way described above, as was proved by determinations of the heat of combustion carried out expressly for this purpose. The sample obtained in this way was then recrystallised from dry chloroform (sample II); the last traces of water in the crystals were removed by distilling off a part of the solvent from the boiling solution, the water then passing over with the solvent. After a part of this sample had been burnt, the remainder was crystallised from dry ether (sample III) and finally from dry benzene (sample IV). All three samples were finely powdered and dried for several days in a vacuum over phosphorus pentoxide.

Merck's salicylic acid ("Präparat von bestimmter Verbrennungswärme") and Berner's samples 571II and 572IV were finely powdered and dried in the same way without other treatment.

*Heat of Combustion of the Salicylic Acid Preparations.*—On account of a small difference in the composition of the products of combustion of benzoic and salicylic acids, a correction of +0.1 cal.<sub>15</sub> must be introduced in the above-mentioned heat capacity in combustions of the latter acid (compare *Rec. trav. chim.*, 1924, **43**, 566). We shall give no details of the measurements. We found the following values for the heat of combustion of salicylic acid per g. (air) ( $v = \text{constant}$ ; 19.5°).

Sample.	Heat of combustion.	Mean.
Merck	5242.4, 5242.7, 5240.7, 5242.4, 5243.2	5242.3
II	5241.5, 5241.8, 5242.2, 5240.0, 5241.6	5241.4
III	5242.5, 5242.5, 5240.4, 5241.5, 5240.8	5241.5
IV	5242.6, 5240.8, 5241.6, 5241.7, 5242.9	5241.9
571 II	5241.6, 5241.5, 5241.7	5241.6
572 IV	5241.2, 5240.1, 5244.5	5241.9

### *Summary.*

Our previous determinations of the heat of combustion of salicylic acid have been submitted to a control. The heat of combustion of this compound was found to be 5241.7 cal.<sub>15</sub> per g. (air) ( $v = \text{constant}$ ; 19.5°), a value practically identical with that found previously. Hence the heat of combustion found by Berner, namely, 5237.4 cal.<sub>15</sub> per g. (air) ( $v = \text{constant}$ ; about 18°), is too low.

This investigation was carried out with the aid of a grant from

the "Hoogewerff Fonds" and we take this opportunity of expressing our thanks to the Advisory Board of this Fund for the support we have received.

LABORATORIUM DER NEDERLANDSCHE HANDELS-HOOGESCHOOL,  
ROTTERDAM.

[Received, February 27th, 1926.]

## CLXXXVIII.—As-Chlorotetrahydroarsinoline and Some Quaternary Arsonium Compounds.

By ELWYN ROBERTS, EUSTACE EBENEZER TURNER, and (in part)  
FRANK WARD BURY.

As-METHYLTETRAHYDROARSINOLINE (Burrows and Turner, J., 1921, 119, 426) readily forms a *dichloride*, which, when heated, is smoothly decomposed to give As-chlorotetrahydroarsinoline, the first simple cyclic chloroarsine of this series to be prepared.

Attempts to prepare arsinolines and arsinolines (or the corresponding intermediate compounds) are described in this paper.

The alternation in the physical properties of a series of benzene derivatives having normal side-chains is a subject of considerable interest. The following table shows that there is a marked alternation in the melting points of the first five members of the series of methiodides of the general formula  $\text{Ph} \cdot [\text{CH}_2]_x \cdot \text{AsMe}_3\text{I}$ .

$\text{Ph} \cdot \text{AsMe}_3\text{I}$ .....	252°	$\text{Ph} \cdot [\text{CH}_2]_3 \cdot \text{AsMe}_3\text{I}$ .....	144°
$\text{Ph} \cdot \text{CH}_2 \cdot \text{AsMe}_3\text{I}$ .....	194—195	$\text{Ph} \cdot [\text{CH}_2]_4 \cdot \text{AsMe}_3\text{I}$ .....	150—151
$\text{Ph} \cdot [\text{CH}_2]_2 \cdot \text{AsMe}_3\text{I}$ .....	203—204*		

\* Previously given (Turner and Bury, J., 1923, 123, 2489) as 200°.

There is also a marked difference in the ease with which the five arsinolines of the type  $\text{Ph} \cdot [\text{CH}_2]_x \cdot \text{AsMe}_2$  are prepared by the interaction of the appropriate Grignard reagent and dimethyl-iodoarsine. The respective percentage yields of phenyl-, phenyl-propyl-, phenylbutyl-, phenylethyl-, and benzyl-dimethylarsine were 80, 65, 45, 45 (97\*), and 20. We regard a low yield as being due to a high tendency, on the part of the arsine, to undergo oxidation, and conversely; we have, however, not conducted quantitative measurements on the subject.

[With F. W. BURY.] In view of the success achieved by Rosenheim and Plato (*Ber.*, 1925, 58, 2000) and by Mills and Raper (J., 1925, 127, 2479), experiments on the resolution of arsenic compounds in progress in this laboratory have been discontinued. Two asymmetric types were under examination; it has been found

\* Preparation carried out in an inert atmosphere (Turner and Bury, *loc. cit.*).

impossible to resolve cyclohexylphenylbenzylmethyldarsonium d- $\alpha$ -bromocamphor- $\pi$ -sulphonate and the phenylbenzylarsinates of strychnine and l-menthylamine. One or two compounds prepared incidentally are, however, now described.

#### EXPERIMENTAL.

*$\gamma$ -Phenylpropyldimethylarsine.*—The dimethyliodoarsine required for this preparation (Burrows and Turner, *loc. cit.*) is most conveniently obtained by passing sulphur dioxide into a solution containing 225 g. of cacodylic acid, 450 g. of potassium iodide, 150 g. of concentrated sulphuric acid, and 1850 c.c. of water.  *$\gamma$ -Phenylpropyldimethylethylarsonium iodide* is formed fairly readily from the arsine and methyl iodide, and separates from alcohol-ether in colourless leaflets, m. p. 118° (Found: I, 33.3.  $C_{13}H_{22}IA$ s requires I, 33.4%).

*$\gamma$ -Phenylpropylmethylchloroarsine* was heated at 200° in a current of dry carbon dioxide, but although it underwent considerable apparent change, no hydrogen chloride was evolved. This is in interesting contrast to the ease with which o-phenoxyphenyldichloroarsine passes into 10-chlorophenoxarsine (Roberts and Turner, J., 1925, 127, 2004).

*Derivatives of As-Methyltetrahydroarsindole.*—The methiodide melts at 239–240°, not at 235°, as previously recorded. The ethiodide is less readily formed than the methiodide, and separates from ether-alcohol in colourless prisms, m. p. 185–186° (Found: I, 34.8.  $C_{12}H_{13}IA$ s requires I, 34.9%). The benzobromide is formed as a glassy mass when the components are warmed together, and is difficult to purify. It crystallises from ether-alcohol in colourless prisms, m. p. 210–211° (Found: Br, 19.9.  $C_{17}H_{20}BrAs$  requires Br, 21.1%).

When the arsinoline was treated with 1 mol. of bromine, and the product with alkali, no *As*-oxide could be detected. The main product was  $\gamma$ -phenylpropyl bromide.

*As-Chlorotetrahydroarsinoline.*—*As*-Methyltetrahydroarsinoline (20 g.) was dissolved in carbon tetrachloride, and a current of dry chlorine allowed to impinge on the surface of the solution. The white solid *dichloride* separated rapidly, and when a slight excess of chlorine was present the mixture was rendered colourless by addition of a drop of arsinoline. The carbon tetrachloride was removed by distillation, and the residue distilled under diminished pressure. Evolution of methyl chloride was regular and rapid, and as soon as it was complete a preliminary fraction distilled at 120–150°/21 mm., and then the whole of the residue at 155°/16 mm. (16 g.). The latter crystallised on cooling, to give large, irregular, hexagonal

rhombs, m. p.  $22^{\circ}$ , and was pure As-chlorotetrahydroarsinoline (Found: Cl, 15.4.  $C_9H_{10}ClAs$  requires Cl, 15.5%).

When a solution of the chloroarsine in diethylaniline was boiled for 5 hours, marked decomposition occurred, but no 3:4-dihydroarsinoline was isolated from the product. A small quantity of an arsine was formed, since the distilled product combined or reacted with methyl iodide.

*Benzyl dimethylarsine*.—Magnesium benzyl chloride reacted smoothly with one equivalent of dimethyliodoarsine. The product was worked up in the usual manner. The final ethereal solution remained clear while being dried over sodium sulphate, but, when filtered, became cloudy. This was due to oxidation and not to the presence of an additive compound with dimethyliodoarsine, since the ethereal solution had, in accordance with usual practice, been washed with alkali. The arsine was finally obtained as a colourless liquid, b. p.  $110^{\circ}/8$  mm. The yield (20%) would probably be improved by carrying out all the operations in an inert atmosphere (compare Turner and Bury, *loc. cit.*).

The *methiodide* is formed readily, and separates from alcohol in colourless leaflets, m. p.  $195$ — $196^{\circ}$  (Found: I, 37.4.  $C_{10}H_{16}IAs$  requires I, 37.6%). The *ethiodide*, formed moderately readily, crystallises from alcohol-ether in colourless leaflets, m. p.  $163$ — $165^{\circ}$  (Found: I, 36.3.  $C_{11}H_{18}IAs$  requires I, 36.1%).

*$\delta$ -Phenyl- $n$ -butyl dimethylarsine*.—This was prepared from  $\gamma$ -phenylpropyl bromide, *via* the corresponding nitrile (von Braun, *Ber.*, 1910, 43, 2843; Rupe, *Annalen*, 1912, 395, 87),  $\delta$ -phenyl- $n$ -butyl alcohol, and  $\delta$ -phenyl- $n$ -butyl bromide (von Braun, *Ber.*, 1911, 44, 2871).

The bromide readily formed a Grignard reagent; this reacted smoothly with dimethyliodoarsine to give a product which, after the usual treatment, including washing with alkali, afforded the arsine as a colourless liquid, b. p.  $150^{\circ}/14$  mm. (yield, 45%).

The *methiodide* is very readily formed, and is sparingly soluble in alcohol, from which it crystallises in colourless leaflets, m. p.  $150$ — $151^{\circ}$  (Found: I, 33.0.  $C_{13}H_{22}IAs$  requires I, 33.4%).

The *ethiodide*, formed moderately easily, separates from alcohol in leaflets, m. p.  $134$ — $135^{\circ}$  (Found: I, 32.5.  $C_{13}H_{24}IAs$  requires I, 32.2%).

*Phenyl- $\beta$ -phenylethyl methylarsine*.—This substance was readily obtained by the interaction of magnesium  $\beta$ -phenylethyl bromide and phenylmethyliodoarsine in ethereal solution. When the ethereal extract of the arsine, obtained by the usual method, was evaporated, a considerable quantity of a gummy solid separated. This was removed before distilling the arsine under diminished

pressure. *Phenyl-β-phenylethylmethylarsine* is a colourless liquid boiling at 187°/12 mm. and 190°/15 mm., and was obtained in 82% yield.

The *methiodide* is formed readily, and crystallises from water in rhombohedra or prisms, m. p. 119° (Found: I, 30.5.  $C_{16}H_{20}IAs$  requires I, 30.6%).

*Action of β-Phenylethyl Bromide on Arsenites and Arsinites.*—

(a) *On sodium arsenite.* A solution of arsenious oxide (0.5 mol.) in aqueous sodium hydroxide (3 mols.) was boiled with the bromide for several days, under reflux. Some bromide was recovered unchanged, and no arsenic acid could be detected in the product.

(b) *On sodium arsenite in presence of copper bronze.* The bromide was stirred and heated at 140—180° for 7 hours in presence of dry sodium arsenite (Kahlbaum) and copper bronze. No change was observed. (c) *On potassium methylarsinite.* An aqueous-alcoholic solution containing methylarsenious oxide (1 mol.), potassium hydroxide (2 mols.), and the bromide (1 mol.) was boiled under reflux for 2 days. Styrene, but no arsenic acid, was formed.

[With F. W. BURY.] *Dicyclohexylphenylarsine.*—This was prepared by adding phenyldichloroarsine to a solution of magnesium cyclohexyl bromide, the reaction product being worked up in the usual manner. The arsine is a colourless liquid, b. p. 220°/14 mm. The *methiodide* and *ethiodide* are formed readily and crystallise from alcohol-ether in prisms, m. p. 187° (Found: I, 27.5.  $C_{19}H_{30}IAs$  requires I, 27.6%), and plates, m. p. 188—189° (Found: I, 26.6.  $C_{20}H_{32}IAs$  requires I, 26.8%), respectively.

*Tricyclohexylarsine.*—When arsenious iodide was added to an ethereal solution of magnesium cyclohexyl chloride or bromide, only half of the calculated quantity reacted. The arsine was, however, obtained mixed with a little dicyclohexyl as a colourless oil, b. p. 235°/12 mm. The *methiodide* was formed readily and crystallised from water in prisms, m. p. 153—154°. The *benzobromide* melts at 197° with slight decomposition (Found: Br, 16.2.  $C_{25}H_{40}BrAs$  requires Br, 16.2%).

*cycloHexylphenylmethylarsine.*—A Grignard reagent prepared from 24 g. of cyclohexyl chloride was treated with phenylmethyl-iodoarsine until the yellow colour of the latter persisted, *i. e.*, when about 75% of the iodo-compound had been added. The reaction product was worked up as usual, and gave 30 g. of *cyclohexylphenylmethylarsine* as a highly refractive oil, b. p. 152—153°/12 mm., having no marked tendency to oxidise.

When the arsine was heated at 100° with one equivalent of benzyl bromide and a little alcohol, large, colourless crystals began to form, but subsequently disappeared. On cooling, only a little white

powder separated, and crystallisation was induced by addition of excess of ether. *cycloHexylphenylbenzylmethyларsonium bromide* was thus obtained; recrystallised from alcohol-ether, it formed rectangular plates, m. p. 193° (Found: Br, 19.0.  $C_{20}H_{26}BrAs$  requires Br, 19.0%).

The corresponding *d-α-bromocamphor-π-sulphonate* was prepared. The crude material melted at 109–113°, and crystallisation experiments gave unpromising results, mixtures of crystalline, amorphous, and gel-like material being obtained.

*Phenylbenzylarsinic Acid*.—Excellent yields of this acid are obtained by the following method, which is more expeditious than that described by Bertheim (*Ber.*, 1915, 48, 350): Crude phenylarsenious oxide (75 g.) as obtained from phenyldichloroarsine and sodium hydroxide was dissolved in 150 c.c. of methylated spirit. Sodium hydroxide (36 g.) in 52 c.c. of water was added. To the hot solution, 60 g. of benzyl chloride were added gradually, keeping the initial vigorous reaction in progress. Sodium chloride separated at once. The mixture was left until cold, freed from alcohol by distillation, acidified, and the resulting precipitate of acid washed with water and ether.

*Strychnine Phenylbenzylarsinate*.—This salt was prepared by mixing hot alcoholic solutions of the base and the acid, and formed colourless needles (Found: N, 4.5; As, 11.4, 11.4.

$C_{21}H_{22}O_2N_2 \cdot C_{13}H_{13}O_2As \cdot 3H_2O$   
requires N, 4.2; As, 11.3%). It had  $[\alpha]_D^{20} - 31.2^\circ$  in 50% aqueous acetone, and when crystallised from this solvent gave a mixture of free acid and strychnine salt. When hot alcoholic solutions of strychnine (1 mol.) and the acid (2 mols.) were mixed, the free acid separated first.

*1-Menthylamine Phenylbenzylarsinate*.—Equivalent quantities of the base and acid were together dissolved in alcohol, and the solution was allowed to evaporate in a vacuum over sulphuric acid. The whole set to a mass of hairy needles. These were collected, dissolved in benzene, and the solution treated with light petroleum; a crystalline precipitate was obtained, which consisted of a mixture of base and acid.

One of us (F. W. B.) wishes to thank the Research Fund Committee of the Society for a grant with which some of the expenses of the work were met.

UNIVERSITY OF LONDON.

[Received, February 17th, 1926.]

CLXXXIX.—*The Resin of Hevea Rubber.*

By GEORGE STAFFORD WHITBY, JACOB DOLID, and FREDERIC HARRISON YORSTON.

THE circumstance that the resin of the rubber from *Hevea brasiliensis* constitutes only a small proportion of the weight of the rubber (on the average, about 2.80%. Compare van Rossem, *Koll.-Chem. Beih.*, 1918, 10, 52; "The Quality of Plantation Rubber," Imp. Inst., 1922, pp. 13, 27, 88, 95) and is of a sticky, semi-fluid consistency has apparently deterred investigators from subjecting it to chemical examination (compare, e.g., Tschirch and Müller, *Arch. Pharm.*, 1905, 243, 141), and when the present investigation was begun but little was known concerning its chemical nature.

It has now been shown that, contrary to Hinrichsen and Kindscher's statement (*Z. angew. Chem.*, 1910, 23, 49), the resin contains several optically active substances (all lævorotatory, with the exception of an amino-acid occurring in very small amounts only) and that sterol substances are present. Hillen's failure to obtain sterol colour reactions (*Arch. Pharm.*, 1913, 251, 94) was probably due to interference of other substances present in the crude extract. Cohen (*Arch. Pharm.*, 1908, 246, 520) examined the resin for lupeol, with negative results. Hinrichsen and Kindscher (*loc. cit.*) found the resin to be largely saponifiable, and Dekker (*Koll.-Chem. Beih.*, 1918, 10, 54), who confirmed this finding, obtained the data shown in the first two columns below. The figures in the third column, which have been added, would seem to suggest that the differences in the percentage of extract unsaponifiable in different forms of *Hevea* rubber are due to differences in the amount of saponifiable matter rather than to differences in the amount of unsaponifiable matter.

Form of rubber.	Acetone extract %.	% extract unsaponifiable.	% unsaponifiable in the rubber.
Fine hard Para .....	3.0	25.4	0.76
Sheet .....	1.8	48.3	0.87
Crêpe .....	3.2	22.0	0.705

A sample of the resin was found by Hinrichsen and Kindscher (*loc. cit.*) to show an iodine absorption of 118%. Beadle and Stevens (*Internat. Cong. Appd. Chem.*, 1912, 24, 581) reported that the resin was partly water-soluble. The presence in it of nitrogenous material was mentioned by Spence and Kratz (*Kolloid-Z.*, 1914, 14, p. 268, footnote), and was confirmed by Dekker (*Meded. Delft*, 1916, 506) by an indirect method. Dekker found acetone extraction to reduce the nitrogen content of two samples of *Hevea* crêpe by 0.051 and 0.029%, respectively, and of a sample of *Hevea* sheet by 0.014%.

Working with a sufficiently large amount of the acetone extract of *Hevea* rubber, the present authors have isolated and identified a sterol, a sterol ester, a sterol glucoside, *d*-valine, quebrachitol, and stearic acid and the liquids, oleic and linoleic acids. The amounts and ratios in which the substances occur vary in different rubber samples. The mixture of unsaturated, liquid fatty acids occurs in much larger amount than any of the other constituents. Titration of the acetone extract of twenty-four samples of smoked sheet and pale crêpe rubber showed that the average total acid content was equivalent to 0.272 g. of potassium hydroxide per 100 g. of rubber. Hence, if the mean molecular weight of the acids is taken as 280, the total acid content of average samples of latex *Hevea* rubber is of the order of 1.4% of the weight of the rubber or roughly one-half of the weight of the acetone extract.

The total amount of solid material which it was actually possible to crystallise from the extract was about 0.65% of the weight of the rubber. As the resin content of the crêpe from which most of the resin examined was obtained was 2.71%, it may be said that of this about 1.9 (=1.25 + 0.65) was definitely accounted for. The balance of about 0.8% represented losses together with unidentified constituents of the liquid, uncrystallisable portion of the resin.

The order of magnitude (%) in which the recognised constituents of *Hevea* resin occurred was estimated roughly as follows :

Sterol ester .....	0.075	Quebrachitol .....	very small amount
Sterol glucoside .....	0.175	Stearic acid .....	0.15
Sterol .....	0.225	Oleic acid .....	} 1.25
<i>d</i> -Valine .....	0.015	Linoleic acid .....	

The high proportion of free fatty acid in the resin of *Hevea* rubber makes this resin unique, not only among the resins of rubbers of various botanical origins, but also among resins in general. In *Hevea* resin, fatty acids predominate, and hence it has a softer consistency, a higher saponification value, and a smaller optical activity than have other rubber resins, in which optically active, unsaponifiable, crystalline substances predominate. The resins obtained by extracting plants with organic solvents contain free fatty acids in a good many cases, but never in large proportions (Power and his co-workers, J., various papers).

The question of the mode of association of the resin constituents with the hydrocarbon in rubber is of some interest. It is probable that the fatty acids occur in solution in the caoutchouc. Rubber, both raw and vulcanised, swells considerably when placed in oleic acid, linoleic acid, molten stearic acid, or the mixed liquid fatty acids actually isolated from *Hevea* rubber. Thus, for example, a sample of smoked sheet placed in the last-mentioned medium

imbibed 4.04 times its weight after 7 days. The sterol glucoside found in rubber is insoluble in all the usual laboratory solvents, including benzene. It probably occurs, not dissolved in the caoutchouc, but in solution in the fatty acids, for the authors have observed that it will dissolve on warming in fatty acids, except in the lowest members, yielding sols which often gel on cooling.

The resin, and especially the fatty acids which it comprises, influence the behaviour of rubber in several important ways (compare Whitby, *Trans. Inst. Rubber Ind.*, 1925, 1, 12; Whitby and Jane, *Second Colloid Symposium Monograph*, 1925, 16).

#### EXPERIMENTAL.

Samples of rubber were extracted with acetone in a large, heavily galvanised iron extractor of the Soxhlet type, 3 ft. high and 1 ft. in diameter. The thimble, which is large enough to hold about 4.5 kg. of rubber, is suspended directly in the vapour of the boiling extractant. The condenser, which sits on a flange at the top of the main extraction vessel, consists of a hollow cone and head through which water circulates and a separate, conical coil of block tin round the cone. The metal of the extractor was attacked slightly in the course of time, zinc salts of fatty acids being found in the extract.

The extracts from a number of different samples of rubber (crêpe, smoked sheet, slab crêpe) were examined. The procedure varied somewhat in different cases, as the proportions of the constituents were not identical in different batches, but in general it was as follows: The batch of rubber was extracted for 70 to 100 hours. The solution was concentrated to about 600 c.c. per kg. of rubber and kept for a week or so at or below 0°. The solid which separated (Fraction A) was removed and the solution (and washings) was concentrated to one-third or less of its volume and again kept in the cold for a week. The solid which separated (Fraction B) was removed and washed with a little cold acetone. The solution and washings were then evaporated on the water-bath to remove as much acetone as possible. The viscous liquid residue is called the Liquid Fraction.

##### *Fraction A.*

This fraction (47 g. of a light brown powder from 21.7 kg. of pale latex crêpe) was separated into a chloroform-soluble sterol ester, a water-soluble amino-acid and quebrachitol, and an insoluble sterolin.

*Sterol Ester.*—Chloroform extracted from fraction A about 10 g. of a sterol ester which, after recrystallisation from alcohol, had  $m.p. 83^{\circ}$  and  $[\alpha]_D^{25} - 11.1^{\circ}$ ,  $-10.8^{\circ}$  (0.2145 and 0.2303 g. in 15 c.c.

of chloroform) (Found: C, 83.0; H, 12.6; iodine absorption, 34.3.  $C_{17}H_{33}O_2 \cdot C_{27}H_{45}$  requires C, 82.8; H, 12.4; iodine absorption, 39.6%). The iodine absorption is due to unsaturation of the sterol part of the ester, the acid part being saturated. (The iodine values obtained for sterols are usually somewhat lower than the calculated values.) The *sterol* obtained by hydrolysing the ester with alcoholic potassium hydroxide crystallised from alcohol in fine, white needles, m. p. 133—134°,  $[\alpha]_D^{25} - 23.2^\circ$  (0.3140 g. in 15 c.c. of chloroform) (Found: C, 82.8; H, 11.4.  $C_{27}H_{46}O$  requires C, 83.9; H, 11.9%) and gave the usual colour reactions and also certain new reactions (Whitby, *Biochem. J.*, 1923, **17**, 5). The acetate crystallised from alcohol in matted crystals, m. p. 113—114°, and gave  $[\alpha]_D^{25} - 18.8^\circ$  (0.1707 g. in 15 c.c. of chloroform). The *acid* obtained by hydrolysis of the sterol ester melted at 73—75° after recrystallisation from alcohol and appeared to have the composition  $C_{17}H_{34}O_2$  (Found: C, 74.5; H, 11.2. Calc.: C, 75.6; H, 12.6%. Found for the *silver* salt: Ag, 28.5.  $C_{17}H_{33}O_2Ag$  requires Ag, 28.5%).

The sterol ester isolated from slab rubber and from smoked sheet melted at 102° and 91—93°, respectively, but the amounts isolated were insufficient for careful examination.

*The Aqueous Extract.*—Addition of alcohol to the concentrated aqueous extract of fraction A (derived from 21.7 kg. of crêpe) precipitated 1 g. of an amino-acid; quebrachitol remained in solution. The two substances could also be separated by precipitating the amino-acid with mercuric nitrate or by evaporating the aqueous extract to dryness and extracting the amino-acid with cold alcoholic hydrochloric acid.

The amino-acid, m. p. about 260° (decomp.), gave (a) the ninhydrin reaction, (b) the pine splinter pyrrole reaction, when heated either alone or with zinc dust, and (c) a blue colour with phenol and sodium hypochlorite (Found: C, 52.2; H, 9.42; amino-N, by micro-van Slyke method, 11.7, 11.6.  $C_5H_{11}O_2N$  requires C, 51.3; H, 9.4; N, 11.9%). It had  $[\alpha]_D^{25} + 22.9^\circ$ ;  $[\alpha]_D^{25} + 26.5^\circ$  (0.1888 g. in 25 c.c. of 20% HCl). For a 3% solution of *d*-valine in 20% HCl, E. Fischer (*Ber.*, 1906, **39**, 2325) obtained  $[\alpha]_D^{25} + 28.8^\circ$ . The total amino-nitrogen in an aqueous extract of the original rubber was 0.0015% (micro-van Slyke method). This corresponds to 0.0126% of valine in the rubber or 0.46% of valine in the acetone extract.

Quebrachitol was first noticed as separating in well-formed crystals from the acetone extract of a sample of smoked sheet which had stood for a long time after the separation of a first fraction. It had m. p. 190° and  $[\alpha]_D^{20} - 80.3^\circ$  (0.2800 g. in 14.5 c.c. of water).

It was subsequently always recognised in fraction A, and in several cases was actually isolated from it.

By means of Scherer's test for inositol (*Annalen*, 1852, **81**, 375; compare Boedker, *Zig. nat. Med.*, **10**, 162) the presence of quebrachitol was detected in forty-five samples of *Hevea* rubber comprising all the usual forms (latex crêpe, lower grade crêpes, smoked sheet, fine hard Para, etc.). For most of these samples the authors are indebted to Dr. O. de Vries. A few grams of the rubber (as little as 1 g. will give a positive result), cut into small pieces, were boiled for 15–30 minutes with glacial acetic acid, which was then evaporated, finally on a water-bath. The material extracted from the residue by a little hot water developed a rose-red colour after the usual nitric acid-calcium chloride treatment.

The isolation of quebrachitol from the latex of *H. brasiliensis* has been recorded by De Jong (*Rec. trav. chim.*, 1906, **25**, 48), and from rubber by Pickles and Whitfield (*P.*, 1911, **27**, 54).

Professor R. P. D. Graham has kindly made crystallographic measurements on some of the crystals which separated from the acetone extract and on larger crystals of quebrachitol which had grown in a sample of evaporated latex serum which had been kept for 9 years. For comparison, there are given below the crystallographic data obtained by Anderson with a sample of quebrachitol isolated by Petrie from *Heterodendron oleaefolium*, Desf. (*Proc. Linnean Soc. N.S. Wales*, 1918, **43**, 857).

*Crystallographic data for l-inositol methyl ether* (by R. P. D. GRAHAM). The crystals were transparent, colourless blades, sometimes attaining a length of 6 mm. or more. *System*: orthorhombic. No cleavage was observed. *Forms and habit*: All the crystals measured exhibited the forms  $a(100)$ ,  $b(010)$ ,  $m(110)$ , and  $q(011)$ . On several of the crystals there were in addition very small facets of the form  $(101)$ . The crystals were elongated in the direction of the vertical axis, and tabular parallel to  $a$  or  $m$ . The faces of the orthorhombic prism,  $m$ , were heavily striated vertically, with a tendency to curvature; but faces of the other forms were smooth and yielded fair reflexions. A peculiarity of the crystals was that, in nearly all the cases observed, only two opposite faces of the prism  $m$  were developed.

*Angular measurements and axial ratios.*

	Limits.	No.	Mean.	Calc.	Anderson.
$b\ m$	52° 26'—53° 19'	5	52° 47'		52° 44'
$c\ q$	39 10—39 35	6	39 22		39 26
$c$	47° 03'	1	47 03	47° 13'	47 43

*Axial ratios*  $a : b : c = 0.7595 : 1 : 0.8204$

0.7609 : 1 : 0.8224 (Anderson).

*The Sterolin.*—The residue of fraction A after removal of the chloroform- and water-soluble portions consisted in all cases of sterol glucoside. After purification through its acetate, it had m. p. 285–290° (decomp.) and  $[\alpha]_D^{25} - 41.7^\circ$  (0.2900 g. in 14.6 c.c. of pyridine) (Found: C, 73.0; H, 10.4.  $C_{33}H_{56}O_6$  requires C, 72.3; H, 10.2%). Its behaviour in the sterol colour reactions and in a new test which enables sterolins to be distinguished from sterols has been described elsewhere (Whitby, *Biochem. J.*, 1923, 17, 5). The *acetate*, prepared by means of hot acetic anhydride, crystallised from alcohol in pearly leaflets, m. p. 165°;  $[\alpha]_D^{25} - 22.4$  (Found: C, 69.1; H, 9.0; Ac, 23.1.  $C_{33}H_{52}O_6Ac_4$  requires C, 68.7; H, 8.9; Ac, 22.5%). The *benzoate* was prepared by treating a pyridine solution of the sterolin with a slight excess of benzoyl chloride, extracting the diluted reaction mixture with ether, and washing the extract with dilute sulphuric acid, dilute potassium hydroxide, and water in succession. The product, recrystallised from ether, had m. p. 198° and  $[\alpha]_D^{25} + 15.7^\circ$ ,  $+ 16.1^\circ$  (0.3256, 0.2637 g., respectively, in 15 c.c. of chloroform).

Hydrolysis of the sterolin by hydrochloric acid in amyl alcohol by Power and Salway's method (J., 1913, 103, 399) gave glucose (osazone, m. p. 201°) and a sterol. The latter, obtained as lustrous plates after recrystallisation, melted at 134.5° and had  $[\alpha]_D^{25} - 31.7^\circ$ ,  $- 32.1^\circ$  (0.2793 and 0.1268 g., respectively, in 15 c.c. of chloroform) (Found: C, 84.3; H, 12.3.  $C_{27}H_{46}O$  requires C, 83.9; H, 11.9%). The acetate of this sterol melted at 115° and showed  $[\alpha]_D^{25} - 38.6^\circ$  (0.0634 g. in 15 c.c. of chloroform). There is little doubt that the sterolin is sitosterol *d*-glucoside (Power and Salway, *loc. cit.*, p. 1022).

The sterol glucosides are soluble, not only in hot amyl alcohol and in pyridine (Power and Salway, *loc. cit.*, p. 399), but also in amines (piperidine and diethylamine), fatty acids (octoic acid), mustard oils (phenylthiocarbimide), and higher ethers (anisole). In many of such liquids the sols set to gels on cooling.

#### Fraction B.

This fraction usually consisted of a mixture of a sterol or sterols and one or more saturated fatty acids. Separation was effected by treating the mixture with alcoholic potassium hydroxide and then extracting the sterol by ether from the mixture of potassium salt and sterol which came out on cooling. In certain cases, either the sterol or the fatty acid predominated so greatly that recrystallisation was sufficient to obtain it in a pure condition.

*The Sterol.*—A sterol was first isolated from the acetone extract of a batch of 4 kg. of smoked sheet rubber, which, when concentrated to 500 c.c. per kg. and kept in the cold, deposited 9 g. of

almost pure sterol as rosettes of crystals. After recrystallisation six times from alcohol, there was obtained a mass of matted, white leaflets, m. p.  $125^{\circ}$ ,  $[\alpha]_D^{25} = -24.6^{\circ}$  (0.2975 g. in 15 c.c. of chloroform) (Found: C, 83.8; H, 13.0.  $C_{27}H_{46}O$  requires C, 83.9; H, 11.9%).

Fischer's method (*Ber.*, 1913, **46**, 4029) of preparing penta-acyl derivatives of sugars is suitable for the acylation of sterols, including cholesterol. The *benzoate*: The sterol described above was treated in chloroform solution with a slight excess of benzoyl chloride and an equivalent amount of quinoline. After a short time, the solution was washed successively with dilute sulphuric acid, dilute sodium hydroxide solution, and water, dried over calcium chloride, and the chloroform evaporated. The residue crystallised from alcohol-chloroform in lustrous plates, m. p.  $144-145^{\circ}$ ;  $[\alpha]_D^{25} = -20.7^{\circ}$  (0.1340 g. in 14.6 c.c. of chloroform) (Found: C, 83.9; H, 9.9.  $C_{27}H_{45}O \cdot CO \cdot C_6H_5$  requires C, 83.3; H, 10.2%). The *propionate*, prepared by a similar method, crystallised from alcohol in lustrous white plates, m. p.  $98^{\circ}$ ;  $[\alpha]_D^{25} = -29.4^{\circ}$  (0.2005 g. in 17 c.c. of chloroform). The *acetate*, prepared by treating the sterol with an excess of acetic anhydride, was obtained as white plates or leaflets, m. p.  $114-115^{\circ}$ ;  $[\alpha]_D^{25} = -30.6^{\circ}$  (0.3169 g. in 14.6 c.c. of chloroform).

A sample of sterol obtained, in the case of a batch of 21.7 kg. of pale latex crêpe, by extracting a mixture of potassium soap and sterol with ether was freed from potassium salt by converting this into the silver salt and extracting the sterol with ether. After several recrystallisations from ether, the sterol was obtained as lustrous plates, m. p.  $134-135^{\circ}$ ;  $[\alpha]_D^{25} = -21.4^{\circ}$  (0.3278 g. in 15 c.c. of chloroform). The *benzoate* had m. p.  $144.5^{\circ}$ , and  $[\alpha]_D^{25} = -12.5^{\circ}$  (0.2393 g. in 15 c.c. of chloroform) (Found: C, 83.1; H, 10.2.  $C_{34}H_{50}O_2$  requires C, 83.3; H, 10.2%).

From the acetone extract of a sample of slab rubber, not quite the whole of the sterol separated when the extract was kept at a suitable concentration. The extract was then saponified, and from the unsaponifiable material ether removed a sterol, m. p.  $133-134^{\circ}$ .

*The Fatty Acid.*—The main fatty acid present in fraction B, previously regarded as a  $C_{20}$  saturated fatty acid and named "heveic acid" (Whitby, *Brit. Assoc. Rep.*, 1923, 432), has now been identified as stearic acid. A sample (equiv., 291) isolated from slab rubber melted at  $65.5-66.5^{\circ}$  after recrystallisation from alcohol and at  $68.5^{\circ}$  after recrystallisation from aqueous acetic acid, benzene, aqueous acetone, and light petroleum in succession. It was then mixed with further quantities of solid acid obtained from crêpe rubber, recrystallised until its melting point was  $67.5-68.5^{\circ}$ , and converted, by treatment of the silver salt with ethyl

iodide in benzene, into the ethyl ester. This after purification had m. p. 32.5—33.5° and  $n_D^{40}$  1.4292. The acid regenerated therefrom had m. p. 68—69° (alone or mixed with stearic acid),  $n_D^{20}$  1.4332,  $n_D^{80}$  1.4300 ( $n_D^{20}$  for stearic acid in the same apparatus, 1.4328). A sample of the ester prepared from the solid acid derived from another sample of rubber had, after distillation and recrystallisation from chloroform, m. p. 31.5° (Found:  $M$ , 314. Calc.:  $M$ , 312).

Another sample of the chief solid acid was isolated from the acetone extract of a sample of latex crêpe rubber as follows: The mixture of the crystallisable substances which separated on allowing the extract, slightly diluted with acetone, to stand for several months was extracted with chloroform. The residue left on removal of the chloroform was separated by several crystallisations from alcohol and ethyl acetate into (a) a sterol ester (less soluble) and (b) a fatty acid (more soluble). The latter after several recrystallisations melted at 67—69° and had an equivalent weight of 295. It was purified further through its barium salt and then, after recrystallisation from acetone, aqueous acetic acid, and chloroform, had m. p. 68.5—69.5° (Found: equiv. by titration, 293, 289).

#### *The Liquid Fraction.*

This fraction was distilled with steam, which removed the last traces of acetone and also mesityl oxide, evidently formed from the acetone during the extraction. No essential oil was present. After removal of the non-volatile oil with ether, the aqueous layer contained a small amount of nitrogenous material precipitable by alkaloidal reagents; phosphomolybdic acid precipitated 2.5 g. (from 21.7 kg. of crêpe rubber) and in the case of slab crêpe, the precipitate given by platinic chloride contained 24.0% of platinum and did not melt at 295°. Both precipitates gave the pyrrole test on ignition.

The Liquid Fraction consisted preponderantly of unsaturated fatty acids, although some evidence was obtained of the presence of a magnesium salt. After steam distillation the fraction was esterified by hydrogen chloride in methyl alcohol at 0°, the ester mixture distilled, and the fraction, b. p. 195°/9 mm.—185°/5 mm., saponified. The free acid thus obtained had, after removal of a little crystalline material, a mean molecular weight (by titration) of 317 and an iodine absorption (Hübl) of 140, 141. *Hydrogenation.* 8.63 G. were treated with purified hydrogen in ether in presence of platinum-black carried on finely-divided barium sulphate. Unfortunately, some of the alkaline sodium hyposulphite solution over which the hydrogen was stored was sucked into the reaction flask, and in consequence only 619 c.c. of hydrogen were taken up

instead of the 1100 c.c. corresponding to the iodine value. Nevertheless, pure stearic acid was isolated in such good yield and so easily that it may be considered certain that only  $C_{18}$  unsaturated acids were present in the liquid submitted to hydrogenation. The crystals obtained after evaporation of the ether had m. p.  $68.5^{\circ}$  after recrystallisation from ethyl acetate and  $69-69.5^{\circ}$  after further recrystallisation from alcohol and from chloroform (Found : equiv., 281, 284). A total of 3.66 g. of stearic acid was isolated and the final mother-liquor left on evaporation 2.34 g. of impure stearic acid. *Oxidation.* The potassium soaps from 3 g. of the mixed acids were oxidised in aqueous solution with 3 g. of potassium permanganate. That part of the product which was soluble in cold ether was extracted with carbon tetrachloride. The portion thus extracted melted at  $60^{\circ}$  after recrystallisation, and was probably impure saturated acid. The portion (0.05 g.) unextracted by the carbon tetrachloride melted at  $124-126^{\circ}$ , had a molecular weight by titration of about 320, and was probably dihydroxystearic acid (*vide infra*). (A sample of dihydroxystearic acid prepared from Kahlbaum's oleic acid melted at  $128^{\circ}$  after several recrystallisations.) That part of the product which was insoluble in cold ether amounted, after recrystallisation from aqueous alcohol, to 0.42 g. and melted at  $160-170^{\circ}$ . By extracting it with boiling water, crystals were obtained, m. p.  $155-156^{\circ}$ , having an equivalent weight (by titration) of 356 and probably representing sativic acid. *Bromination.* A sample of the mixed acids was brominated in cold ethereal solution by Muggenthaler's method. No ether-insoluble bromide was obtained, and hence linolenic acid was absent. A small amount of a bromide melting, after recrystallisation from light petroleum, at  $112^{\circ}$  was obtained. (Linoleic acid tetrabromide melts at  $113-114^{\circ}$ .)

In order to identify the liquid acids with greater certainty, the solvent was removed from the acetone extract of 11 kg. of latex crêpe rubber, and the residue was boiled with water, in order to eliminate any mesityl oxide and to extract water-soluble constituents. The material was then boiled with 5% potassium hydroxide solution in excess of the amount equivalent to the acid known to be present in the rubber, and, after most of the material had gone into solution, the liquid was evaporated and distributed on pumice. This was then dried on a steam-bath and extracted with light petroleum, which removed, in addition to sterol and other unsaponifiable material, some potassium linoleate. This salt separated on cooling and after recrystallisation was obtained as a pale yellow powder (21 g.), which rapidly became brown in the air. Oxidation with potassium permanganate converted it

into sativic acid, insoluble in light petroleum or ether, melting at 165° after one recrystallisation from alcohol, and having an equivalent weight of 338 (sativic acid, 348). The pumice was now boiled with water and the acids liberated from the soap solution thus obtained were washed and dried [Found: *M* (mean), 340, 340. Iodine absorption, 144, 145%]. The potassium salts derived from 19 g. of the acids gave, on oxidation with permanganate: (a) 0.95 g., soluble in light petroleum, melting at 45–60° after two recrystallisations, and probably representing impure saturated acid; (b) 0.85 g. of dihydroxystearic acid (white crystals, m. p. 128–130°. Found: C, 67.8; H, 11.8%); (c) 2.7 g. of sativic acid. The last was separated by fractional crystallisation into portions, m. p. 169.5° and 154°, respectively. Nicolet and Cox (*J. Amer. Chem. Soc.*, 1922, **44**, 144) have shown that the two *dl*-mixtures of tetrahydroxystearic acids formed by the oxidation of linoleic acid can be separated by fractional crystallisation, the melting point of one being 171° and of the other 153°.

The zinc salt of a fatty acid was left on the pumice after the extraction of the soaps. It melted at 123°, and was probably impure zinc stearate derived from the zinc of the galvanised iron extractor and the stearic acid of the resin. A specimen of the zinc salt prepared from a somewhat impure sample of the solid acid isolated from the resin (m. p. 67–69°), by heating the acid in cymene solution with zinc oxide, melted at 123°.

Hence the presence of oleic and linoleic acids in the Liquid Fraction can be regarded as established; and, since further only  $C_{18}$  acids are present, it seems safe to assume that the higher liquid fatty acids in rubber consist of oleic and linoleic acids exclusively. The purest sample of the mixed liquid fatty acids isolated showed an iodine absorption of 140 (*vide supra*). As this sample probably contained a small amount of solid acid as impurity, it is probable that the amount of linoleic acid present is considerably more than twice that of oleic acid. This conclusion is supported by the relative yields of dihydroxy- and tetrahydroxy-stearic acids obtained on oxidation.

The authors wish to thank the National Research Council of Canada for a grant of money, Mr. G. D. Kratz and Mr. C. W. Bedford for samples of acetone extract, and Mr. W. B. Wiegand and Dr. E. A. van Valkenburgh for gifts of rubber.

CXC.—*Some Fatty Acid Derivatives.*

By GEORGE STAFFORD WHITBY.

This paper describes the use of the silver salts of the fatty acids (which are obtainable by a convenient procedure described in the experimental part) for the preparation of derivatives such as the glycerides, acid anhydrides, and esters by double decomposition with appropriate halogen compounds. Certain mixed triglycerides have been prepared by treating  $\beta$ -acyl dichlorohydrins with such silver salts:

$\beta$ -Acyl dichlorohydrins can be prepared by the action of acyl chlorides not only on  $\alpha$ -dichlorohydrin, but also on epichlorohydrin: *i.e.*, acyl chlorides add on to epichlorohydrin in the same sense that hydrogen chloride does, the chlorine assuming the  $\alpha$ -position:

This has been shown to be the case for propionyl, butyryl, and stearyl chlorides.

The silver salts of the fatty acids react very easily with acyl chlorides, yielding acid anhydrides, and readily with alkyl halides, yielding esters. In a homologous series of esters of palmitic acid and in a similar series of esters of stearic acid, the melting point falls from the methyl ester to a minimum in the butyl ester.

Heintz (*Ann. Phys.*, 1852, **87**, 21, 267; 1854, **92**) concluded that the fatty acids derived from the saponification of spermaceti comprised stearic acid. The present author has isolated cetyl stearate from spermaceti by fractional crystallisation.

## EXPERIMENTAL.

*Silver Salts of Fatty Acids.*—Silver salts of both higher and lower fatty acids were obtained as fine, white powders, which suffered no discoloration when kept for 3 years in the light, by the following procedure: To a 2–4% alcoholic solution of the acid were added, in either order, 1 equiv. of aqueous ammonia (*d ca.* 0.9) and 1 equiv. of silver nitrate (dissolved in twice its weight of water; or dissolved in its own weight of water, and the warm solution diluted with alcohol). After 2–3 hours, the precipitate was filtered off, dried on a porous plate, powdered, and, if desired, dried at 50° for several hours. In the case of the higher fatty acids, the silver salt was precipitated in a more easily filterable form at about 50° than at room temperature. The yields were almost theoretical. Silver

stearate, palmitate, laurate, myristate, hexoate, butyrate, propionate, acetate, and oleate prepared by this procedure were shown to be pure by determining their silver content. The stearic acid used melted at  $69.5^{\circ}$ , and the palmitic acid at  $62.5^{\circ}$ .

From the higher fatty acids, silver salts were also obtained as white powders, stable in the light, by a modification of Krafft's method (*Ber.*, 1888, 21, 2266); the precipitates, however, were contaminated with a small amount (usually about 1%) of the free fatty acid, which could be removed by washing with alcohol or extraction with ether: Silver nitrate (1 equiv.) dissolved in a little water was treated with sufficient aqueous ammonia to re-dissolve the precipitate formed. The solution was added to an alcoholic solution of the fatty acid, precipitation completed by the addition of water, and the readily-filterable silver salt washed with alcohol and dried on a porous plate.

The solubility of silver palmitate and stearate in water at  $20^{\circ}$ , determined colorimetrically (Whitby, *Z. anorg. Chem.*, 1910, 67, 68), was 0.00123 g. and 0.00065 g., respectively, per litre. These two salts therefore fall in line with the silver salts of the lower acids, the solubilities of which change from member to member in a comparatively regular manner (Lieben, *Monatsh.*, 1884, 15, 404). Silver palmitate and stearate being less soluble than silver chloride, sodium chloride does not precipitate silver chloride from a solution of silver palmitate or stearate, held up by the minimum quantity of ammonia. Silver palmitate, being more soluble than silver stearate, requires less ammonia to cause it to dissolve in alcohol, and, conversely, it requires more water to precipitate it from ammoniacal alcoholic solution.

The silver salts of the higher fatty acids swell, disperse, and, on cooling, yield gels in various organic liquids, *e.g.*, aromatic hydrocarbons, on heating (compare Whitby, *Science*, 1921, 53, 580). Silver oleate yields gels more readily than does silver palmitate or stearate. Thus it gives a gel in benzene, whereas silver stearate requires the higher-boiling xylene to yield a firm gel; in toluene, it gives only a weak gel, and in benzene it merely swells. Silver oleate gives a weak gel in amyl alcohol. In *n*-propyl alcohol, it swells and disperses, but on cooling separates as flocks, not as a gel. Gelation in organic liquids can be obtained at a lower point in the fatty acid series in the case of the silver than in the case of the alkali salts. Thus, silver hexoate dissolves in hot xylene and on cooling the sol will set to a weak gel, whereas potassium and sodium hexoates remain undispersed in boiling xylene.

*β-Acyl Dichlorohydrins.*

The  $\alpha$ -dichlorohydrin used was prepared by the action of fuming hydrochloric acid on epichlorohydrin.

*β-Butyryl Dichlorohydrin.*—(a) A mixture of 29.58 g. of  $\alpha$ -dichlorohydrin and 23.72 g. of butyryl chloride was, after the initial reaction had subsided, warmed at 50° to complete the reaction, moisture being excluded (loss, 7.95 g. Calc., 7.82 g.). Distillation yielded a product, b. p. 223.5°, having a fruity odour,  $n_D^{20}$  1.4540,  $d_{20}^{20}$  1.1796, saponification number 843 (Calc. for  $C_7H_{12}O_2Cl_2$ , 845.5). (b) A mixture of 23.05 g. of epichlorohydrin and 29.05 g. of butyryl chloride (ca. 10% excess) was heated under reflux for 8 hours at 75°, the entry of moisture being prevented. The twice-distilled product had b. p. 223.5°,  $n_D^{20}$  1.4540,  $d_{20}^{20}$  1.1792, saponification number 841.5. Truchot (*Compt. rend.*, 1865, 61, 1170) gives b. p. 226°/738 mm. and  $d_4^{11}$  1.194.

*β-Propionyl dichlorohydrin* was prepared in similar ways to those mentioned above, except that in (b) the mixture of epichlorohydrin and propionyl chloride was heated in a sealed tube at 135° for 3 hours. The methods gave identical products, b. p. 208°,  $d_{20}^{20}$  1.2222.

*β-Palmityl Dichlorohydrin.*—Reaction between 13.79 g. (ca. 20% excess) of  $\alpha$ -dichlorohydrin and 22.15 g. of palmityl chloride was completed by heating the mixture for 1 hour in a boiling water-bath (loss, 2.93 g. Calc., 2.94). The product, which set solid on cooling, crystallised from alcohol in white crystals, m. p. 34.4°,  $n_D^{20}$  1.4527 [Found: saponification number, 456.7; Cl, 19.2 (by saponification), 19.1 (by Carius).  $C_{15}H_{30}O_2Cl_2$  requires Cl, 19.3%; saponification number, 458.7]. Palmitic acid isolated after saponification, 68.97 (calc., 69.76%).

*β-Stearyl Dichlorohydrin.*—(a) This was prepared from  $\alpha$ -dichlorohydrin and stearyl chloride in the manner described for the preparation of  $\beta$ -palmityl dichlorohydrin. It had m. p. 39.5° and  $n_D^{20}$  1.4528 (Found: saponification number, 424.1; Cl, 17.8.  $C_{21}H_{40}O_2Cl_2$  requires Cl, 17.85%; saponification number, 426.0). Stearic acid isolated after saponification, 72.18 (calc., 71.91%). (b) 20.8 G. of stearyl chloride were heated with 6.8 g. of epichlorohydrin in a sealed tube at 130° for 3½ hours. The product, on recrystallisation from alcohol, readily yielded pure  $\beta$ -stearyl dichlorohydrin. It contained a small amount of material of low melting point and very slight solubility in alcohol, the nature of which was not investigated.  $n_D^{20}$ , 1.4530. Saponification number, 423.

*Mixed Triglycerides.*

*β-Palmitodistearin* (*β-Palmityl αα'-distearyl glyceride*).—(a) Powdered *β*-palmityl dichlorohydrin (1 mol.) and silver stearate (2 mols.) were mixed and heated either for 3 hours at 155° or for 5 hours at 135°. An ethereal extract of the product slowly deposited the fat as a pale cream, microcrystalline solid, m. p. 63·5°, and 64·8° after recrystallisation from ether; the crystals from the mother-liquor had the same melting point.  $n_D^{20}$  1·4467. Mean dispersion ( $n_F - n_C$ ), 0·00788. Saponification number, 196·2 ( $C_{55}H_{106}O_6$  requires 195·2). 1·6269 G. of the mixed silver salts prepared, by the method described earlier, from the mixed fatty acids obtained on saponification gave 0·4595 g. of silver (calc., 0·4593 g.). Freedom of the product from stearic or palmitic acid was shown by the fact that addition of silver nitrate followed by ammonia to an alcoholic solution produced no precipitate. The fat was practically insoluble in cold alcohol.

(b) The glyceride was also prepared from *β*-palmityl dichlorohydrin and silver stearate, reacting in hot phenetole for 2½ hours. The filtrate, on cooling, deposited the fat as rosettes or sheaves of needles, m. p. 64°. After recrystallisation from ether, the product agreed in melting point and saponification number with that described above.

The m. p. of *β*-palmitodistearin is given as 63° by Kreis and Hafner (*Ber.*, 1903, 36, 2766) and Bömer and Limprick (*Z. Nahr. Genussm.*, 1913, 25, 354) and as 67·1° by Amberger and Bromig (*Biochem. Z.*, 1922, 130, 252).

*β-Stearodipalmitin* (*β-stearyl αα'-dipalmityl glyceride*) was prepared from *β*-stearyl dichlorohydrin and silver palmitate by method (a). M. p. 63·3° (Amberger and Bromig, *loc. cit.*, give 59·1°). Saponification number, 202·6 ( $C_{53}H_{102}O_6$  requires 201·8).

*β-Butyrodipalmitin* (*β-Butyryl αα'-dipalmityl glyceride*).—With the aid of some ether, silver palmitate (2 mols.) and *β*-butyryl dichlorohydrin (1 mol.) were mixed. The ether was removed by warming on the water-bath, and the mixture heated at 170° for ½ hour with occasional stirring. When cold, the product was extracted with ether, silver chloride filtered off, and the ether removed. The residue was dissolved in alcohol and treated with the quantity of alcoholic potassium hydroxide necessary to neutralise the free acid present. The alcohol was then removed at 40° under reduced pressure, the residue extracted with dry chloroform, the chloroform removed, and the product recrystallised from alcohol. It then had m. p. 43·6°,  $n_D^{20}$  1·4431,  $n_D^{25}$  1·4397,  $n_D^{30}$  1·4359; saponification number, 265·6 ( $C_{41}H_{74}O_6$  requires 263·3). 100 G. of absolute alcohol at 20° dissolve 0·55 g. of *β*-butyrodipalmitin.

*$\beta$ -Palmitodibutyryn* ( *$\beta$ -Palmityl  $\alpha\alpha'$ -dibutyryl glyceride*).—An intimate mixture of  $\beta$ -palmityl dichlorohydrin (1 mol.) and silver butyrate (2 mols.) was heated at 150° for 40 minutes, being stirred at intervals. The procedure used to isolate  $\beta$ -butyrodipalmitin was then followed. It was necessary to cool the alcoholic solution in ice in order to obtain crystals. These had m. p. 17°, and 18° after recrystallisation from alcohol.  $n_D^{20}$  1.4530. Saponification number, 388 ( $C_{27}H_{50}O_6$  requires 385.1).

#### *Acid Anhydrides.*

*Propionic Anhydride*.—Silver propionate (31.8 g.) and propionyl chloride (16.25 g.) developed considerable heat on mixing. No propionyl chloride came over on distillation. The yield of the crude anhydride was 20.0 g. (88%), and on redistillation this gave 80% of pure propionic anhydride, b. p. 165°.

*Butyric Anhydride*.—(a) From silver butyrate and butyryl chloride in the manner just described, a good yield of butyric anhydride, b. p. 193°, was obtained. (b) Lachowiz's method of preparing acetic and propionic anhydrides (*Ber.*, 1884, 17, 1218; 1885, 18, 2920) gave a poorer yield of butyric anhydride than method (a). A mixture of 40 c.c. of butyryl chloride and 600 g. of powdered lead nitrate (dried at 100°) was heated on the water-bath under reflux for 2–3 hours; it was then extracted with dry benzene, and the extract distilled. By several redistillations of the fraction b. p. 165–200°, a 50% yield of butyric anhydride was obtained.

*Palmitic Anhydride*.—A mixture of 6.40 g. of palmityl chloride and 8.19 g. of silver palmitate was heated and stirred on the water-bath for 10 minutes, and, when cold, was extracted with anhydrous ether. The product, recrystallised from ether, had m. p. 62.6°. Another sample had m. p. 63.0° after recrystallisation from benzene. Saponification number, 226; *M*, cryoscopic in benzene, 402 [ $(C_{15}H_{31}\cdot CO)_2O$  requires saponification number 226.8; *M*, 394]. 100 G. of absolute alcohol at 20° dissolve 0.18 g. of palmitic anhydride.

*Stearic Anhydride*.—This was prepared from stearyl chloride and silver stearate in a similar way to that just described. After recrystallisation from ether, the substance was obtained as large, shining plates, similar in appearance to stearic acid. M. p. 70.5°. Saponification number, 202.5; *M*, cryoscopic in benzene, 540 [ $(C_{17}H_{35}\cdot CO)_2O$  requires saponification number, 203.7; *M*, 550.7]. 100 G. of absolute alcohol at 20° dissolve 0.023 g. of stearic anhydride. The solubility in ether was clearly less than that of stearic acid.

The anhydrides of palmitic and stearic acids, although very similar to the corresponding acids in melting point and appearance, are much less soluble and have higher refractive indices. The following measurements were all made with the same instrument:

*Refractive indices of some fatty acids and their anhydrides.*

Propionic acid : $n_D^{17}$ 1.3874.	Propionic anhydride : $n_D^{17}$ 1.4041.
<i>n</i> -Butyric acid : $n_D^{18}$ 1.3990.	<i>n</i> -Butyric anhydride : $n_D^{18}$ 1.4143.
Palmitic acid : $n_D^{70}$ 1.4309.	Palmitic anhydride : $n_D^{70}$ 1.4359.
Stearic acid : $n_D^{80}$ 1.4300.	Stearic anhydride : $n_D^{80}$ 1.4362.

*Esters of Palmitic and Stearic Acids.*

*Cetyl Palmitate : Cetyl Stearate.*—These were prepared by heating a mixture of the appropriate silver salt (made from a sample of the pure acid) and recrystallised cetyl iodide (m. p. 21.9°) in a boiling water-bath for  $\frac{1}{2}$  hour, with stirring at intervals. The reaction mixture was extracted with ether, silver iodide filtered off, and the ethereal solution allowed to deposit crystals. The yields were practically theoretical, and the products, which consisted of lustrous, white plates, were so pure that recrystallisation from ether or glacial acetic acid failed to change the original melting point. Saponification numbers : cetyl palmitate, 117.0 ( $C_{15}H_{31} \cdot CO_2 \cdot C_{16}H_{33}$  requires 116.7); cetyl stearate, 111.1 ( $C_{17}H_{35} \cdot CO_2 \cdot C_{16}H_{33}$  requires 110.3). Both esters were readily soluble in acetone, carbon disulphide, or chloroform, and were very soluble in benzene. Ethereal solutions were occasionally supersaturated, but crystallisation was immediately induced by touching with ice a point in the vessel.

	Cetyl palmitate.	Cetyl stearate.
Melting point .....	51.6°	56.6°
$n_D^{80}$ , $n_D^{85}$ .....	1.4429, 1.4415	—
$n_D^{70}$ .....	1.4398	1.4410
100 G. of abs. ether dissolve at 22° .....	21.01 g.	9.08 g.
"    "    "    "    0° .....	2.30 g.	0.73 g.
"    "    alcohol    "    22° .....	0.0495 g.	0.0594 g.

Turbidity temperature (Valenta test, with 2 c.c. of glacial acetic acid and 2 c.c. of ester) .....	109°	Turbid to b. p.

*Cetyl Stearate from Spermaceti.*—400 G. of a sample of spermaceti (m. p. 42–44°;  $n_D^{70}$  1.4397; turbidity temperature 77°; saponification number 125.8; iodine absorption 5.89%) were recrystallised from ether nineteen times; 2.2 g. were obtained of a product with a constant melting point of 56.6° and agreeing in saponification number, refractive index, and turbidity temperature with cetyl stearate. On the basis of determinations of the amount and melting point of the material in the mother-liquors from the successive

crystallisations, and of determinations of the melting point of artificial mixtures of cetyl palmitate and cetyl stearate, a rough estimate of the amount of cetyl stearate in the sample of spermaceti examined was made as 1.1%. A second sample of spermaceti was also examined. 1200 G. (original m. p. 41—44°) yielded, after ten crystallisations, 1.5 g. of crystals, m. p. 55.5°, having a saponification number of 111.5 (calc., 110.5) and giving cetyl alcohol (m. p. 50° after several recrystallisations from alcohol) and stearic acid (m. p. 65° after three recrystallisations from alcohol) on hydrolysis.

*Benzyl Palmitate*.—Equivalent quantities of silver palmitate and benzyl chloride were heated, with stirring at intervals, for  $\frac{1}{2}$  hour at 145°. The ester was extracted with ether and recrystallised from alcohol. M. p. 36° (compare Shonle and Row, *J. Amer. Chem. Soc.*, 1921, 43, 361).  $n_D^{20}$  1.4620. 100 G. of absolute alcohol at 16° dissolve 3.30 g.

*Benzyl stearate* was prepared similarly to benzyl palmitate. M. p. 44.3° (Shonle and Row, *loc. cit.*, give m. p. 45.8°),  $n_D^{20}$  1.4627. 100 G. of absolute alcohol at 16° dissolve 0.685 g.

*Homologous Series of Esters*.—The esters the physical constants of which are recorded in the following table were prepared from the appropriate silver salt and alkyl halide. In the case of methyl stearate, ethyl palmitate, and ethyl stearate a mixture of equivalent amounts of the silver salt and the alkyl iodide was gradually heated in xylene to 100° and maintained at that temperature for about 10 minutes. Silver iodide was filtered off, and washed with hot xylene. The xylene solution was, if necessary, concentrated under reduced pressure, the ester allowed to crystallise, and then recrystallised from alcohol to a constant melting point.

Palmitate.	M. p.	$n_D^{50}$ .	$n_D^{78}$ .	Saponification number.	
				Found.	Calc.

n-Octyl .....	31.8	1.4373	1.4300	143	141.5

In the case of the other esters listed, with the exception of the cetyl esters, reaction was brought about by heating a mixture

of equivalent quantities of the silver salt and the alkyl iodide alone, without xylene, for  $1\frac{1}{2}$  hours at  $100^\circ$ . The product was extracted with hot alcohol. In the case of the octyl esters a mixture of the silver salt and octyl bromide was heated for  $2\frac{1}{2}$  hours at  $130$ – $140^\circ$ .

Both in the palmitate and in the stearate series the melting point reaches a minimum in the *n*-butyl esters, but the refractive index increases continuously.

McGILL UNIVERSITY, MONTREAL.

CXCI.—*The Conditions underlying the Formation of Unsaturated and Cyclic Compounds from Halogenated Open-chain Derivatives. Part VIII. Products derived from Pimelic Acid. An Application of Bischoff's Dynamic Hypothesis.*

By ALBERT HASSELL and CHRISTOPHER KELK INGOLD.

IN general, the action of alkalis on the  $\alpha$ -halogen derivatives of dibasic acids proceeds in three ways. Thus, monobromoglutaric acid yields a hydroxy-acid (I), a ring-acid (II), and an unsaturated acid (III), in addition to substances derived from the decomposition of these.

If the quantity of unsaturated acid formed is small, the reaction may be regarded as a competition between hydroxylation and ring-formation, and may be used to estimate the relative ease of ring-formation in the different cases. This method has been applied to a number of glutaric and adipic acids, with results explicable on the assumption that the volumes of groups attached to a central carbon atom determine the inclination of its valencies and the consequent tendency of that atom to participate in a ring of given type (Ingold, J., 1921, 119, 305, and later).

The halogen derivatives of pimelic acid have now been investigated, and, despite the fact that in this case there are difficulties in the way of a precise numerical comparison, the general results accord with the hypothesis. The ring formed is a five-membered one, and the ratio (ring-formation) : (hydroxylation) is much greater than in any case previously investigated.

In the case of the  $\alpha\alpha'$ -dihalogen-adipic esters (IV), concentrated

alkalis gave a small quantity of a *cyclobutene* acid (VI), and a considerable amount of muconic acid (VII) and of the hydroxy-acids (V).

When  $\alpha\alpha'$ -dibromopimelic ester (VIII) was examined, a greatly increased tendency to ring formation was noticed. Under various conditions, a considerable proportion of the material was transformed into the *cyclopentene* acid (IX), although this acid did not always survive the conditions of its formation. When concentrated alkalis were employed, a second principal reaction gave rise to a doubly-unsaturated open-chain acid (X) (see below); the question as to whether this undergoes subsequent isomeric change is discussed below. So far as could be ascertained, dihydroxypimelic acids were not produced.

The constitution of the ring-acid (IX) follows from its identity with the acid synthesised by Haworth and Perkin (J., 1894, 65, 978) from the saturated *cyclopentane* acid (XI), the dibromo-ester (XII) of which, on treatment with potassium iodide, yielded the ester (XIII):

In the presence of concentrated alkalis, the unsaturated ring-acid (IX) undergoes change into the isomeric acid (XIV), the reaction being analogous to the conversion of citraconic acid into itaconic acid, and of  $\Delta^1$ -tetrahydrophthalic acid into the  $\Delta^2$ -acid. The change is not complete, and definite evidence of its reversibility has been obtained. At the same time, a small amount of the saturated hydroxy-ring acid (XV) is produced.

It is noteworthy that whereas the *cyclopropane* hydroxy-ring acid (XVI) is quantitatively converted into the isomeric ketoglutaric acid (XVII) by alkalis (Ingold, *loc. cit.*), the hydroxycyclopentane acid (XV) shows no tendency to pass into  $\alpha$ -ketopimelic acid

(XVIII). The two cases evidently represent the two limiting conditions of the keto-cyclol change.

Although formula (X) must represent the structure of the unsaturated open-chain acid initially produced from dibromopimelic ester, it is possible that this acid changes into the isomeride (XIX) under the conditions of the experiment. It is known that under these conditions  $\alpha\beta$ -unsaturated acids readily come into equilibrium with their  $\beta\gamma$ -unsaturated isomerides, and in this case the  $\beta\gamma$ -compound possesses a conjugated system from which it might be expected to derive sufficient stability to render the isomeric change practically non-reversible. The acid appears to be identical with the "piperylenedicarboxylic acid" obtained by Willstätter (*Ber.*, 1895, 28, 3287) by the exhaustive methylation of tropinic acid (XX):

These reactions do not, of course, prove the structure, but the tendency to the production of conjugated systems by the exhaustive methylation process is well known, and is illustrated by the exhaustive methylation of piperidine.

A remarkable reaction, which has not been observed in any of the shorter-chain series previously investigated, is that which leads to the formation of considerable quantities of the meso- and racemic forms of the dimethoxy-acid  $\text{CO}_2\text{H} \cdot \text{CH}(\text{OMe}) \cdot [\text{CH}_2]_3 \cdot \text{CH}(\text{OMe}) \cdot \text{CO}_2\text{H}$  when methyl-alcoholic potassium hydroxide is employed as the hydrolysing agent. Although the occurrence of this reaction creates difficulties when the attempt is made to extend to the pimelic acid series the method of numerical comparison previously employed, it is in accord with the view that the conditions governing all these reactions are essentially spatial; for whereas steric influences would prevent the accumulation of as many as four bulky groups ( $2\text{MeO}$  and  $2\text{CO}_2\text{H}$ ) in 1:5- and 1:6-positions, there is no obstacle in the way of their occupying 1:7-positions, and hence this reaction is not encountered in the glutaric and adipic acid series, and is met with for the first time in the pimelic acid series. It may be predicted that the occurrence of this reaction, under the conditions specified, will be found to be a peculiarity of the higher series, and that it will be prominent in the suberic and azelaic acid series.

## EXPERIMENTAL.

Pimelic acid was prepared by hydrolysis of the ethyl pentane-tetracarboxylate produced from ethyl sodiomalonate and  $\alpha$ -dibromopropane. It was dibrominated in the form of its chloride, and the dibromo-chloride converted into ethyl dibromopimelate, which was treated with 6*N*-methyl-alcoholic potassium hydroxide, as in the previous investigations of this series. The acid product, a pale yellow syrup, was dissolved in water, neutralised with ammonia, and a concentrated aqueous solution of lead acetate was added in four or five successive portions until no further precipitation occurred, the solutions being kept cold throughout. The various fractions of lead salt were collected separately and decomposed with a small excess of dilute sulphuric acid, the filtrates from the lead sulphate being concentrated in a vacuum and extracted with ether. The acid regenerated in this way from the first fraction of lead salt solidified almost completely, and some of the intermediate fractions, on being seeded with the solid and kept for some weeks, deposited crystals. These fractions were then again submitted to the fractional precipitation of lead salts, and some further crops of crystalline acid were thus obtained.

*Piperylenedicarboxylic Acid (XIX).*—The solid acid, after two crystallisations from ether, melted at 169° (Found : C, 53.7; H, 5.3.  $C_7H_8O_4$  requires C, 53.8; H, 5.1%), and corresponded closely in its properties with the acid obtained by Willstätter by exhaustive methylation of tropinic acid. The yield of purified material was 6.2% of the theoretical. The tetrabromide melted with decomposition at 217° (Found : Br, 67.0. Calc. : Br, 67.2%).

On oxidation with eight atoms of available oxygen in the form of 4% permanganate at the ordinary temperature, a small amount of malonic acid and much oxalic acid were obtained. On reduction by a large excess of sodium amalgam in boiling aqueous solution, a semi-solid product was obtained from which pimelic acid was isolated by draining and crystallisation from ether.

*cycloPentanol-1 : 2-dicarboxylic Acid (XV).*—The syrupy acids recovered from the lead salts, together with those obtained from the aqueous filtrates by extraction with ether after acidification, and desiccation over potassium hydroxide to remove acetic acid, were dissolved in ether and extracted with successive small quantities of water. The first extract, on evaporation in a vacuum, gave a residue which in course of time partly solidified. The remaining extracts gave syrups. The solid was drained (5.5% unpurified) and crystallised from acetone-benzene, from which it separated in small prisms, m. p. 159–160° (Found : C, 48.6; H, 5.8.  $C_7H_{10}O_5$  requires C, 48.2; H, 5.7%).

The *silver* salt was prepared from the neutral ammonium salt (Found: Ag, 55.5.  $C_7H_8O_5Ag_2$  requires Ag, 55.7%).

The *ethyl* ester was prepared by boiling the silver salt with ethyl iodide in ether solution; b. p. 168—171°/10—11 mm. (Found: C, 57.1; H, 7.8.  $C_{11}H_{18}O_5$  requires C, 57.4; H, 7.8%). On heating with acetic anhydride in a sealed tube at 180°, an oil was obtained which, on hydrolysis by hydrochloric acid, gave *cyclopentene-1:2-dicarboxylic acid*, m. p. 178°.

$\Delta^1$ -*cyclopentene-1:2-dicarboxylic Acid* (IX).—The syrupy residues from the ethereal and the various aqueous solutions obtained in the preceding separation were combined and esterified with ethyl alcohol and sulphuric acid. The esters, after several distillations, yielded a fraction, b. p. 146°/11 mm., which was hydrolysed by boiling with hydrochloric acid under a condenser sufficiently short to permit the escape of alcohol vapour. On evaporation of the aqueous solution, a solid product was obtained, which melted indefinitely at 140—150°, and after several crystallisations from water yielded a small quantity of the  $\Delta^1$ -*cyclopentene acid*, which was identified by analysis (Found: C, 53.9; H, 5.1. Calc.: C, 53.8; H, 5.1%) and by a mixed melting point determination.

$\Delta^2$ -*cyclopentene-1:2-dicarboxylic Acid* (XIV).—This acid appears to be the main constituent of the mixture, m. p. 140—150° (19% of the theoretical yield), but the separation of the last traces of the 178°-acid necessitates several alternate crystallisations from water and ethyl acetate. This acid is very much more soluble in water than the  $\Delta^1$ -isomeride; it separates from water or ethyl acetate in small prisms, m. p. 146—147° (Found: C, 53.5; H, 5.1.  $C_7H_8O_4$  requires C, 53.8; H, 5.1%).

*2:3-Dibromocyclopentane-1:2-dicarboxylic acid* was obtained when the  $\Delta^2$ -acid was exposed to bromine vapour for several days. The product, after being freed from bromine, was crystallised twice from glacial formic acid, from which it separated in small, dense prisms, which decompose with much frothing at 165° (Found: Br, 50.4.  $C_7H_8O_4Br_2$  requires Br, 50.6%).

On heating for a few minutes with boiling 64% aqueous potassium hydroxide, both the  $\Delta^1$ - and  $\Delta^2$ -*cyclopentene acids* yield a mixture consisting mainly of the  $\Delta^2$ -acid, along with a small amount of the  $\Delta^1$ -acid. In one experiment, starting with the  $\Delta^1$ -acid, a small amount of the hydroxy-ring acid was also isolated. The method of separation of these mixtures was substantially the same as that already described.

*Ethyl  $\alpha\alpha'$ -Dimethoxypimelate*.—In the distillation of esters (above) a large fraction (35% of the theoretical yield) was obtained, b. p. 160—175°/10 mm. This consisted essentially of a mixture of the

meso- and racemic forms of the dimethoxy-ester, and the central fraction, b. p. 166—169°/10 mm., gave correct figures on analysis (Found: C, 56·8; H, 8·7.  $C_{13}H_{24}O_6$  requires C, 56·5; H, 8·7%).

Both the central fraction and the main fraction (the former, b. p. 166—169°/10 mm., and the latter, b. p. 160—175°/10 mm.), on hydrolysis by means of hydrochloric acid, gave a syrupy acid which could not be induced to crystallise, although it yielded a silver salt having the correct silver content for the dimethoxy-compound (Found: Ag, 50·2.  $C_9H_{14}O_6Ag_2$  requires Ag, 49·8%). It was therefore digested with a small excess of pure thionyl chloride until sulphur dioxide ceased to be evolved, and after the excess of reagent had been removed at 100°, the acid chloride was treated with dry ammonia in ether solution. This process yielded a mixture of two crystalline amides.

The esters, b. p. 160—175°/10 mm., were mixed with concentrated aqueous ammonia (3 vols.), and the mixture was shaken frequently until it became homogeneous (3—6 days).

*αα'-Dimethoxypimelamide (A-form).*—This amide crystallised practically completely from the aqueous ammonia solution. It melted at 209—210°, and after one crystallisation from water was obtained pure, as prisms, m. p. 212°. The mixture of amides obtained from the ethereal ammonia solution yielded the A-amide in a pure condition after two crystallisations from water (Found: C, 49·2; H, 8·3.  $C_9H_{18}O_4N_2$  requires C, 49·5; H, 8·3%). The amide is readily soluble in hot water, sparingly soluble in cold, fairly easily soluble in methyl or ethyl alcohol or acetone, and almost insoluble in ethyl acetate, chloroform, or benzene.

*αα'-Dimethoxypimelamide (B-form).*—The ammonia solution from the esters, after the A-amide had been collected, was evaporated on the water-bath until, on cooling, it set to a stiff paste of crystals, which were drained on porous porcelain and crystallised from water and ethyl acetate; the compound separated in fluffy balls of minute needles, m. p. 167°. The aqueous solution from the decomposition of the acid chlorides, after the A-amide had been removed, was evaporated to dryness, and the residue extracted from the ammonium chloride with boiling ethyl acetate, from which, on concentration and cooling, the B-amide separated almost pure. It was crystallised from ethyl acetate (Found: C, 49·3; H, 8·2%). This amide is extremely soluble in hot water and very easily soluble in cold; it is fairly easily soluble in hot ethyl acetate, but almost insoluble in cold; it is easily soluble in acetone or methyl or ethyl alcohol, but insoluble in chloroform or benzene.

*αα'-Dimethoxypimelic Acid (A-form).*—A solution of the A-amide (1 g.) in 10 c.c. of concentrated sulphuric acid was treated between

0° and 5° with a strong aqueous solution of 0.6 g. of sodium nitrite delivered by a fine capillary tube dipping beneath the liquid, the addition occupying about 1.5 hours, during which the mixture was continually stirred. The solution was poured into water and extracted with ether, from which the A-acid was obtained as a clear gum (Found: C, 49.0; H, 7.3.  $C_9H_{16}O_6$  requires C, 49.1; H, 7.3%. Found for the *silver* salt: Ag, 49.6.  $C_9H_{14}O_6Ag_2$  requires Ag, 49.8%).

*αα'-Dimethoxypimelic Acid* (B-form).—This acid was prepared similarly from the B-amide and had similar properties (Found: C, 49.1; H, 7.4%. Found for the *silver* salt: Ag, 49.5%).

We desire to record our thanks to the Royal Society for a grant, with which part of the expense of this investigation has been met.

## CXCII.—*The Conditions underlying the Formation of Unsaturated and Cyclic Compounds from Halogenated Open-chain Derivatives. Part IX. Products derived from Suberic and Azelaic Acids.*

By FRANK ROBERT GOSS and CHRISTOPHER KELK INGOLD.

ACCORDING to the hypothesis underlying this series of investigations, the action of concentrated methyl-alcoholic alkali on ethyl  $\alpha\alpha'$ -dibromosuberate should pursue a course similar to that observed in the pimelic acid series.

The bromination of suberic acid has been investigated by Gauthier, Hell, and Rempel (*Ber.*, 1882, 15, 149; 1885, 18, 814), who isolated a dibromo-acid of m. p. 173°.  $\alpha\alpha'$ -Dibromosuberic acid (I) should exist in meso- and racemic modifications, and a second form, m. p. 118–120°, has now been isolated. Both forms are produced together in the ordinary Hell-Volhard process of bromination, the less fusible acid in the greater quantity.

It appears impossible at present to assign configurations to these two acids, because, on treatment with dilute alkalis, both yield the same  $\alpha\alpha'$ -dihydroxysuberic acid (II), so that in one case or the other an inversion must occur at one of the two asymmetric carbon atoms.

By the action of alcoholic alkali on the less fusible dibromo-acid, Hell and Rempel (*loc. cit.*) obtained an acid,  $C_8H_{10}O_4$ , which

they termed "suberocolic acid," but they were unable to ascertain whether it was a doubly unsaturated open-chain acid (III) or a cyclohexene acid such as (IV). It has now been found that the acid has an open-chain structure, for, on partial reduction, it forms a dihydro-derivative which is still unsaturated, and on vigorous reduction gives suberic acid.

The acids (IV) and (V) are, however, produced along with (III) when ethyl dibromosuberate is treated with concentrated alkalis under the conditions described in the experimental part of this paper. It is probable that (IV) is the first product, although it changes into (V) to a large extent under the conditions employed in its formation.

The cyclic acids had previously been prepared by the reduction of benzene derivatives, and Baeyer observed the conversion of (IV) into (V) by the action of alkalis (*Annalen*, 1890, 258, 209). He appears, however, to have regarded the change as complete, whereas, actually, the action is a balanced one, the acid (V) undergoing limited conversion into (IV) under identical experimental conditions.

When methyl-alcoholic alkali is used, considerable quantities of the meso- and racemic forms of the dimethoxy-acid

are produced in agreement with the prediction made in the preceding paper.

The general rules deduced in the preceding parts of this series suggest that the principal product of the action of concentrated methyl-alcoholic alkali on ethyl  $\alpha\alpha'$ -dibromoazelate (VII) should be the dimethoxy-acid (VIII) (in which the methoxyl groups occupy 1:9-positions) and that the by-products, if any, should consist of the dihydroxy-acid (IX) and the unsaturated acid (X). Further, it is not to be expected that cycloheptane ring closure would take place to any considerable extent, although some might occur, as in the cyclobutane series (Part II); an acid of constitution (XI) (if formed) might pass into its open-chain ketonic isomeride (XII).

The experiments now described show that under the conditions of hydrolysis which have been uniformly employed during these investigations the dibromo-ester (VII) is converted to the extent of at least 80% into a mixture of meso- and racemic methoxy-acids of formula (VIII) in striking agreement with the conclusions summarised in the preceding paper. Considerable difficulty was experienced in isolating the by-products of the reaction, but the dihydroxy-acid (IX) was obtained as a mixture of meso- and racemic isomerides, and an unsaturated acid, which may have been (X), was present. The production of the ring-acid (XI) could not be established with certainty, but an acid which appears to have the open-chain ketonic structure (XII) was isolated.

#### EXPERIMENTAL.

Suberic acid was prepared from castor oil, as described by Baker and Ingold (J., 1923, 123, 128).

*αα'-Dibromosuberic Acid (A-form).*—Suberic acid (60 g.) was warmed with 60 c.c. of thionyl chloride until sulphur dioxide ceased to be evolved, and the product treated on the steam-bath with 45 c.c. of bromine, added gradually to keep pace with the absorption. The product was poured into absolute formic acid and boiled until carbon monoxide ceased to be evolved; on cooling, 60 g. of the dibromo-acid, m. p. 160–170°, separated. After two crystallisations from water, this acid melted at 172–173° (Found: Br, 48.3. Calc.: Br, 48.2%).

*αα'-Dibromosuberic Acid (B-form).*—The formic acid mother-liquors were evaporated, and the pasty residue was drained on porous porcelain, and extracted with boiling chloroform until the m. p. of the undissolved portion rose above 160°. (This, after crystallisation from water, yielded a further 6 g. of the A-acid.) The residue from the chloroform solution was drained and crystallised several times from the same solvent; 20 g. of B-acid, m. p. 120–121°, were thus obtained (Found: Br, 48.0.  $C_8H_{12}O_4Br_2$  requires Br, 48.2%).

*Ethyl αα'-Dibromosuberate.*—Suberic acid (60 g.) was brominated as before, and the product poured into ethyl alcohol. The ester was extracted with ether after the addition of water, washed with dilute sodium carbonate solution, and distilled. It boiled constantly at 230°/31 mm., the yield being almost theoretical (Found: Br, 41.0.  $C_{12}H_{20}O_4Br_2$  requires Br, 41.2%).

*αα'-Dihydroxysuberic Acid.*—This substance is formed when either the A- or the B-form of αα'-dibromosuberic acid is boiled with 2N-aqueous sodium carbonate. The product, which is extracted with ether after acidification, is purified through the barium salt,

and thus obtained as a colourless gum which sets to a hard, crystalline mass, m. p. 166—168°, during the course of several months (Found: C, 46·8; H, 6·8.  $C_8H_{14}O_6$  requires C, 46·6; H, 6·8%).

*Suberocolic Acid*.—Ethyl  $\alpha\alpha'$ -dibromosuberate was treated with 6*N*-methyl-alcoholic potassium hydroxide under conditions comparable with those used in the previous investigations of this series. The cooled product was mixed with an equal volume of absolute ethyl alcohol, and the insoluble salts were collected, washed with ethyl alcohol, drained, dissolved in the minimal amount of water, and decomposed with concentrated hydrochloric acid. The sparingly soluble acid thus obtained was crystallised from boiling water (100 parts), from which it separated in branched needles, m. p. 253° (decomp.)—a considerably higher m. p. than that recorded by Hell and Rempel (Found: C, 56·5; H, 5·9. Calc.: C, 56·5; H, 5·9%). The yield was 11% of the theoretical.

*Oxidation of Suberocolic Acid*.—On oxidation with alkaline permanganate, suberocolic acid gives (as it should) succinic and oxalic acids, but not in the expected yields. In one experiment, 0·8 g., on treatment with 140 c.c. of 3% permanganate (7 atoms of available oxygen), gave 0·5 g. of calcium oxalate (theory, 1·2 g.) and 0·3 g. of succinic acid (theory, 0·55 g.).

*Reduction of Suberocolic Acid*.—The acid (0·5 g.) was reduced with 30 g. of 4% sodium amalgam on the steam-bath during 3 hours. After the mercury had been removed, the solution was acidified and extracted with much ether.

*Dihydrosuberocolic Acid (A-form)*.—The residue from the ether, after draining on porous porcelain, melted at 125—160°. After twice crystallising from water, small rosettes of needles were obtained, m. p. 170° (Found: C, 55·6; H, 7·0.  $C_8H_{12}O_4$  requires C, 55·8; H, 7·0%). The acid instantly decolorises cold alkaline permanganate, and on vigorous reduction (see below) yields suberic acid.

*Dihydrosuberocolic Acid (B-form)*.—This acid is formed along with suberic acid when suberocolic acid is reduced by boiling an aqueous solution with 50 g. of 4% sodium amalgam, added gradually during 4 hours. It separates from water in needles, m. p. 125° (Found: C, 55·7; H, 7·0%). The acid instantly decolorises cold alkaline permanganate, and on prolonged boiling with water and sodium amalgam yields suberic acid.

Suberic acid was separated from the B-form of dihydrosuberocolic acid by fractional crystallisation from hot water, and was identified by analysis (Found: C, 55·1; H, 8·0. Calc.: C, 55·2; H, 8·0%) and by comparison with a genuine specimen.

*$\Delta^2$ -cyclohexene-1:2-dicarboxylic Acid*.—The aqueous filtrate

from the suberocolic acid was extracted with ether, the residue obtained on evaporating the ether was rubbed with water, and the filtered solution evaporated in a vacuum. The residue obtained on evaporating the alcoholic solution with water was extracted with ether after acidification, and the residue from the concentrated and filtered ethereal solution was fractionally crystallised from ether. The combined residues were evaporated with water on the water-bath, and the crystals obtained after partial esterification of the residue were crystallised from water and identified by their properties, by analysis (Found: C, 56.3; H, 6.0. Calc.: C, 56.5; H, 5.9%), and by the m. p. of the anhydride (74°) prepared from them.

*Δ<sup>2</sup>-cycloHexene-1:2-dicarboxylic Acid*.—The acids separated by means of water contained this cyclohexene acid and suberocolic acid, which were separated by fractional crystallisation from water. The combined residues from the other ethereal and aqueous solutions were boiled with acetyl chloride for a short time, and the residue obtained by vacuum desiccation over potassium hydroxide was dissolved in ether and washed with sodium carbonate solution. The residue from the ether was dissolved in boiling water, from which the cyclohexene acid (4.7%) was obtained in a pure condition by evaporation and three crystallisations from water. It was identified by its properties, by analysis (Found: C, 56.4; H, 6.0. Calc.: C, 56.5; H, 5.9%), and by conversion into the anhydride of the *Δ<sup>1</sup>*-acid, as described by Baeyer (*loc. cit.*).

*αα'-Dimethoxysuberic Acid (A-form)*.—The sodium carbonate washings, on acidification and extraction with ether, yielded a mixture of acids which was separated into two fractions by boiling with ether. The sparingly soluble portion crystallised from a small amount of water in leaflets or rosettes of small needles (yield 20.4%), m. p. 145–146° (Found: C, 51.0; H, 7.6. C<sub>10</sub>H<sub>18</sub>O<sub>6</sub> requires C, 51.3; H, 7.7%).

*αα'-Dimethoxysuberic Acid (B-form)*.—On subjecting the more soluble fraction to repeated fractional crystallisation, from ether and water alternately, a further quantity of A-acid was obtained, whilst the B-acid became concentrated in the mother-liquors, partly on account of its greater solubility, and partly because of its much slower speed of crystallisation. It was finally obtained (2.8%) as rosettes of needles, m. p. 117–118° (Found: C, 51.7; H, 7.6%).

*Azelaic acid* was prepared by the oxidation of ricinoleic acid, as described by Baker and Ingold (J., 1923, 123, 128), and dibrominated in the form of its acid chloride. The dibromo-ester prepared from the dibromo-chloride was hydrolysed with 6*N*-methyl-alcoholic potassium hydroxide, as described in the earlier investigations of

this series. The acid product, a yellow syrup, was treated in various ways in the hope of inducing crystallisation, but without success, and it was therefore esterified with ethyl alcohol, and the ester carefully fractionated under reduced pressure, through a short column. After four distillations, the following fractions were obtained :

	(i).	(ii).	(iii).	(iv).	(v).	Residue.
B. p./30 mm. ...	198—205°	205—218°	218—221°	221—240°	240—260°	260°
Wt. (g.) ...	5.2	7.9	125.3	6.9	4.4	6.0
G./degree	0.7	0.6	41.8	0.4	0.2	—

*αα'-Dimethoxyazelaic Acid* (II).—The main fraction (iii), b. p. 218°/30 mm., on redistillation boiled mainly at 218—219°/30 mm. (Found: C, 58.9; H, 9.3. *Ethyl dimethoxyazelate*,  $C_{15}H_{28}O_6$ , requires C, 59.2; H, 9.2%). Both the main fraction and the central fraction gave on hydrolysis by hydrochloric acid a liquid mixture of the *meso*- and racemic forms of *αα'-dimethoxyazelaic acid* (Found: C, 52.8; H, 8.4.  $C_{11}H_{20}O_6$  requires C, 53.2; H, 8.0%), which, even after purification through the *silver* salt (Found: Ag, 46.5.  $C_{11}H_{18}O_6Ag_2$  requires Ag, 46.8%), could not be induced to solidify, and was therefore digested with thionyl chloride until sulphur dioxide ceased to be evolved. After the excess of thionyl chloride had been removed in a vacuum at 100°, the acid chloride was dissolved in ether and treated with dry ammonia; a crystalline precipitate, which, however, was a mixture of isomerides, was then obtained. Repeated crystallisation from water yielded one of the individuals in a pure condition as small plates, m. p. 164—165° (Found: C, 54.0; H, 8.6.  $C_{11}H_{22}O_4N_2$  requires C, 53.7; H, 8.8%). The same *αα'-dimethoxyazelamide* was obtained by digesting the ester with aqueous ammonia (*d* 0.880) for a month. Stellate clusters of crystals were formed which, after two crystallisations from water and one from ethyl acetate, gave small plates identical with the above. The more soluble isomeride could not be isolated in a pure condition: Crystals of the correct composition, having m. p. 143—146°, were obtained, but as in the course of numerous crystallisations small amounts of the amide, m. p. 164—165°, were obtained from them, they were concluded to be a difficultly separable mixture.

*αα'-Dihydroxyazelaic Acid* (III).—Fractions (iv) and (v) obtained in the above preparation were combined with corresponding fractions in three similar experiments and fractionally distilled four times. *Ethyl αα'-dihydroxyazelate*, b. p. 235—240°/16 mm., was thus obtained (3.7 g.) (Found: C, 56.9; H, 8.9.  $C_{13}H_{24}O_6$  requires C, 56.5; H, 8.7%). The *acid* obtained from it by hydrolysis with hydrochloric acid was a clear syrup which did not solidify, and from which no crystalline amide could be prepared (Found: C, 49.4; H, 7.7.

$C_9H_{16}O_6$  requires C, 49.1; H, 7.3%. Found for the *silver salt*: Ag, 49.7.  $C_9H_{14}O_6Ag_2$  requires Ag, 50.2%.

*$\alpha$ -Ketoazelaic Acid (VI).*—Fractions (i) and (ii) obtained in the preceding preparations gave on hydrolysis with mineral acids a syrupy acid which instantly decolorised cold alkaline permanganate, but the only crystalline products which could be obtained from it had not this property. Fractional distillation of the esters yielded no fraction of constant boiling point, and treatment with ammonia gave an impure mixture of amides from which only the dimethoxy-amide described above could be isolated. By hydrolysis of a fraction, b. p. 198—205°/23 mm., however, an acid was obtained which partly solidified after several months. On crystallisation from ether, rosettes of needles, m. p. 175°, were obtained (Found by micro-analysis: C, 53.5, 53.7; H, 7.1, 7.1.  $C_9H_{14}O_5$  requires C, 53.4; H, 7.0%). The amount obtained (0.05 g.) was insufficient for a detailed examination, but since the substance resembled  $\alpha$ -keto-glutaric acid in giving a dull reddish-brown colour with ferric chloride, it is believed to be  $\alpha$ -ketoazelaic acid, and not the isomeric hydroxycycloheptane acid.

We desire to record our thanks to the Royal Society for a grant with the aid of which some of the expense of this investigation has been defrayed.

### CXCIII.—*The Mechanism of Tautomeric Interchange and the Effect of Structure on Mobility and Equilibrium. Part I. The Three-carbon System.*

By CHRISTOPHER KELK INGOLD, CHARLES WILLIAM SHOPPEE, and JOCELYN FIELD THORPE.

It has been shown (Birch, Kon, and Norris, J., 1923, **123**, 1361; Birch and Kon, *ibid.*, p. 2440; Kon and Linstead, J., 1925, **127**, 616, 815) that the mobility of the three-carbon system, which reaches a maximum in glutaconic esters (Type I), is also exhibited to a more limited degree in  $\alpha\beta$ - and  $\beta\gamma$ -unsaturated esters (Type II), in which only one terminal carbethoxyl group is present, and in analogous unsaturated ketones and nitriles. This paper deals with the general question of the influence of substituents on tautomeric mobility, and includes a study of the case in which,

in addition to one terminal carboethoxyl group, a second carboethoxyl group is attached to the central atom of the three-carbon system (Type III).

A noteworthy contrast between systems (I) and (II) is that, whilst compounds of type (I) (glutaconic esters) usually attain equilibrium in the absence of an added reagent so that the isomeric forms cannot be isolated as distinct individuals, substances belonging to type (II) frequently require the addition of an alkaline catalyst, such as alcoholic sodium ethoxide, to bring about interconversion of the forms. Type III is found to resemble type II in this respect; on the other hand, there are important differences between these two types in the general character of the equilibria to which they attain.

Citraconic and itaconic esters (IV and V) belong to type III, and they can, of course, be obtained as distinct individuals. There are, however, definite indications of their interconvertibility in the presence of alcoholic sodium ethoxide. Thus Hope found (J., 1912, 101, 894) that if citraconic ester were treated with ethyl sodiomalonate in ether or benzene, the normal addition compound (VI) was formed; whereas if he used alcohol as solvent, an isomeric ester (VII) was obtained, which could also be prepared directly from itaconic ester.

A re-examination of this reaction has shown that *both* the ester (VI) and its isomeride (VII) are formed from either citraconic or itaconic ester under a considerable variety of conditions, *e.g.*, by treatment with an equivalent or a large excess of sodium ethoxide in cold or in hot ethyl alcohol, or with sodium in boiling benzene. Under other conditions, only one isomeride could actually be isolated in the pure condition, the formation of the other being established by the production of derivatives.

These experiments, a fuller account of which is given below,

strongly emphasise the suggestion that citraconic and itaconic esters are tautomeric in the presence of sodium ethoxide, just as are the esters (and nitriles, etc.) of type II previously discussed. Hope, however, advanced the opinion that the interconversion in the presence of sodium ethoxide might take place through the adding on and splitting off of alcohol in accordance with the following scheme, and he succeeded in isolating an ethoxy-derivative to which formula (VIII) was assigned.

This view has, of course, the same mechanical simplicity as other "adding on and splitting off" theories of isomeric change, and it is necessary to explain why we regarded it as improbable. First it has been shown (E. H. Ingold, J., 1925, 127, 469) that although, in reversible addition reactions, fission corresponding with addition in the direction favoured by polar influences is in general readily effected, yet fission corresponding with addition in a non-favoured direction takes place with difficulty or not at all. The conversion of (VIII) into (V), involving as it does the removal of a  $\beta$ -ethoxyl group along with an  $\alpha$ -hydrogen atom, would be a fission of the latter class, and would certainly not take place under the experimental conditions employed. Secondly, in all alcohol-additions to unsaturated esters, the ethoxyl group takes up the same position as does the  $-CH(CO_2Et)_2$  group in the corresponding additions of ethyl malonate. Hence, regarding the malonic ester addition products (VI) and (VII) as derived from (IV) and (V), respectively, we see that if citraconic ester formed an ethoxy-compound it should have formula (IX), whilst if itaconic ester gave one it should have formula (X); and either of these on losing alcohol would, of course, pass back into the ester from which it was derived. Thus, not only would an ester of constitution (VIII) not be formed, but, even if it were, it would not undergo the changes which it was invented to explain.

Proof that Hope's ethoxy-ester has in reality formula (X) was obtained by converting the corresponding ethoxy-acid (XI) with hydrobromic and hydriodic acids into the bromo-acid (XII) and the iodo-acid (XIII), respectively, and into the lactone (paraconic acid) of the hydroxy-acid (XIV), all of which were identified by comparison with specimens synthesised for the purpose. The isomeric bromo- and hydroxy-acids corresponding with the ethoxy-esters (VIII) and (IX) are known and their m. p.'s and properties

are such that they could not be confused with the substances obtained.\*

Thus, there is no evidence that an ethoxy-ester intervenes in the conversion of citraconic ester into itaconic ester; on the contrary, itaconic ester obviously must intervene in the conversion of citraconic ester into the ethoxy-ester obtained; and, naturally, the same ethoxy-ester can be obtained from itaconic ester directly.

Our view of the effect of sodium ethoxide and other alkaline reagents in promoting the interconversion of these and the other three-carbon tautomerides is best made clear by reference to a recent paper by Holmes and Ingold (this vol., p. 1305), in which it is shown that a hydrogen atom attached to a hydrocarbon radical may be extracted in the form of its ion (that is, the nucleus only) by the action of a powerful negative ion such as hydroxyl, and that this process is facilitated if the hydrogen atom is already in a state of *incipient* ionisation owing to the presence in the molecule of a group (electron-sink) which exerts a pull on the electrons involved in binding the hydrogen atom. Now the carbethoxyl group, like all groups which are *m*-directive in aromatic substitution, is regarded as a powerful electron-sink (compare Allen, Oxford, Robinson, and Smith, this vol., p. 401; Ingold and Ingold, *ibid.*, p. 1310), and hence the "mobile hydrogen atom" in citraconic and itaconic ester, and in similar pairs of three-carbon tautomerides, may be assumed to be in a state of incipient ionisation owing to small electron displacements in the directions

The former scheme is precisely similar to that given by Ingold and Ingold for *m*-substitution in the benzene ring (*loc. cit.*, Case 2, p. 1312). The conditions under which the isomeric change may occur will now depend entirely on the extent to which this preliminary loosening of the potential hydrogen ion has taken place.

\* Dr. Hope, to whom these data were privately communicated, is in complete agreement with the structural conclusions.

† For explanation of symbols, see Ingold and Ingold, *loc. cit.*, p. 1312, footnote.

If incipient ionisation is considerable, mere loose combination with neutral solvent molecules (ordinary hydrion solvation) will be sufficient to draw the hydrogen nucleus away. If, on the other hand, it is slight, the more powerful attraction of a negative ion will be required to effect removal, and it is in this way, we believe, that sodium ethoxide, a source of negative ethoxyl ions, acts in facilitating the interconversion of three-carbon tautomerides. As the hydrogen nucleus is drawn away, so the electron displacements, originally minute, are enabled to progress in the sense of formulæ (XV) and (XVI), until, when ionic dissociation is complete, the displacement also is complete, the negative ionic charge appearing on the oxygen atom; thus (XV) and (XVI) give the common ion (XVII).

The second half of the process, the recombination of the negative ion (XVII) with hydrion, is similarly comparable with *op*-substitution, the ion (XVII) corresponding in structure with a phenoxide ion (*loc. cit.*, Case I, p. 1312). In each of these ions there is assumed to be a weak tendency towards a return of the electrons, giving (in different electromeric phases) small negative charges in the  $\alpha$ - and  $\gamma$ - (or *o*- and *p*-) positions, to which, therefore, either positive ions, or the positive ends of incipiently ionised molecules, become attracted. In the case now under consideration, the positive ions would be solvated hydrions, and as combination proceeds, so the electrons would be drawn back in the sense of formula (XVII) until either the neutral molecule (XV) or its isomeride (XVI) is regenerated (compare with diazo-coupling).<sup>\*</sup> Or, an incipiently ionised molecule, such as water or alcohol, may be attracted, and the positive end of it (hydrogen) transferred to the three-carbon system by reaction in a cycle (compare with *op*-nitration, *loc. cit.*).

This view of activation in tautomeric change represents a rational development of principles previously formulated by E. H. Ingold (*Chem. and Ind.*, 1923, 42, 1246),<sup>†</sup> and we would apply it not only

<sup>\*</sup> The hydrions will, of course, also approach and combine with the negatively charged oxygen atom, but this produces no new isolable isomeride and is easily reversible (ordinary ionic dissociation). It is the circumstance that, when the hydrion approaches  $C_\alpha$  or  $C_\gamma$  the electrons return along the chain to that point and so *bind* the hydrion, which (according to this view) gives to the  $\alpha\beta$ - and  $\beta\gamma$ -unsaturated isomerides their stability as individuals.

<sup>†</sup> Read to Section B of the British Association at Liverpool, September, 1923.

to three-carbon tautomerism, but also, with appropriate modifications, to all other mobile-hydrogen tautomeric systems, including ring-chain systems. Illustrations of its applications are, however, now confined to certain effects of structure on three-carbon tautomerism.

The effect of the terminal groups on the *mobility* of the three-carbon system (compare *inter alia*, Ingold and Piggott, J., 1922, 121, 2381; Birch, Kon, and Norris, *loc. cit.*) may readily be correlated with directive action in benzene substitution. Thus the smaller mobility of systems terminated by a carbethoxyl or carbonyl group, as compared with similar systems terminated by an acetyl group, is regarded as due to the competition :

This is only a particular case of the general principle that the greater the electron-giving tendency possessed by a group R (as indicated by its *op*-directive power in aromatic substitution) the smaller will be the mobility of a three-carbon system terminated by  $\cdot\text{CO}\cdot\text{R}$ . Thus the sequence  $\text{NH}_2 > \text{OH} > \text{Cl} > \text{CH}_3 > \text{H} > \text{CO}_2\text{Et}$  for *op*-directive power leads to the sequence

for the enhancement of three-carbon mobility. Similar series apply to related phenomena discussed by E. H. Ingold (*loc. cit.*) and, in passing, it may be noticed that the difference  $-\text{CO}\cdot\text{Cl} > -\text{CO}\cdot\text{OH}$  is utilised in the Hell-Volhard method of brominating aliphatic acids through their chlorides. The reason for the greater mobility of three-carbon systems in which there are two terminal carbethoxyl groups (glutaconic esters, type I) as compared with those in which there is only one (types II and III) is too obvious to require elaboration.

A general discussion of the effect of groups on the three-carbon *equilibrium* would necessarily be lengthy, but the method of treatment can be illustrated by means of a few examples. In the simple case of a three-carbon system activated by one terminal group, say a carboxyl group, six types of modification by substitution are possible, since either an *op*-directive group (electron source) or a *m*-directive group (electron-sink) might be introduced into either the  $\alpha$ -, or the  $\beta$ -, or the  $\gamma$ -position.

As illustration, we may consider the introduction of an electron sink into the  $\beta$ -position, the effect of which is to displace the

equilibrium in the direction favouring the  $\beta\gamma$ -unsaturated isomeride. For example, the isomeric changes

form a striking contrast (compare also Baeyer, *Annalen*, 1890, 258, 165; Hassell and Ingold, this vol., p. 1465; Goss and Ingold, *ibid.*, p. 1471). The reason for this effect is clearly seen if we consider the return of the electrons in the ion (XVII). Two routes are originally open, (a) and (b) (XVIII), but one of these (a) clashes with path (c) provided by the  $\beta$ -group; hence the hydrogen ion combines preferentially at the  $\alpha$ -carbon atom:

Similarly, in aromatic substitution, the introduction of a *m*-directing group in the *m*-position to a powerful *op*-directing group tends to facilitate substitution in the position *between* the two groups.

Again, the introduction of an *op*-directing group (electron source) in the  $\gamma$ -position will oppose (a), and in the absence of disturbing factors should therefore favour the  $\beta\gamma$ -unsaturated isomeride.  $\gamma$ -Alkyl groups are known to have this effect (compare *inter alia*, Wallach, *Annalen*, 1912, 394, 376; Beesley, Ingold, and Thorpe, J., 1915, 107, 1080; Birch, Kon, and Norris, *loc. cit.*; Kon and Linstead, *loc. cit.*). Analogous considerations may be applied to other cases, and the comparison with aromatic substitution obviously gives great scope for the prediction of the relative magnitude as well as the direction of the effect to be expected from different substitutions in different positions.

The analogy between tautomerism and reversible additive reactions has been emphasised in a number of recent memoirs, and a discussion of the application of these views to that subject will be given in an ensuing paper.

#### EXPERIMENTAL.

Citraconic anhydride was obtained (3 kg.) from citric acid, and the fraction, b. p. 204–205°/760 mm., esterified as described by Hope. It is important to distil the anhydride under ordinary

pressure to isomerise any itaconic anhydride. The ethyl citraconate had b. p. 118—120°/20 mm. (yield, 80%). Ethyl itaconate, b. p. 119—120°/20 mm., was prepared from itaconic acid.

*Addition of Ethyl Sodiomalonate to Ethyl Citraconate and Ethyl Itaconate and Separation of the Products.*—Ethyl sodiomalonate was prepared in the usual manner, with ethyl alcohol as solvent and the theoretical quantity of sodium, and the ethyl citraconate (1 mol.) added, the temperature being kept at 15°. After 24 hours, the pale yellow product was poured into water, and the product extracted with ether and washed with sodium carbonate. The residue obtained on evaporation of the ether was subjected to a long series of fractional distillations, as a result of which it was partly separated into two products: (a) b. p. 198—199°/10 mm., and (b) b. p. 190—191°/10 mm. The former (a) was ethyl *n*-butane- $\alpha\beta\delta$ -tetracarboxylate, since on hydrolysis by hydrochloric acid it gave *n*-butane- $\alpha\beta\delta$ -tricarboxylic acid, m. p. 121°, which was identified by comparison with a specimen prepared by hydrolysing the product of condensing ethyl sodioethanetricarboxylate with ethyl  $\beta$ -iodopropionate. The fraction (b) consisted of ethyl *n*-butane- $\alpha\beta\gamma$ -tetracarboxylate, since on hydrolysis it gave *trans*- $\alpha$ -methyltricarballic acid, m. p. 185°.

In view of the unsatisfactory character of this separation, the crude product obtained from the condensation of 525 g. of citraconic ester and 455 g. of ethyl malonate was treated in the following manner. An ethereal solution was shaken with 2*N*-aqueous sodium hydroxide and then mixed with 100 c.c. of ice-water and 50 c.c. of 50% potassium hydroxide. This alkaline solution was extracted twice with ether, the combined ethereal extracts were evaporated, and the residue was fractionally distilled. A first fraction (8 g.) had b. p. 140—180°/12 mm., and the main fraction (22 g.) b. p. 180—192°/12 mm.; on redistillation, this gave a colourless oil (20 g.), b. p. 189—190°/11 mm., consisting of ethyl *n*-butane- $\alpha\beta\gamma$ -tetracarboxylate (Found: C, 55.5; H, 7.5. Calc.: C, 55.5; H, 7.5%), since it yielded *n*-butane- $\alpha\beta\gamma$ -tricarboxylic acid on hydrolysis. The potassium hydroxide solution was acidified and extracted with ether, and the extract washed thoroughly with saturated aqueous sodium hydrogen carbonate. On evaporation of the extract, an oil (15 g.) was obtained, which on distillation gave a fraction (6.5 g.), b. p. 205—210°/15 mm., consisting of ethyl cyclopentan-3-one-1:2:4-tricarboxylate. On boiling this with hydrochloric acid for one hour and evaporating the solution, cyclopentanone-3-carboxylic acid, m. p. 62—64°, b. p. 170—174°/17 mm., was obtained. The more volatile ester fraction (5 g.), b. p. below 200°/15 mm., contained the ethyl cyclopentanonedicarboxylate and

ethyl *cyclopentanone*carboxylate described below. The sodium hydrogen carbonate solution was acidified with hydrochloric acid and extracted with ether, and the residue (60 g.) from the extract esterified with ethyl alcohol and sulphuric acid in the usual manner. An ethereal solution of the esters so obtained was washed with aqueous sodium hydrogen carbonate and then with aqueous potassium hydroxide at 0°. The ester (20 g.) on fractional distillation gave 12 g. of an oil, b. p. 200—204°/12 mm., consisting of ethyl *n*-butane- $\alpha\beta\delta\delta$ -tetracarboxylate (Found: C, 54.7; N, 7.4. Calc.: C, 55.5; H, 7.5%), since on hydrolysis only *n*-butane- $\alpha\beta\delta$ -tricarboxylic acid was obtained. The sodium hydroxide solution was acidified with hydrochloric acid and extracted with ether, and the extract washed with aqueous sodium hydrogen carbonate and then with ice-cold 10% aqueous potassium hydroxide. The ether extract on evaporation gave a resin. The potassium hydroxide solution was acidified and extracted with ether; ethyl *cyclopentanone*-1:2:4-tricarboxylate was then obtained. The sodium hydrogen carbonate solution was reacidified with hydrochloric acid, and the product obtained on extraction with ether was esterified with alcohol and sulphuric acid. The esters, after being washed in ethereal solution with aqueous sodium hydroxide and distilled, yielded, in addition to a small amount of substance, b. p. below 140°, a main fraction, b. p. 210—245°/12 mm., consisting essentially of ethyl dicarboxy*cyclopentenyl*malonate (see below). The sodium hydroxide solution was treated at 0° with excess of carbon dioxide, and the oil thus precipitated was extracted with ether. The residue from the ether on distillation gave a small fraction, b. p. below 145°/12 mm., and a main fraction, b. p. 145—154°/12 mm., consisting of ethyl *cyclopentanone*dicarboxylate (see below). The carbonated solution was rendered acid, and the product extracted with ether and re-esterified with alcohol and sulphuric acid. The esters so obtained, after being washed in ethereal solution with alkali and distilled, gave principally a fraction, b. p. 230—240°/12 mm., consisting mainly of ethyl dicarboxy*cyclopentenyl*malonate.

The various "low" fractions mentioned in the course of the foregoing account were combined and examined. They consisted principally of unaltered ethyl malonate, ethyl mesaconate, and ethyl itaconate, a possible indication of the reversibility of the reaction.

The same nine substances, namely, ethyl malonate, itaconate, mesaconate, butane- $\alpha\alpha\beta\gamma$ -tetracarboxylate, butane- $\alpha\beta\delta\delta$ -tetracarboxylate, *cyclopentanone*-mono-, -di-, and -tri-carboxylate, and dicarboxy*cyclopentenyl*malonate, were obtained, by the same method of separation, when the original condensation was carried

out at 80°, and also when ethyl itaconate was substituted for ethyl citraconate in either experiment. Similar condensations carried out with itaconic and with citraconic ester, both at 15° and at 80°, with the difference that the quantity of sodium employed was twice the theoretical, yielded the same products, together with a pale yellow mixture of sodium compounds the nature of which has not yet been elucidated. Other condensations were carried out in boiling benzene as the solvent, the ethyl sodiomalonate being prepared from "molecular" sodium and ethyl malonate. When ethyl citraconate was used, not only ethyl butane- $\alpha\beta\gamma$ -tetracarboxylate, but also  $\alpha\beta\delta\delta$ -tetracarboxylate and the *cyclopentane*-esters were obtained. The use of excess of sodium made no difference to these results, and the yellow sodium compounds were not obtained as when alcohol was used as solvent. Other condensations were effected by the aid of molecular sodium (1 mol.) in dry ether. In this case, using ethyl citraconate, ethyl butane- $\alpha\beta\gamma$ -tetracarboxylate was obtained in 80% yield, and the  $\alpha\beta\delta\delta$ -ester was not isolated; but it must have intervened in the production of ethyl *cyclopentanone*-tetracarboxylate, which was identified by hydrolysis to *cyclopentane*-3-carboxylic acid, m. p. 62°. The use of excess of sodium did not affect this result. Similar experiments using ethyl itaconate in place of ethyl citraconate led to 65–75% yields of ethyl *n*-butane- $\alpha\beta\delta\delta$ -tetracarboxylate, which was identified through its amide (m. p. 255°; compare Michael and Schulthess, *J. pr. Chem.*, 1892, 45, 57) and hydrolysis product. The *cyclopentane* esters were also obtained, but ethyl *n*-butane- $\alpha\beta\gamma$ -tetracarboxylate could not be identified. The presence of excess of sodium did not affect this result.

It appears, therefore, that the mobility of the unsaturated esters is less in benzene and ether than in alcoholic sodium ethoxide, and that in ether particularly, possibly on account of its low b. p., there is very little interchange.

The following compounds are new.

*Ethyl cyclopentanone*-3-carboxylate is a colourless oil, b. p. 109–111°/10 mm. It gives no colour with ferric chloride (Found: C, 61.4; H, 7.7.  $C_8H_{12}O_3$  requires C, 61.5; H, 7.7%). The *semicarbazone* was prepared by means of semicarbazide acetate and crystallised from ethyl alcohol in needles, m. p. 153.5° (Found: C, 50.6; H, 7.2.  $C_9H_{15}O_3N_3$  requires C, 50.7; H, 7.0%). The ester can be prepared by way of the acid chloride, which is obtained when phosphorus pentachloride acts on *cyclopentanone*-3-carboxylic acid.

*Ethyl cyclopentanone*-2:4 (or 2:3)-dicarboxylate has b. p. 150°/10 mm. and 160°/18 mm. It gives a deep red colour with ferric chloride (Found: C, 57.6; H, 7.3.  $C_{11}H_{20}O_5$  requires C, 57.8;

H, 7.0%). A semicarbazide could not be prepared. On hydrolysing the ester with hydrochloric acid, cyclopentanonecarboxylic acid, m. p.  $64^{\circ}$ , was obtained.

*Ethyl 2:4 (or 2:3)-Dicarboxycyclopentenylmalonate (or Ethyl 2:4 [or 2:3]-dicarboxycyclopentylidenemalonate).*—A number of crude specimens of this ester (51 g.) were combined and carefully distilled; 43 g. of a pure fraction, b. p.  $240\text{--}245^{\circ}/16\text{ mm.}$ , were then obtained (Found: C, 58.3; H, 7.1.  $\text{C}_{18}\text{H}_{26}\text{O}_8$  requires C, 58.3; H, 7.1%). The ester was unsaturated and gave no colour with ferric chloride. It showed an exaltation of refractivity of 1.9 units for sodium light ( $n_D^{20}$  1.46719;  $d$  1.13273). The acid obtained on hydrolysis was a syrup, and may have been a mixture of the endocyclic and exocyclic unsaturated acids, since the parent ester would almost certainly be tautomeric. From the first fractions obtained in the distillation of the above ester, a semicarbazone was obtained which was identified with that described above, m. p.  $153.5^{\circ}$ .

*Formation and Constitution of Ethyl  $\omega$ -Ethoxymethylsuccinate.*—This ester may be prepared either from citraconic ester, as described by Hope, or from itaconic ester. Using Hope's method, we found some difficulty in obtaining the ethoxy-ester free from unsaturated esters, but after a series of careful fractionations, about 15–20% of an ester, b. p.  $137\text{--}140^{\circ}/23\text{ mm.}$ , was obtained which decolorised permanganate only slowly. It gave correct figures on analysis and on treatment with aqueous ammonia yielded  $\omega$ -ethoxymethylsuccinamide, which was isolated by evaporating the ammonia solution in a vacuum and crystallising the residue from water. Thus obtained, the amide formed prisms, m. p.  $149\text{--}150^{\circ}$  (Found: C, 48.4; H, 7.8.  $\text{C}_7\text{H}_{14}\text{O}_3\text{N}_2$  requires C, 48.3; H, 8.0%). By the use of itaconic ester (20 g.), sodium (0.16 g.), and alcohol (96 c.c.), and by keeping the mixture at the ordinary temperature overnight, a product was obtained which, after four fractional distillations, yielded 3 g. of an unsaturated ester, b. p.  $130\text{--}135^{\circ}/23\text{ mm.}$ , and 5 g. of an ester, b. p.  $137\text{--}140^{\circ}/23\text{ mm.}$ , which only slowly decolorised alkaline permanganate. The unsaturated ester, on treatment with ammonia, was converted into mesaconamide, m. p.  $176\text{--}177^{\circ}$  (Found: C, 47.0; H, 6.3. Calc.: C, 46.9; H, 6.2%) and must therefore have consisted largely of mesaconic ester. The saturated ester was evidently the same ethoxy-ester as that obtained from citraconic ester, since it gave the same amide, m. p.  $149\text{--}150^{\circ}$ , on treatment with ammonia and the same acid on hydrolysis (Found: C, 56.6; H, 8.6. Calc.: C, 56.9; H, 8.6%). The ethoxy-acid obtained on hydrolysis had the m. p. and properties described by Hope.

*$\alpha$ -Iodopropane- $\beta\gamma$ -dicarboxylic Acid.*—The ethoxy-acid (2 g.) was boiled for 2 hours with "Zeisel" hydriodic acid, and the ethyl iodide formed allowed to escape. The resulting solution was extracted with ether, and the extract washed with thiosulphate solution, dried, and evaporated. The residue immediately solidified with evolution of heat, and after crystallisation from ethyl acetate-ligroin had m. p.  $138^{\circ}$  (Found: C, 23.9; H, 2.7. Calc.: C, 23.2; H, 2.7%). It was identified by direct comparison and a mixed m. p. determination with a specimen of  $\alpha$ -iodopropane- $\beta\gamma$ -dicarboxylic acid prepared for the purpose.

*$\alpha$ -Bromopropane- $\beta\gamma$ -dicarboxylic Acid.*—The ethoxy-acid was boiled for 3 hours with hydrobromic acid ( $d$  1.49), and the product extracted with ether. The residue obtained at once solidified, and after crystallisation from ethyl acetate-petrol had m. p.  $137^{\circ}$ . It was identified by the m. p. of a mixture with a genuine specimen.

*Paraconic Acid.*—Both the iodo- and the bromo-acid were treated with excess of silver oxide in aqueous suspension; heat was generated and the silver halide precipitated. The acid extracted with ether after addition of mineral acid solidified in an evacuated desiccator and then melted at  $50$ – $53^{\circ}$ . After crystallisation from ether-chloroform, paraconic acid was obtained, m. p.  $57^{\circ}$ , and identified by direct comparison and a mixed m. p. determination with an authentic specimen.

We take this opportunity to record our thanks to both the Chemical Society and the Royal Society for grants with the aid of which the cost of this investigation has been defrayed.

## CXCIV.—*The Constitution of Polysaccharides. Part IX. The Degradation of Cellulose to an Anhydrotrisaccharide.*

By JAMES COLQUHOUN IRVINE and GEORGE JAMES ROBERTSON.

In former papers from this laboratory it was shown that cotton cellulose is composed of 1:5-anhydroglucose residues\* and the question was discussed as to the number of such residues present in the unpolymerised molecule of the polysaccharide. It was

\* See Appendix for discussion and revision of numerical nomenclature as applied throughout this paper.

pointed out (Irvine and Hirst, J., 1923, 123, 518) that the simplest view which satisfies the primary conditions is that cellulose is a polymerised di(1 : 5-anhydroglucose) (*loc. cit.*, p. 524, Formula IV) but that a formula of this type is at variance with the highest authentic yield of cellobiose octa-acetate so far obtained from a normal cellulose. In order to accommodate this result and yet preserve the greatest simplicity of structure, it was suggested that cellulose may be regarded as a polymeride of tri-1 : 5-anhydroglucose. The suggestion was tentative, as shown by the following significant extract from the argument:—"in the meantime it is prudent to select a formula for cellulose which will give a yield of cellobiose approximating to this figure (50—60%) rather than to the higher value 105.5." The same reasonable caution has been exercised in our other references to this question, but nevertheless the views expressed have been generally invested with a rigidity and finality for which no claim was made. The present position is that the exact number of anhydroglucose residues which form the cellulose molecule remains unknown and speculation regarding this factor must be guided from time to time as knowledge accumulates. Recently, X-ray spectrographic methods have been brought to bear on the problem and the results are interpreted as indicating that the  $C_6$  residues are marshalled in even numbers. This conclusion is opposed to the idea that the molecular unit is an anhydro-trisaccharide, but the results of standard chemical methods of attacking constitutional questions must equally be taken into account, even if, for the time being, they conflict with data obtained by purely physical processes. Obviously, the anhydro-trisaccharide formula need no longer be considered if convincing chemical evidence is forthcoming that the cellulose molecule is of a single type and definitely contains an even number of  $C_6$  residues. But it will be generally agreed that the acceptance of any particular molecular formula must rest ultimately on the depolymerisation of cellulose to the simplest non-reducing compound possessing the empirical formula  $C_6H_{10}O_5$  and retaining the 1 : 5-anhydro-linking. Further, such a compound should be capable of undergoing the reverse change of polymerisation without disturbance of the characteristic 1 : 5-anhydride ring and without forming complex glucosides of the type produced by the polymerisation of glucosan (Irvine and Oldham, J., 1925, 127, 2903). This prospect is still remote, but we now submit experimental evidence, bearing on the problem, which has been obtained by studying the graded acetolysis of cotton cellulose.

A review of the scattered literature and more particularly of papers which have appeared in the past few years reveals that acetolysis is an extremely complex process and is not confined to a

succession of reactions conducted on cellulose triacetate. Much recent work rightly emphasises the esterifying effect of the sulphuric acid employed in acetolysis, but nevertheless the earlier researches of Klein and of Schliemann reveal the essential nature of the changes involved. These workers showed that even when the yield of cellulose octa-acetate is as much as 60% of the cellulose used, degradation products persist which may be regarded as simple dextrans and possess a greater complexity than a disaccharide. These dextrin acetates are dextrorotatory and appear to be the immediate precursors of cellobiose octa-acetate, so that acetolysis may be regarded as a series of ill-defined steps as represented below. The scheme does not include the formation of aceto-sulphates as, from the point of view of the present investigation, these products arise from secondary reactions, and as cellulose has been completely converted into 2 : 3 : 6-trimethyl glucose, it is also unnecessary to make separate provision for isocellobiose acetate.

Cellulose  $\rightarrow$  Acetylated cellulose  $\rightarrow$  Acetylated cellulose dextrans  $\rightarrow$   
[X]  $\rightarrow$  Cellobiose octa-acetate  $\rightarrow$  Glucose penta-acetate.

Acetylation and depolymerisation are the essential features of the earlier reactions, and the opening of anhydro-rings by hydrolysis is specially characteristic of the two final stages, but there is no sharp line of demarkation between these different types of change. The hypothetical stage indexed as [X] therefore represents the formation of compounds in which the maximum depolymerisation of cellulose has taken place, whilst the specific hydrolytic action responsible for the formation of cellobiose octa-acetate is a minimum. The present investigation deals with the exploration of this group of acetolysis products.

Several workers, notably Bertrand, Hess, and Pringsheim, have occupied themselves with what is essentially the same subject of research and have obtained results of great interest. It is, however, a difficult matter to define exactly the experimental conditions under which acetolysis can be controlled so as to give consistent results. The physical condition of the cellulose used and the treatment to which it has been subjected, minute variations in the purity of the reagents employed, the temperature and other factors still unrecognised, combine to affect the series of reactions profoundly. In consequence, through no fault of the observers, the statements in the literature are occasionally conflicting. We find, however, that the progress of acetolysis can be ascertained by systematic physical examination of samples of the product and that it is possible to arrest the reactions at a stage immediately before cellobiose octa-acetate is formed and when insoluble dextrans are

present in minimum amount. This result was secured by working between two limiting conditions, the first being that no trace of crystalline structure should be observable in the solid product when examined by ordinary microscopic methods. Control experiments showed that as small a proportion as 3% of cellobiose octa-acetate can be identified with certainty in this way. The second limiting condition was that a solution of the product in chloroform should be dextrorotatory and should show only a faint cone of light when viewed in the ultramicroscope. This secured that insoluble dextrans constituted less than 7% of the total. The product obtained when these conditions were preserved was a white amorphous powder and the composition was that of a cellulose triacetate, but its properties presented a sharp contrast with those of a normal acetate of the polysaccharide. In particular, it displayed a much wider range of true solubility, possessed a distinct, although indefinite, melting point, and was dextrorotatory. The change of sign from the laevorotation characteristic of cellulose triacetate is in itself proof that extensive depolymerisation had taken place. Despite the uniformity in properties and composition displayed by different preparations, the product was a mixture and contained at least two constituents which reduced Fehling's solution, the ratio of the cuprous oxide formed before and after acid hydrolysis being 1 : 2.2. The greatest caution must be exercised in interpreting all analytical data in the case of acetolysis products and consequently the nature of the degraded acetate was ascertained by submitting it to (1) deacetylation and (2) methylation. Treatment with aqueous dimethylamine eliminated the acetyl groups and enabled dextrans to be removed. The main product thus obtained was freely soluble in water but, owing to secondary reactions between reducing groups and the alkaline reagent (Irvine, Thomson, and Garrett, J., 1913, 103, 238), the material was contaminated with alkylamino-derivatives and could not be completely separated into its constituents. This section of our work is being continued, but it may be stated that we have isolated from the above mixture an amorphous disaccharide which was present to the extent of about 20%. The sugar melted with decomposition at 180°, and had  $[\alpha]_D + 14^\circ$  in water, but until this extension of the research is complete it is impossible to characterise the compound definitely as an *isocellobiose*.

These experimental difficulties were overcome by submitting the mixture of degradation compounds to the methylation process, which was adjusted so as to eliminate both alkylated disaccharides and dextrans. Contrasted with the behaviour of cellulose under parallel conditions, the methylation proceeded with remarkable smoothness and no difficulty was experienced in obtaining the fully

substituted derivative, a result which supplies additional evidence that extensive depolymerisation of the polysaccharide had been accomplished. As only the material insoluble in sodium hydroxide was collected, any disaccharide or monosaccharide constituents were retained in the alkaline liquors and were thus eliminated. Methylated dextrans, amounting to 6% of the total weight, were left undissolved on treatment with ether, so that, so far as molecular complexity is concerned, the product finally isolated was intermediate between lower dextrans and disaccharides. In this way, a 50% yield of a white, amorphous powder was obtained which was readily soluble in organic solvents, and possessed the properties of a glucoside. Molecular-weight determinations by the cryoscopic method in benzene solution, and confirmed by Rast's process, gave the value 656, showing that the substance was derived from a trisaccharide. The analytical composition also corresponded exactly with that required for  $[C_6H_7O_2(OMe)_3]_3$  and the combined results might well have been accepted at this stage as conclusive. The behaviour on hydrolysis, however, warrants the conclusion that only 70% of the material consisted of tri(trimethyl anhydroglucose), the remainder being the corresponding methylated trisaccharide. This evidence was obtained by heating with acid methyl alcohol, which effected hydrolysis and the condensation of the liberated sugars with the solvent. The product of this reaction was isolated by vacuum distillation and consisted of a mixture of trimethyl methylglucoside (90%) with tetramethyl methylglucoside (10%). This opinion was verified in two ways. The mixture of glucosides was hydrolysed and the sugars thus obtained consisted exclusively of 2:3:6-trimethyl glucose and 2:3:5:6-tetramethyl glucose, both of which were isolated in crystalline form in yields which correspond with the above composition. Further, precisely the same result was obtained when the original methylated product was hydrolysed by means of aqueous acid to give the corresponding sugars directly without the intermediate formation of the glucosides. The combined evidence leads to the opinion that, under the conditions specified, cellulose can be degraded to a mixture of acetates derived from the following compounds in the proportions stated:—

1. Dextrans .....	6%	3. Triglucose .....	15%
2. Anhydro-triglucose .....	35%	4. Diglucose .....	20%

Although the results clearly favour the idea that anhydro-triglucose forms part of the cellulose aggregate, the possibility remains that anhydro-diglucose molecules may also be concerned in the polymerisation which leads to the polysaccharide. This possibility has been foreshadowed by the work of Irvine and Oldham (*loc. cit.*), who showed that the polymerisation of  $\beta$ -glucosan

involves both odd and even numbers of the monomeric unit, and is emphasised by consideration of the yields of the various products obtained in the present research. Although our work was carried out under conditions as nearly as possible quantitative, only 76% of the degraded acetates was accounted for in the form of pure derivatives. Further, during the original acetolysis, about 30% of the cellulose was converted into soluble or volatile products. Making allowance for these factors, it follows that the yield of trisaccharide derivatives actually obtained by us is of the order 35% when referred to the weight of cellulose originally employed. This is a minimum value and there seems no reason for doubt that at least one-third of the polysaccharide is based upon the triglucose unit. The remaining two-thirds of the polymerised aggregate remains unknown and the research is consequently being continued on the following lines: (1) the constitutional study of the tri- and di-saccharide products of graded acetolysis, (2) the polymerisation of these products and (3) the quantitative relationship between the tri- and di-saccharides.

#### *Discussion of Results.*

The views expressed in the present paper depend on the conversion of cellulose into simple methylated compounds, one of which is derived from triglucose and one from the corresponding anhydro-triglucose. Although it was possible to separate these two constituents from other compounds, it proved impossible to separate them from each other and thus the conclusions are in part based upon analytical figures. This in itself would be insufficient, but although there is ample supplementary evidence, it is necessary to discuss the results critically and to consider in how far explanations other than that offered are valid. Much depends on the fact that tetramethyl glucose is formed as a scission product when the above methylated mixture is hydrolysed, and the obvious suggestion is that the small amount of this sugar which was isolated may be traced to glucose penta-acetate or to cellobiose octa-acetate present in the original starting material. This possibility is discounted by the fact that the degraded acetates were amorphous, although this observation does not exclude the presence of an *isocellobiose* acetate. Of greater importance is the technique employed in the methylation which, on the basis of control experiments, was adjusted so as to eliminate both mono- and di-saccharides.

It is therefore evident that the tetramethyl glucose did not originate in glucose or in cellobiose, but in a polyhexose containing more than two  $C_6$  residues. If the methylated material which yielded the tetramethyl glucose consists of a single chemical individual,

it follows that ten  $C_6$  groups are present, but, in such an event, the molecular weight would exceed 2000. If, on the other hand, the material is a mixture, one component must be a fully methylated reducing sugar containing any number of glucose residues from three to nine, the remaining constituent being the corresponding poly(trimethyl anhydroglucose). The number of possible mixtures which satisfy the analytical data is large and in the following table some typical examples are given, all of which possess practically the same composition and would give the results obtained in this investigation.

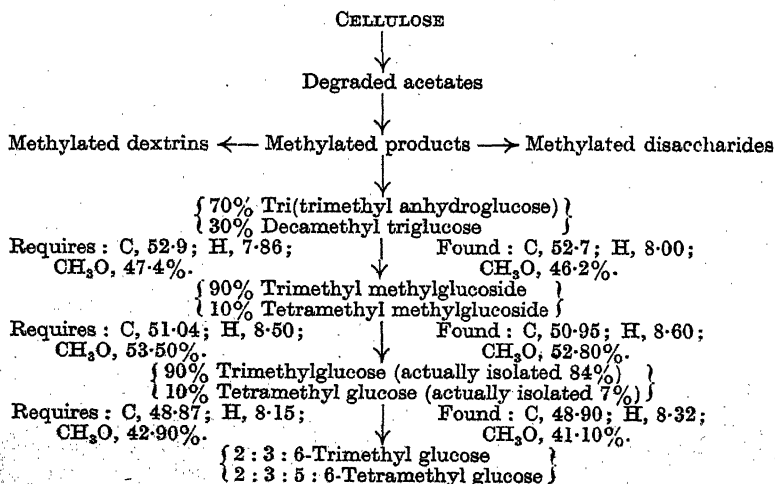

I. A mixture containing 70% of a tri(trimethyl anhydroglucose) and 30% of a methylated trisaccharide. (Molecular weight approximately 625.)

II. A mixture containing 60% of a tetra(trimethyl anhydroglucose) and 40% of a methylated tetrasaccharide. (Molecular weight approximately 834.)

III. A mixture containing 50% of a penta(trimethyl anhydroglucose) and 50% of a methylated pentasaccharide. (Molecular weight approximately 1043.)

IV. A mixture containing 40% of a hexa(trimethyl anhydroglucose) and 60% of a methylated hexasaccharide. (Molecular weight approximately 1251.)

The list reveals that the molecular-weight determinations are discriminative and, as the value 656 was obtained, lead to a definite decision on the question of molecular magnitude. The consistency of our results is also displayed by the following scheme, which serves to simplify the series of reactions :

*Appendix.*

Subsequent to the completion of the paper now communicated, the subject of the ring structure of glucose has been re-opened by Charlton, Haworth, and Peat (this vol., p. 89), who bring forward evidence that the stable form of the sugar is an amylene-oxide. That the oxydic ring in glucose may occupy different positions was first experimentally verified by one of us ten years ago, and the necessity to take all the different possibilities into account has repeatedly been emphasised (Irvine, "Some Constitutional Problems in Carbohydrate Chemistry," *J.*, 1923, **123**, 900). For a considerable time it has been recognised by workers in this field that as the  $\gamma$ -oxydic formula for glucose depended on collateral rather than on direct experimental evidence, it might require modification and that to have the position of the oxygen ring settled experimentally would mark an advance in sugar chemistry. We do not commit ourselves at this stage to unqualified acceptance of the modified formula for glucose—the suggestion offered introduces a number of simplifications and is worthy of extended trial—but we defer our opinion until results obtained by the ultimate oxidation of tetramethyl glucose are available.

The formulæ of a number of methylated sugars may, however, be adjusted, *e.g.*, 2:3:5-trimethyl glucose would be described as the 2:3:4-form, but from the point of view of the present research greater importance is attached to the sugar known as 2:3:6-trimethyl glucose. A review of the constitutional study of this compound does not justify altering the position of the methyl groups, so that by shifting the ring to the neighbouring carbon atom the formula becomes :

The linkage present in cellulose would thus presumably be through positions 1 and 4 in place of 1 and 5 and the polysaccharide would therefore be described as poly-(1:4-anhydroglucose). It would, however, be premature to accept this conclusion as final, in view of the fact the particular variety of trimethyl glucose now under consideration can react as a  $\gamma$ -sugar. This possibility has been pointed out by Irvine and Hirst (*J.*, 1922, **121**, 1221) in their study of the condensation of the compound with methyl alcohol, and it follows that the formation of this sugar is not absolutely diagnostic as to the structure of the complex from which it originates. This possibility and its effect on constitutional questions are discussed in a forthcoming paper.

The application of a poly(1:4-anhydroglucose) structure to

cellulose may now be considered and the opportunity may be taken to simplify the alternative structural formulæ applicable to this unit, as further consideration has shown that, provided  $\alpha$ - and  $\beta$ -configuration is not taken into account, only two possibilities exist.\* These as modified are :

The position of the potential reducing groups is indicated in block type.

In view of the results communicated in this paper, and taking into account the increasing importance attached to the formation of *isocellobiose* from cellulose, it would be inadvisable to exclude formula II entirely. The retention of both types formulated above accounts for the formation of isomeric cellobioses and it is possible that both may function, although unequally, in the polymerisation process which leads to cellulose.

#### EXPERIMENTAL.

*Graded Acetolysis of Cotton Cellulose.*—The material employed was provided by Mr. William Rintoul of Messrs. Nobels, Ltd., and was identical with that used in our other investigations (see previous papers). Systematic experiments showed that when the temperature at which acetolysis is conducted is maintained uniformly at 15°, the best results were obtained when the reagent consisted of acetic anhydride and sulphuric acid in the ratio of 5.9 parts to 1 part

\* I am indebted to Dr. A. Geake of the Shirley Institute (British Cotton Industry Research Association), who first kindly directed my attention to this simplification.—J. C. I.

by weight. These conditions having been established, the remaining factor, *viz.*, the duration of the reaction, was determined, in the first instance approximately, by microscopic examination of samples of the product. When precipitated by water, dissolved in alcohol, reprecipitated and dried, the material showed a wide range of solubility in organic solvents including benzene. These solutions, which were dextrorotatory, did not give films on evaporation and no trace of crystalline matter was visible in the residue, although control experiments with artificial mixtures showed that 3% of cellobiose octa-acetate can be detected in this way. Further, when dissolved in chloroform, the solution was practically optically clear when viewed in the ultramicroscope, a faint cone of light being, however, visible owing to the persistence of a small proportion of higher dextrans. The control experiments were conducted throughout the entire series of products ranging from a normal cellulose triacetate to cellobiose octa-acetate. A typical preparation is now described, but as the reaction is affected by numerous factors, including the surface condition of the cotton, it is necessary to state that in order to obtain consistent results the acetolysis must be standardised by the physical examination indicated above.

The cellulose (40 g.), dried at 110°, was added gradually to a mixture of 400 c.c. of acetic anhydride and 40 c.c. of sulphuric acid, the pasty mass being kept at 15° and thoroughly stirred for 5 hours. The cellulose was noticeably affected in 90 minutes and dissolved within 24 hours, giving a faintly yellow liquid. During the subsequent 72 hours the colour changed to orange, but the solution remained clear and as at this stage the ultramicroscopic test was satisfactory the liquid was poured into 4 litres of water. The solid thus precipitated showed a tendency to coagulate to a plastic mass which was disintegrated by grinding under water to give a fine flaky powder. After filtration, the product was thoroughly washed with water and dried slowly at 30–40°/10 mm. Thereafter it was dissolved in hot rectified spirit and reprecipitated by the addition of water. Average yield of dry solid = 50 g., when the duration of the acetolysis varied from 95 to 101 hours.

The material was only slightly soluble in hot absolute alcohol, but easily soluble in rectified spirit. It was also readily soluble in cold acetic acid, acetone or chloroform, but less so in benzene. It melted without decomposition, but the temperature of fusion varied between 120° and 160° in different preparations. Moisture (determined at 110°), 1.35%; ash, negligible; sulphur, absent. Found: C, 49.9; H, 5.8; Acetyl, 64.2. Cellulose triacetate requires C, 50.0; H, 5.55; Acetyl, 62.5%. The specific rotation varied

from about  $+10^{\circ}$  to  $+20^{\circ}$ , but in the work now described material was selected which gave the following values :

Preparation	Solvent.	c.	$[\alpha]_D$ .
I.	Chloroform.	1.75	$+20.3^{\circ}$
II.	"	2.58	19.4
III.	Acetone.	1.76	22.1

The acetate reduced Fehling's solution and as this result is important experimental details are given. A weighed quantity (0.3289 g.) was dusted into an excess of boiling Fehling's solution, the boiling being continued for 4 minutes. The weight of dry cuprous oxide thus obtained was 0.1467 g. In order to determine the effect of hydrolysis on the reducing power, 0.3289 g. of the acetate was dissolved in 60% alcohol containing 6% of hydrogen chloride, and the solution was boiled under a condenser for 4 hours. Thereafter the alcohol was replaced by 8% aqueous hydrochloric acid, and the mixture again boiled for 8 hours. A trace of solid matter remained undissolved and the solution, which was practically colourless, was neutralised and added to boiling Fehling's solution. As the weight of cuprous oxide obtained was 0.3250 g., the ratio of the reducing power before and after hydrolysis is 1 : 2.2. Attempts to eliminate the reducing component of the mixture effected only negligible separation but revealed, as the following experiment shows, that little significance can be attached to melting points in these compounds.

18 G. of the acetate were dissolved in 250 c.c. of hot rectified spirit and, on cooling, a first fraction of 12 g. separated. On adding 270 c.c. of water to the mother-liquor a precipitate formed and after further dilution to 850 c.c. the liquid was set aside over-night. The second fraction thus obtained weighed 5.4 g.

	Original material.	Fraction I.	Fraction II.
M. p. ....	$155^{\circ}$	$130-140^{\circ}$	$140-148^{\circ}$
C .....	49.9%	49.6%	49.6%
H .....	5.8%	5.75%	5.6%
$[\alpha]_D$ in chloroform ...	$+18.5^{\circ}$	$+20.3^{\circ}$	$+19.4^{\circ}$

Molecular weight determinations by Rast's process or by the cryoscopic method in acetic acid gave very variable results, owing apparently to the presence of a small quantity of insoluble dextrin. The presence of this impurity was confirmed by digesting the acetate with 2*N*-sodium hydroxide at  $25^{\circ}$  for 3 hours. On neutralisation, a flocculent precipitate separated which darkened on washing and drying. This product, which was present only in small amount, had the properties of a dextrin, decomposed at  $220^{\circ}$ , and gave C, 44.5; H, 6.4% [ $(C_6H_{10}O_5)_x$  requires C, 44.4; H, 6.2%].

*Methylation of the Depolymerised Acetate.*—As the direct replace-

ment of acetyl by methoxyl in one operation is not of general application, the details of a typical experiment are quoted. The acetate (46 g.) was suspended in 225 c.c. of 2*N*-sodium hydroxide and disintegrated by mechanical stirring. After the temperature had been raised to 30°, small equivalent quantities of methyl sulphate and 30% sodium hydroxide were added at short intervals and, when three-fourths of the reagents had been introduced, the temperature was gradually raised to 70° and maintained at this point until the remainder of the methylating mixture had been added. Total reagents used : 110 c.c. of methyl sulphate and 110 g. of sodium hydroxide in 180 c.c. of water.

After completion of the reaction by heating at 100° for 35 minutes, the product remained in solution and was extracted with chloroform. The extract was dried and the solvent removed, when a clear syrup remained which set on cooling to a glass. Yield, 14 g.; OMe, 38.1%. The products of three similar preparations were united and subjected to three further methylations. As the methoxyl content increased, the solubility in alkali diminished so that the methylated product could be removed by filtration and, an important point, the process of chloroform extraction was discontinued so that the disaccharide derivatives remained in the alkaline liquor. Yield, 30 g.; OMe, 45.6%. Five subsequent methylations did not affect the methoxyl content, which agrees exactly with that required for a trimethyl cellulose.

The product was ground to a white solid and extracted repeatedly with boiling ether, which left a small residue (6%) undissolved. This had OMe, 43.7%, and was evidently derived from the cellulose dextrin present in the starting material. On removal of the solvent ether, the main product (94%) was isolated as a clear, colourless glass which could be powdered to a fine white solid softening at about 40°. This proved to be essentially tri(trimethyl 1 : 5-anhydroglucose) mixed with the corresponding methylated trisaccharide. Properties : readily soluble in cold ether, chloroform, benzene, or acetone, less soluble in methyl alcohol, rectified spirit or water ; no action on Fehling's solution until after acid hydrolysis. Found : C, 52.7; H, 8.0; OMe, 46.2. A mixture of 70% of tri(trimethyl anhydroglucose) and 30% of a fully methylated trisaccharide requires C, 52.9; H, 7.9; OMe, 47.4%.

Solvent.	c.	$[\alpha]_D^{20}$ .
Chloroform .....	3.564	+7.0°
Benzene .....	1.682	10.1
Acetone .....	3.367	15.7

*Molecular Weight.*—The mean of two determinations by Rast's method was 662. The mean of three consistent results by the

cryoscopic method with benzene as solvent was 663, and an independent repetition of the same process gave 642. The calculated value for the mixture postulated above is 625.

*Simultaneous Hydrolysis and Condensation with Methyl Alcohol.*—The mixture of methylated trisaccharide derivatives (4.3552 g.) was dissolved in methyl alcohol containing 1% of hydrogen chloride and heated at 110° for 70 hours. The solution, which was pale yellow and contained no suspended matter, was then neutralised with silver carbonate, filtered, and evaporated to dryness. 4.562 G. of a colourless glucosidic syrup remained, corresponding with a yield of 92% of the theoretical maximum. On distillation, the liquid boiled at 115°/0.3 mm. and 3.87 g. were collected in two fractions to permit of duplicate analyses. On the basis that the original methylated is a mixture of 70% of tri(trimethyl anhydroglucose) and 30% of a fully methylated trisaccharide, the above product of hydrolysis should consist of trimethyl methylglucoside (90%) and tetramethyl methylglucoside (10%). This was verified by analysis. Fraction I: C, 50.9; H, 8.3; OMe, 52.6. Fraction II: C, 50.95; H, 8.6; OMe, 52.8%. Calculated for the mixed glucosides: C, 51.0; H, 8.5; OMe, 53.5%.

*Hydrolysis of the Mixed Glucosides.*—The syrup (2.67 g.) was dissolved in 110 c.c. of 8% hydrochloric acid, a trace of charcoal added, and the solution boiled under a condenser until the rotation was constant. The subsequent treatment was as usual and as the mixed sugars, isolated initially as a syrup, weighed 2.2 g., the yield was 88%. In order to separate the sugars, the syrup was dissolved in water, and the solution thoroughly extracted with chloroform. The aqueous solution was evaporated to dryness under diminished pressure, the resulting syrup being redissolved in absolute alcohol which was, in turn, evaporated. Finally, the sugar was dissolved in pure dry ether and after filtration the solvent was slowly evaporated. On nucleation with 2:3:6-trimethyl glucose, the product solidified to a hard mass of crystals (1.85 g.), m. p. 105°; permanent  $[\alpha]_D$  in water, for  $c = 1.058$ , + 71.8° (Found: C, 48.5; H, 8.05; OMe, 41.6. Calc.: C, 48.65; H, 8.1; OMe, 41.9%).

The remaining methylated sugar was isolated from the chloroform solution, which was dried and evaporated, as a syrup weighing 0.25 g. This crystallised on keeping and, when purified from light petroleum, gave pure 2:3:5:6-tetramethyl glucose displaying the standard physical constants. Yield of trimethyl glucose: yield of tetramethyl glucose = 84%:7%. Calc., 90%:10%.

*Direct Hydrolysis of the Methylated Product.*—A 5% solution in 8% hydrochloric acid was fully hydrolysed on boiling for 30 minutes, and the sugars formed were isolated by standard methods. The

product was a clear syrup which, in accordance with the composition of the starting material, should consist of trimethyl glucose (90%) and tetramethyl glucose (10%) (Found: C, 48.9; H, 8.3; OMe, 41.1. The above mixture requires C, 48.9; H, 8.15; OMe, 42.9%).

*Deacetylation of the Degraded Cellulose Acetates.*—20 G. of the finely-powdered acetate were added to 66 c.c. of 33% aqueous dimethylamine. An appreciable rise of temperature took place and the liquid was cooled to 15° and kept, with frequent shaking, for several days. For the first 48 hours the liquid thickened, but after 96 hours it had become much more mobile. After 9 days, water was added and insoluble dextrans were removed by filtration through charcoal, the filtrate being evaporated to dryness under diminished pressure. A golden syrup remained which was thoroughly mixed with successive quantities of ether to remove acetodimethylamide, the undissolved residue being dissolved in a little water and precipitated by excess of absolute alcohol. A white, amorphous powder was thus obtained (1.85 g.) which sintered at 170° and melted with decomposition at 180° (Found in material dried in a vacuum at 110° until of constant weight: C, 42.3; H, 6.6; *M*, cryoscopic in water, 315. A disaccharide requires C, 42.1; H, 6.4%; *M*, 342). The product is therefore a disaccharide other than cellobiose; it reduced Fehling's solution both before and more particularly after hydrolysis with acids. For  $c = 4.2735$ ,  $[\alpha]_D^{20}$  was  $+14.04^\circ$ , no mutarotation being observed within 24 hours.

The alcohol mother-liquor which had yielded the above disaccharide gave on evaporation under reduced pressure 6.4 g. of a syrup. This was dissolved in water, the solution agitated with chloroform to remove traces of acetodimethylamide, and the aqueous portion neutralised and recovered. By means of fractional extraction with boiling alcohol, the material was separated into two portions, but it was found impossible to eliminate dimethylamino-glucosides, and consequently this section of the investigation is being continued by different methods.

Acknowledgment is made to the Carnegie Trust for the award of a Fellowship which enabled one of us to take part in the investigation.

CXCV.—*The Constitution of Polysaccharides. Part X.  
The Molecular Unit of Starch.*

By JAMES COLQUHOUN IRVINE and JOHN MACDONALD.

WE have naturally included the important case of starch as part of our programme of research on the constitution of polysaccharides, applying the same principles and methods as in the analogous examples of cellulose and inulin. The same limitations have also been imposed on the scope of the investigation, which has been confined meanwhile to determining the linkage of the individual glucose residues in starch so as to arrive at the structure of the simplest molecule (or molecules) which, by polymerisation, form the polysaccharide. Our work has not been concerned with the magnitude of these polymerides or with the individual constituents of starch, nor has it included the differences between one variety of starch and another so far as these may be attributed to variations in the nature and amount of extraneous compounds rather than to inherent differences in molecular structure.

Hitherto, the experimental evidence applicable to the constitutional study of starch has been obtained mainly through biochemical agency and, in introduction to the present communication, only two types of such reactions may be selected from the abundant literature on this subject. These are: (a) the conversion of starch into a series of simple amyloses in each of which the empirical formula  $(C_6H_{10}O_5)_n$  is retained, and (b) the formation, through changes which are in part hydrolytic, of maltose, isomaltose, and, ultimately, of glucose. An adequate structural representation of starch must accommodate the above reactions and it is evident that the constitution of maltose is of special importance as bridging the gap between the closed-ring structure of the polyamyloses and the  $C_6$ -chain of glucose. Generally speaking, the application of ordinary chemical methods has led to few results which bear directly on the constitution of starch, as the processes of substitution and disruption are not sharply differentiated. An exception is provided, however, in the method of methylation, by means of which the hydroxyl groups in starch may be substituted by methoxyl groups which survive hydrolysis, thereby giving a methylated glucose. Work on these lines was commenced in this laboratory 6 years ago, but no detailed account of our results has so far been published, although reference has been made occasionally to some of the conclusions at which we have arrived. The delay has been due, not so much to the fact that the methylation of starch presented severe

experimental difficulties, as to the necessity which arose to suspend the research and devote a series of separate investigations to the constitution of maltose. Meanwhile, other workers have attempted to convert starch into its fully methylated derivative, but have failed, it having been found impossible to replace all the hydroxyl groups by methoxyl. Our experience in this respect was, at first, no different, and consequently we were compelled to subject an incompletely methylated starch to hydrolysis and to separate the mixture of methylated glucoses thus produced. In such constitutional studies, this is unsatisfactory procedure and cannot be regarded as giving an adequate view of structure, but our earlier work revealed that an invariable product of the reaction was a crystalline sugar, which was identified as 2 : 3 : 6-trimethyl glucose. This result was altogether unexpected. Unless the action of diastase on starch is in part synthetic, there can be little reason to doubt that, in the starch molecule, glucose residues are joined in the same manner as in maltose, and it follows that the trimethyl glucose obtainable from starch should be identical with that from maltose. Haworth and Leitch, however, state that the disaccharide gives 2 : 3 : 4-trimethyl glucose, and the formula for maltose advocated by these authors, either in its original form (J., 1919, 115, 809) or as subsequently modified (Charlton, Haworth, and Peat, this vol., p. 99), does not admit of the formation of 2 : 3 : 6-trimethyl glucose from any compound containing the maltose structure. The evidence before us was thus conflicting. Obvious sources of error, such as the possible presence of hemi-celluloses, had been carefully excluded, but other explanations suggested themselves, one being that the glucose residues in starch might not be symmetrically attached to each other, as one pair might possess the maltose structure and another the linkage characteristic of cellobiose. This idea was expressed in formulæ (*Brit. Assoc. Reports*, 1922, 33; J., 1923, 123, 898) in which an attempt was made to reconcile our results with those from which the structure of maltose was deduced, but further investigation showed that no satisfactory formula for starch could be constructed on the basis of Haworth's constitution of maltose. This became apparent when we succeeded in methylating starch completely, as, on hydrolysing the product, 2 : 3 : 6-trimethyl glucose was obtained in yields which showed that this sugar must be regarded as the essential and not as an adventitious product of the series of reactions. Concurrently, and by arrangement with Professor Pringsheim, hexa-amylose was subjected similarly to methylation and hydrolysis. The result was equally emphatic, as the same crystalline sugar was obtained as from starch. Finally,

the tri-hexosan prepared by the depolymerisation of starch (Pictet, *Helv. Chim. Acta*, 1922, 5, 640; 1924, 7, 932) was similarly treated and was likewise found to give the same variety of trimethyl glucose.

Only two alternative conclusions could be drawn from the above discordant evidence; the first, that maltose has no structural relationship to starch, was rejected as improbable and we were forced to the opinion that the constitution attributed to maltose was incorrect. This we have ascertained to be the case (Irvine and Black, this vol. p. 862), it having been shown that, in common with starch, polyamyloses and cellulose, maltose yields 2 : 3 : 6-trimethyl glucose unmixed with the 2 : 3 : 4-isomeride. The present communication is therefore submitted on the basis of a corrected constitution for maltose.

We find that the methylation of starch displays a number of features which distinguish the polysaccharide from either cellulose or inulin. Methyl groups are introduced fairly readily by repeated action of methyl sulphate and alkali, but the methoxyl content quickly reaches a limit of 36—37%, this value indicating that only seven hydroxyl groups out of nine have undergone alkylation. Methylated starch of this composition appears to be a definite compound possessing a characteristic optical activity, and, in consequence, the conclusion might be drawn that there are not three hydroxyl groups in each  $C_6$  unit. This inference would be unwarranted, however, as the partly methylated starch was capable of acetylation to the exact extent required to substitute the remaining hydroxyl positions. Further, the methylated starch, when regenerated from the acetate, still preserved its resistance to further methylation. Another distinguishing property displayed by starch during methylation is that the reaction is definitely arrested at the dimethyl stage when conducted by means of silver oxide and methyl iodide. When these reagents are applied to a methylated starch containing less than two methoxyl groups per  $C_6$  unit, the methoxyl content is increased to 32—33%, but no further. Similarly, the same reagents have only a limited effect in raising the methoxyl content when applied to methylated starch which has been alkylated by means of methyl sulphate beyond the dimethyl stage. In the above respects, starch resembles the polyamyloses closely and presents features which are also recognisable in the case of maltose. As the methylation of starch proceeded, the colour reaction with iodine vanished, the usual progressive changes in solubility were observed, and the rotation increased in the dextro-sense. Simultaneously, the protein and inorganic constituents were eliminated, particularly when the

silver oxide reaction was employed, as, in this case, they were precipitated in the form of insoluble double compounds with silver iodide. It is important to observe that these precipitates contained combined carbohydrate, thus indicating that nitrogen and phosphorus form part of the polymerised aggregate. In consequence, the same methylated starch was finally obtained, irrespective of the starting material used, but in large-scale experiments we employed only purified rice-starch. Reference to the experimental details will indicate the manner in which the derivatives of hemi-celluloses were removed so as to separate constituents which would otherwise have introduced complications.

Although four successive applications of methyl sulphate and alkali converted the polysaccharide into a derivative containing 37% of methoxyl, this did not represent the limit of the reaction. Subsequent methylations slowly increased the methoxyl content and, after 24 treatments, the value (43.7%) agreed closely with that required for a trimethyl starch. There are thus three distinct stages observable in the alkylation, the products in each case displaying a constancy in composition and properties which warrants the conclusion that they are three consecutive compounds. These are :

	% OMe (found).	Ratio of OMe groups to initial OH groups.	$[\alpha]_D$ in $\text{CHCl}_3$ .
I. Dimethyl starch .....	32.7	6 : 9	+ 135.7°
II. Methylated starch .....	36.3	7 : 9	169.5
III. Trimethyl starch .....	43.7	9 : 9	216.5

It will be observed that the specific rotation increased regularly with the rise in methoxyl content, and this behaviour we have verified over a wide range in composition, thus affording powerful evidence that frequent repetition of the methylation process does not cause structural rearrangement.

The hydrolysis of each type of methylated starch was undertaken, the method of heating with methyl alcohol and hydrogen chloride being employed so as to isolate the liberated sugars in the form of the corresponding methylglucosides. Compound I gave essentially a dimethyl methylglucoside, the description of which is deferred to a later communication, while II yielded a mixture from which 2 : 3 : 6-trimethyl methylglucoside (1 mol.) was isolated, together with a dimethyl methylglucoside (2 mols.). In the case of III (trimethyl starch) the reaction furnished a conclusive result, as 2 : 3 : 6-trimethyl methylglucoside melting at 57.5° was obtained in excellent yield. A careful search for the isomeric 2 : 3 : 4-form was made, both by fractional distillation and by fractional crystal-

lisation of the glucoside, but no trace of this compound was detected. These results were confirmed by hydrolysis of the total glucosides with aqueous acid and isolation of crystalline 2 : 3 : 6-trimethyl glucose. All syrupy products were examined, but the 2 : 3 : 4-isomeride was definitely absent.

In the course of this section of our work it was necessary to compare critically the constants of the isomeric 2 : 3 : 6- and 2 : 3 : 4-trimethyl  $\beta$ -methylglucosides, as these compounds, which show a close resemblance, have been utilised in certain structural studies of disaccharides as a means of discriminating between the isomeric trimethyl glucoses. The following values were determined on specimens of the compounds obtained either by the limited action of methyl alcohol and hydrogen chloride or through the agency of the corresponding acetobromo-derivatives.

	Source.	M. p.	$[\alpha]_D$ .
2 : 3 : 6-Trimethyl methyl-glucoside.	2 : 3 : 6-Trimethyl glucose from cellulose, or Trimethyl starch.	57.5°	-29.3° in MeOH
2 : 3 : 4-Trimethyl methyl-glucoside.	2 : 3 : 4-Trimethyl glucose (synthetic), or Trimethyl glucosan.	93—94	-23.1 in MeOH

The glucosides cannot be distinguished with certainty through their specific rotations, and the melting points, although far apart, are greatly affected by impurities or by the presence of varying proportions of  $\alpha$ - and  $\beta$ -forms. It follows that trustworthy identification of these reference compounds is possible only when both the melting point and the specific rotation agree with the standard values. In addition, the polarimetric curve of the hydrolysis of each compound is diagnostic, and in the case of the equilibrium mixture of the  $\alpha$ - and  $\beta$ -2 : 3 : 6-isomerides displays two maxima separated by a minimum. The identification of these isomeric glucosides is nevertheless difficult and failure to discriminate between them may lead to erroneous conclusions as to structure. In this connexion, it may be recalled that Haworth and Wylam (J., 1923, 123, 3125) obtained from gentiobiose a trimethyl methylglucoside melting at 92.5° and showing  $[\alpha]_D$  -25.1° in methyl alcohol. This was regarded as the 2 : 3 : 4-variety, a conclusion which is doubtless correct. But in studying the constitution of raffinose (Haworth, Hirst, and Ruell, J., 1923, 123, 3131) another preparation, possessing nearly the same specific rotation, but melting at 74°, is also claimed to be 2 : 3 : 4-trimethyl methylglucoside. The statements are irreconcilable, as, if the melting point of the latter preparation was depressed by the presence of the stereoisomeric  $\alpha$ -form, the specific rotation would

not remain the same, but would be displaced in the dextro-direction. In our examination of these glucosides we have never encountered a form of 2 : 3 : 4-trimethyl methylglucoside melting at 74° and the inconsistency becomes more acute if it be assumed that this figure is a misprint for 94°. We cannot accept, therefore, Haworth's constitution for raffinose, a conclusion further justified by the fact that it contains a melibiose residue based on the formula for maltose recently shown to be incorrect.

### *Discussion of Results.*

As starch is not a uniform homogeneous polysaccharide, limitations must be placed on any discussion regarding constitution, but the results now contributed afford proof that starch consists essentially of a mixture of polymerides which are based on the same molecular unit. The structural similarity displayed by these constituents lies in the fact that there are three hydroxyl groups present in the same positions in each  $C_6$  chain, and it is thus possible to elucidate the constitutional factors which are common to all the components. The expression "starch," as used in this discussion, applies therefore to constituents, amounting to 60—70% of the total, which conform to the above generalisation in that they are convertible into 2 : 3 : 6-trimethyl glucose, but differ in the degree of polymerisation.

The possibility that starch may be derived from  $\beta$ -glucosan has already been rejected and is again refuted by the results of the present investigation. There remains consideration of the relationship to maltose and to isomaltose, but here complications are at once encountered. These difficulties are due in part to inadequate knowledge of isomaltose, but are mainly attributable to the confusion which has arisen regarding the constitution of the diglucoses as a class. So far, three disaccharides (maltose, cellobiose, and isocellobiose) have been shown to be convertible into 2 : 3 : 6-trimethyl glucose, and the present research clearly points to the idea that isomaltose will be found to give precisely the same result. The formation of the above trimethyl glucose cannot, in consequence, be regarded as final evidence of the linkage of two glucose residues, as such a result fails to discriminate between two alternatives. It follows, also, that the oxydic ring in glucose cannot be restricted to the amylenoxide linkage alone, as otherwise it would be impossible to formulate all the diglucoses in terms of their properties. For example, the disaccharides postulated below are definitely isomeric and contain glucose residues with different oxygen rings, but each compound would be convertible into 2 : 3 : 6-trimethyl glucose, type I giving in the first place the  $\gamma$ -form of the sugar which

reverts to the stable variety, while type II would give the same final product directly.

Glucose 5-glucoside.

Glucose 4-glucoside.

It may be presumed that as cellobiose and *isocellobiose* form one structural pair, maltose and *isomaltose* will form the other, and the above types can therefore accommodate all four sugars. Pending the completion of further experimental work now in progress, it is inadvisable definitely to assign maltose and cellobiose to their respective types, but, in order to render the present discussion intelligible, formula I may be ascribed arbitrarily to maltose, in which case cellobiose conforms to formula II.

If starch is based on an anhydro-disaccharide unit, the simplest formula for the unpolymerised molecule becomes :

The hydrolysis of the "maltosan" postulated above would give maltose as the only disaccharide, the change including opening of one anhydro-linking followed by adjustment of the unstable oxygen ring in the non-reducing glucose component. Taking into account the difficulty in certifying that any preparation of maltose consists of a single homogeneous chemical individual, it is doubtful if the yield of maltose from starch is as great as that which would be given by a compound of the maltosan type. It would not be justifiable, however, at this stage to exclude maltosan as one of the molecular

units of starch, particularly as polyamyloses exist which contain an even number of  $C_6$  chains. The formula does not, however, admit of the formation, from starch, of a trihexosan or tri-amylose, and consequently consideration must also be given to a constitution based on the union of three glucose residues. Two possibilities exist :

No conclusive evidence exists which would serve to discriminate between these possibilities. A compound possessing formula (III) could undergo hydrolysis to give only maltose and glucose, whilst, according to formula (IV), maltose, an isomaltose and a non-reducing diglucose might result. This is perhaps improbable, as the existence of such hydrolysis products could scarcely have escaped detection, but, in any case, neither of the formulæ reveals the  $\alpha$ - or  $\beta$ -configuration of the individual glucose residues. The structures thus fail to account for the fact that starch is convertible into maltose under one set of conditions and into isomaltose when the conditions are changed. Similarly, they do not explain why the polyamyloses can be classified in  $\alpha$ - and  $\beta$ -series.

We do not share the view that the  $\alpha$ - or  $\beta$ -configurations of the methylated glucosides obtained from trimethyl starch afford a true index of the glucose configuration in the starch molecule and purely chemical methods of investigation throw little light on this important aspect of the structural problem. This evidence is, however, rapidly being accumulated in the important researches of Ling and Nanji, and if the results obtained by these workers are not utilised in the

present discussion it is owing solely to the desire to avoid trespass on their field of work.

Limiting the discussion to conclusions drawn from chemical reactions alone, the structures elucidated above may now be tested according to the peculiar behaviour of starch during methylation. The formation of a definite dimethyl starch (*i.e.*, 6 hydroxyl groups out of 9 substituted) is explained in terms of either formula, as the primary alcohol groups are the last to be methylated. Both formulæ also accommodate the production of a trimethyl starch but only formula (IV) offers any explanation as to why methylation can be arrested at the dimethyl stage (*i.e.*, when 6 hydroxyl groups out of 9 have been substituted) and thereafter slows down abruptly when 7 hydroxyl groups out of 9 have been alkylated. For this reason, formula (IV) is retained for further consideration. Much importance must be attached to the fact that methylated starch containing 37% of methoxyl is a definite compound which breaks down on hydrolysis to give exactly 2 molecules of dimethyl glucose and 1 molecule of trimethyl glucose. Reference to the experimental part will show that this compound was obtained under varying experimental conditions on eight successive occasions, so that the composition ascribed to it is unlikely to be fortuitous. Accepting this result, it follows that the molecular unit of starch must contain either nine or a multiple of nine hydroxyl groups. In other words, the simplest unit would be a trihexosan and the next possibility a hexahexosan. In order to explain the existence of polyamyloses containing an even number of  $C_6$  chains, it is, however, necessary to select the hexahexosan as the basal unit, so that the cyclic formulæ given above must be doubled, with a corresponding increase in the structural possibilities involved.

It is thus apparent that, approaching the study of starch by strictly chemical methods, conclusions are reached in close agreement with those arrived at in recent studies of enzyme action. It will be equally apparent that both types of investigation are necessary to solve the main factors involved in the starch problem, (1) the  $\alpha$ - or  $\beta$ -configuration of adjacent hexose residues, (2) the positions through which these residues are coupled, and (3) the degree of polymerisation undergone by the basal unit.

The research, which we regard only as preliminary, is being continued in various directions.

#### EXPERIMENTAL.

The starting material used in the research consisted of purified wheaten, potato, or rice starch, but the first-mentioned variety was discarded in favour of the others, which were found to give the same

methyated derivatives. To facilitate description, it may be stated that, throughout the work, all evaporations and distillations were conducted under reduced pressure.

*Dimethyl Starch.*—With a few modifications, the methylation was carried out as described by Irvine and Steele (J., 1920, 117, 1474) in the parallel case of inulin, and the following is the account of one typical experiment. 32 G. of starch were mixed with 150 c.c. of water and stirred mechanically whilst 160 c.c. of 12½% sodium hydroxide solution were added. This had to be conducted slowly, as otherwise the starch coagulated to a stiff jelly, a condition which is unsuitable for methylation. Thereafter, 140 c.c. of 50% sodium hydroxide solution and 80 c.c. of methyl sulphate were run in simultaneously, the addition being extended over 3 hours and adjusted so as to maintain the alkaline reaction. The liquid was kept at 35° and was vigorously stirred during the reaction, which was completed by heating at 100° for 40 minutes. After cooling, an equal volume of rectified spirit was added, and carbon dioxide passed through the solution for a prolonged period. The precipitated sodium salts were then removed by filtration through linen, and the filtrate was cautiously neutralised with dilute sulphuric acid. If kept over-night, a crop of sodium sulphate and sodium methyl sulphate separated, but as part of the product was retained by the crystals it was advisable to evaporate the liquid to a thick syrup and repeat the methylation a second time on the total product. In this and similar evaporations it was necessary to add barium carbonate, as otherwise acidity developed and hydrolysis occurred. For the same reason, the temperature was restricted to under 60°.

The aqueous-alcoholic solution of the product, obtained after the second methylation, was evaporated to dryness, and the residue extracted repeatedly with a large excess of boiling chloroform. The inorganic residues were similarly treated and yielded a further quantity of the methylated product showing the same composition (OMe, 22.7—23.6%). A third methylation was conducted on the material extracted by chloroform and thereafter the methylated starch was completely soluble in aqueous alcohol and was no longer occluded by the inorganic salts. The isolation of the product by extraction with chloroform was carried out as already described, but difficulty was experienced in filtering the chloroform solution by ordinary methods, as the methylated starch formed continuous films on the filter-paper. On removal of the solvent, a stiff syrup remained, readily convertible into a white powder; soluble in cold water, hot alcohol, and in chloroform, insoluble in ether. Traces of reducing sugars were present and the aqueous solution gave a

yellow colour with iodine which was not discharged on heating. OMe = 27.2%. Yield 22 g.

The silver oxide reaction was now applied to the product, which was boiled with excess of methyl iodide to which methyl alcohol was gradually added until the solution became comparatively clear. Silver oxide (51 g.) was then added in small amounts, and the mixture kept at the boiling point for 8 hours. Boiling ethyl alcohol was used as the extracting agent, the turbid solution being evaporated and the residue dissolved in chloroform. The silver salts were also extracted in a Soxhlet apparatus with the same solvent, the extracts being united and the product recovered. Repetition of the alkylation in the same manner had very little effect on the methoxyl content, but, apparently owing to depolymerisation, the solubility of the product in methyl iodide increased steadily with each treatment. Concurrently, and contrary to general experience, the experimental loss increased with the solubility in methyl iodide.

No. of silver oxide methylations.	Wt. of methylated starch.	Vol. of MeOH required.	Methoxyl content.
1	21 g.	65 c.c.	27.8%
2	19	39	28.8
3	15	20	28.6
7	6	3	28.9

The loss in yield was due to combination of part of the product with silver iodide as in the case of methylating glucosamine (Irvine and Hynd, J., 1912, 101, 1128). On extracting the plastic solid with boiling water for several hours the solution contained carbohydrate, a secondary amine and phosphate.

Various attempts to purify the methylated starch obtained by the above operations were made, the most successful being boiling in chloroform solution with charcoal, but as this involved loss the material was separated into two portions by allowing an ethyl alcohol solution to stand in the cold. Any insoluble syrup which separated was removed and again methylated by the silver oxide reaction, so that ultimately the entire product was obtained in the soluble form. As the material had now acquired complete solubility in methyl iodide, two further methylations were given without the use of any extraneous solvent. In this way, dimethyl starch was obtained as a white powder, free from mineral matter and soluble in water, the solution giving no colour with iodine (Found: C, 50.4; H, 7.4; OMe, 32.7. Dimethyl starch requires C, 50.5; H, 7.4; OMe, 32.7%).  $[\alpha]_D$  in chloroform + 135.7° for  $c = 1.916$ .

*Hydrolysis of Dimethyl Starch.*—This reaction was conducted in the first place by heating a dilute solution in 2.5% hydrochloric acid on a boiling water-bath for 3 hours. As the solution remained turbid,

the acid concentration was raised to 4% and heating was continued for an additional 3 hours, the reaction being completed by raising the temperature to 110° for 30 minutes. On filtering, a small quantity of a brown solid remained behind, and as this material still contained methoxyl it apparently consisted of one component of dimethyl starch which is highly resistant to hydrolysis. The clear filtrate, containing dimethyl glucose in solution, was treated so as to remove organic acids and was finally extracted with boiling acetone. The extract contained a thick syrup which when dissolved in ethyl acetate partially crystallised, but the solid could not be isolated in sufficient amount for identification. The solubilities, rotation and analytical composition of the syrup were, however, identical with those ascribed to 2 : 3-dimethyl glucose (Irvine and Scott, J., 1913, 103, 575). Yield 75%.  $[\alpha]_D + 50.3^\circ$  in acetone for  $c = 1$  (compare 2 : 3-dimethyl glucose,  $[\alpha]_D + 50.9^\circ$  in the same solvent).

*Preparation of Methylated Starch.*

The expression "methylated starch" is applied to the derivative in which seven hydroxyl groups out of nine have undergone methylation, the formation of this compound being characterised by a sharp cessation in the methoxyl increase. In each experiment, 32 g. of starch were used, the initial procedure being as described in the preparation of the dimethyl derivative. After four successive treatments with methyl sulphate, the insolubility of the product in the alkaline liquor enabled the isolation to be greatly simplified. The liquid was poured away from the coagulated mass of organic material and the latter was dissolved in boiling rectified spirit, the solution being neutralised with dilute sulphuric acid. After removal of the precipitated sodium salts, the filtrate was evaporated in the presence of barium carbonate, and the residue extracted with boiling chloroform. Removal of the solvent left a stiff syrup which was boiled with dry ether to remove traces of solvent, a treatment which converted the product into a white flaky powder (Found in material dried at 100°/15 mm.: C, 51.1; H, 7.6; OMe, 35.5. "Methylated starch" requires C, 51.2; H, 7.5; OMe, 37.0%). Yield 21 g.

When the above methoxyl content had been attained the application of the silver oxide reaction had practically no effect on the composition (Found: C, 51.1; H, 7.5; OMe, 36.3%;  $[\alpha]_D$  in methyl alcohol  $+ 186.3^\circ$  for  $c = 1.934$ , in chloroform  $+ 168.1^\circ$  for  $c = 2.029$ ). Methylated starch displayed the same range of solubility as dimethyl starch and similarly had no action upon Fehling's solution. When acetylated by means of acetic anhydride in presence of sodium acetate, it was converted into a granular acetate showing  $[\alpha]_D$  in chloroform  $+ 191.7^\circ$ . The acetyl content (11.8%) agreed

with the value calculated on the basis that two out of nine hydroxyl groups originally present in starch resisted methylation and, on subjecting the acetate directly to the methyl sulphate reaction, the original material was regenerated (OMe = 36%).

Similarly, the use of diazomethane was ineffective in raising the methoxyl value, which remained remarkably steady in eight successive preparations of methylated starch (Found : OMe, 35.6; 35.4; 35.2; 36.3; 35.8; 35.2; 35.4; 35.5%). The specific rotation in chloroform also showed little variation, the extremes being  $[\alpha]_D +151.5^\circ$  and  $152.6^\circ$  for  $c = 1.25$ . These results point to the idea that methylated starch is a homogeneous definite compound, but it may be emphasised that the above specific rotation is greatly increased if in the preparation of the compound the methyl sulphate reaction is supplemented by treatment with silver oxide and methyl iodide. Typical examples are quoted :

Methylations.			
(a) With methyl sulphate.	(b) With methyl iodide.	$[\alpha]_D$ .	Solvent.
4 followed by	1	+168.1°	Chloroform.
4           "	3	169.5	"
5           "	2	173.9	"
4           "	3	186.2	Methyl alcohol.

Reasons exist for the belief that this alteration in rotatory power is attributable to depolymerisation.

#### *Hydrolysis of Methylated Starch.*

A 10% solution of methylated starch in methyl alcohol containing 1% of hydrogen chloride was kept at the boiling point until the activity was nearly constant. Initially, the solution was opalescent, but rapidly cleared so that accurate readings were possible. Some typical results are quoted below, the complete series giving a smooth, unbroken curve.

Time from start (hours) ...	2	3	5	6	7	8
$[\alpha]_D$ .....	+114.4°	+99.8°	+81.7°	+75.0°	+70.3°	+69.8°

The product, consisting of a mixture of methylated glucosides, was isolated in the usual manner and formed a clear viscous syrup. Practically the whole of the material dissolved in boiling ether and the syrup obtained on removal of the solvent was dried at  $100^\circ/1$  mm. Yield 21.8 g. from 23 g. of methylated starch.

The two components, *viz.*, trimethyl and dimethyl methylglucosides, were separated by a tedious method which need not be described as it has been superseded by a superior process. The trimethyl methylglucoside was finally distilled at  $120^\circ/0.7$  mm. as a colourless liquid ( $n_D$  1.4585) which crystallised. When purified

from light petroleum, the crystals melted at  $57^{\circ}$  and showed  $[\alpha]_D - 20^{\circ}$  in methyl alcohol (Found: C, 50.6; H, 8.5; OMe, 52.2. Calc. for trimethyl methylglucoside: C, 50.8; H, 8.5; OMe, 52.5%). The glucoside was converted into crystalline tetramethyl glucose by the usual processes, thus showing that it belongs to the stable type, and when hydrolysed with aqueous hydrochloric acid gave crystalline 2:3:6-trimethyl glucose in 94% yield (mutarotation in methyl alcohol  $+ 83^{\circ} \rightarrow 68.3^{\circ}$ . OMe, 41.8. Calc. for trimethyl glucose, 41.9%). A careful search for tetramethyl glucose and for 2:3:4-trimethyl glucose gave entirely negative results. The dimethyl methylglucoside fraction distilled at  $140^{\circ}/0.4$  mm. as a viscous liquid (Found: C, 48.6; H, 8.1; OMe, 42.0. Calc.: C, 48.6; H, 8.1; OMe, 41.9%). As the compound was unknown, it was examined in some detail. On complete methylation, it was converted into tetramethyl methylglucoside, the  $\beta$ -isomeride being present in excess, and when condensed with benzaldehyde it gave a benzylidene derivative. This crystallised imperfectly and could not be characterised definitely as the benzylidene dimethyl methylglucoside described by Irvine and Scott (J., 1913, 103, 575), although the similarity was very marked. Hydrolysis of the glucoside with aqueous hydrochloric acid gave the corresponding dimethyl glucose as a clear glass. This had the correct analytical composition and showed  $[\alpha]_D + 56.6^{\circ}$  in acetone solution, but the material failed to crystallise. The sugar formed no phenylosazone and did not condense with acid acetone, properties which further suggest that the compound was 2:3-dimethyl glucose, but oxidation with nitric acid under the conditions described by Haworth and Leitch (*loc. cit.*) gave a complex mixture. It was, in fact, the study of this reaction which directed our attention to the untrustworthy nature of such oxidations.

With regard to the yields of the glucosides obtained from methylated starch it is important to note that tetramethyl methylglucoside was absent and monomethyl methylglucoside was present to an extent not exceeding 5%. The ratio of the dimethyl to the trimethyl methylglucoside was 1.85:1, a result which shows that 2 molecules of the former were produced to 1 molecule of the latter (calc., 1.88:1). This was confirmed by repeating the complete series of experiments.

#### *Preparation of Trimethyl Starch.*

The methylation of starch may be carried to completion by continuing the methyl sulphate reaction in the manner now described. At the conclusion of the fourth methylation, when the reaction mixture was raised to  $100^{\circ}$  to destroy excess of methyl sulphate, the

liquid was saturated with salt. The hot liquor was then poured away, leaving the methylated starch adhering to the flask as a plastic mass. On adding hot water, a homogeneous syrup was gradually formed, and this was subjected directly to the next methylation, but at regular intervals the product was separated in a pure condition in order to ascertain with certainty the yields and analytical composition. The homogeneous aqueous syrup was therefore carefully neutralised with sulphuric acid and, after dilution with water, extracted by shaking with chloroform. The residue left on evaporation of the solvent was dried and taken up in dry chloroform, the solution being boiled for 20 minutes with charcoal and filtered hot. A hard, brittle material was left on removal of the chloroform and this, on boiling with ether, was converted into a white, amorphous powder. The treatment with ether eliminated traces of solvent and also removed a small quantity of depolymerised material. The following table indicates the progressive nature of the methylation :

No. of methylations .....	5	10	14	20	24
% OMe .....	35.5	39.6	41.4	43.2	43.7
$[\alpha]$ in $\text{CHCl}_3$ ( $c = 1.7$ ) ...	+173.9°	+196.8°	+204.8°	+207.2°	+216.5°

At each stage, the carbon and hydrogen values were consistent with the methoxyl content, thus showing that the methylation proceeded without molecular rupture.

Starting from 32 g. of starch, the average yield after ten methylations was 15 g. and thereafter the experimental loss was regular, amounting to less than 0.4 g. per treatment. The final product (10 g., m. p. 143—146°) was a white powder less soluble in hot water than in cold, insoluble in ether, readily soluble in chloroform and in methyl alcohol. The aqueous solution was neutral, had no action upon Fehling's solution and gave no coloration with iodine (Found : C, 52.6; H, 8.0; OMe, 43.75. Calc. for trimethyl starch : C, 52.9; H, 7.8; OMe, 45.6%).

#### *Hydrolysis of Trimethyl Starch.*

*Method (a). Uncontrolled Hydrolysis.*—An 8% solution of methylated starch in methyl alcohol containing 1% of hydrogen chloride was heated at 100° for 24 hours and thereafter at 130° for 12 hours. The solution, which remained practically colourless, was neutralised with silver carbonate, filtered, taken to dryness, and the residue dissolved in ether. On filtering and evaporating, a colourless syrup remained (yield 94% of the theoretical amount) which was distilled under 0.1 mm. pressure. As the first drops of the distillate showed  $n_D$  1.4551 and had OMe 51.4%, tetramethyl methylglucoside was definitely absent. The main fraction (yield

84%), which showed  $n_D$  1.4583 and OMe 51.9%, consisted of trimethyl methylglucoside, a small, undistilled residue (OMe, 44%) being left in the flask. As under the conditions of the experiment the methylated glucoside was a mixture of  $\alpha$ - and  $\beta$ -forms, it failed to crystallise (Found: C, 50.6; H, 8.4; OMe, 51.9. Calc. for trimethyl methylglucoside: C, 50.85; H, 8.5; OMe, 52.5%.  $[\alpha]_D$  in methyl alcohol + 69.8° for  $c = 1$ ).

The glucoside was thereafter hydrolysed by heating at 100° in 5% aqueous hydrochloric acid, the progress of the reaction, which was followed polarimetrically, displaying the characteristic double change in activity.

Time from start.	$[\alpha]_D$ for $c = 5$ .	Time.	$[\alpha]_D$ .
15 minutes.	+69.1°	3 hours.	+69.3°
45 minutes.	79.2	3 hours 45 minutes.	72.4
1 hour 45 minutes.	74.6	4 hours.	76.4
2 hours 30 minutes.	63.9		

The hydrolysis sugar, on isolation, crystallised immediately and completely, the m. p. before crystallisation being 70–80°, and, after purification from ether, 114°. This value remained unaffected on admixture with an authentic specimen of 2 : 3 : 6-trimethylglucose obtained from cellulose. The yield of crystalline sugar was 77% and the mother-liquors contained only a small quantity of uncrystallisable syrup. Contrary to expectation, this was not the isomeric 2 : 3 : 4-trimethyl glucose, as on conversion into the corresponding acetobromide and thereafter into trimethyl  $\beta$ -methylglucoside the product, after recrystallisation, melted at 57.5°. The compound also showed the correct mixed melting point and the standard specific rotation for 2 : 3 : 6-trimethyl methylglucoside.

*Method (b). Graded Hydrolysis.*—In this case, the hydrolysis was controlled so as to trace the stages of the reaction. The methylated starch (12 g.) was dissolved in 250 c.c. of methyl alcohol containing 1% of hydrogen chloride and boiled under a reflux condenser until the activity of the solution diminished to a minimum. This point was reached in from 8 to 9 hours and the product was isolated in the usual way. When distilled under 0.8 mm., 10.5 g. of pure trimethyl methylglucoside were obtained, whilst 2.8 g. remained undistilled. The distillate crystallised readily and, after purification from low-boiling petroleum, melted at 57.5° and showed  $[\alpha]_D -29.3^\circ$  in methyl alcohol for  $c = 1$ . When it was hydrolysed with 5% aqueous hydrochloric acid, the specific rotation altered from  $-25.4^\circ$  to + 59.5° in 200 minutes, and crystalline 2 : 3 : 6-trimethyl glucose was ultimately obtained, the yield being 82%. A portion of the trimethyl methylglucoside failed to crystallise, but this material, which presumably contained the  $\alpha$ -isomeride, was recovered from

the tile and hydrolysed separately. In this case also, 2:3:6-trimethyl glucose was the only sugar formed.

As already stated, 2.8 g. of non-volatile material were left undistilled when the hydrolysis of methylated starch was conducted as now described. The substance was a hard glass and consisted of depolymerised trimethyl starch (Found: C, 52.5; H, 8.0; OMe, 43%), as the composition remained unaltered but the solubility had increased while the specific rotation had diminished to  $+86.9^\circ$  in chloroform. Hydrolysis took place only when this material was heated for many hours at  $130^\circ$  with methyl alcohol containing 1% of hydrogen chloride, but the essential product was, as before, 2:3:6-trimethyl methylglucoside (OMe 41.6%;  $n_D$  1.4590). This, in turn, was converted into crystalline 2:3:6-trimethyl glucose, the identity of which was confirmed by transformation into the corresponding  $\beta$ -methylglucoside. No trace of the 2:3:4-isomeride could be detected.

The authors gratefully acknowledge their indebtedness to the Carnegie Trust for a Research Scholarship and a Research Fellowship which enabled one of them to devote 4 years to the investigation.

## CXCVI.—*The Ultra-violet Spectra of Praseodymium, Neodymium, Samarium, Europium, and Erbium.*

By JAMES HENRY GARDINER.

VERY little work has been done in the photography of the ultra-violet absorption spectra of the rare earths, possibly on account of the rarity of the elements themselves and of the difficulty of photography.

Having in my possession specimens of many of the rarer elements in a state of purity, I thought that it would be of interest to place on record photographic reproductions of the absorption spectra of some of them. The five named above were found to give well-defined absorption bands in the region under examination; these spectra are shown together with a photograph of the light used to produce them. Photographs of this character lose much of their value unless care is taken to ensure uniformity in the conditions under which they are produced.

The spectrograph used is of novel design and has been constructed

purposely for this class of work; it consists essentially of a pair of quartz "Cornu" prisms with plano-convex collimating and object lenses. The "comparison spectrum" that is given in each case is put into position without any movement of the film by passing the radiation into the spectrograph through an aperture in a metal disc which is fixed in front of the slit; this disc has holes of different sizes and in different positions and it can be moved so as to confine the radiation entering the instrument to any one of them at will.

For this work it was necessary to use a very narrow slit, and it was essential for purposes of comparison that there should be no variation from the width in any of the spectra. A thick brass plate with a slot 2 mm. wide and 10 mm. long was made, and by the point, slot, and plane method it could be accurately fixed in the optical centre of the quartz train; upon the flat surface of the plate, jaws of hard steel with accurately ground edges were clamped at the determined width of 0.03 mm. This device of a slit with jaws that are immovable removes any possibility of accidental variation in its width such as would arise if it were adjusted by a screw.

All the photographs given are made with the same slit. The light used for the absorption spectra was produced by passing a high-tension current between electrodes of metallic uranium, producing a spark very rich in ultra-violet radiation. The spectrum of uranium has such a great number of lines so close together that, for the present purpose, it may be regarded as continuous.

At the top of each absorption spectrum and slightly overlapping it, is projected the spark spectrum of an alloy of the metals zinc, cadmium, mercury, and tin. These elements give well-defined lines of which the wave-lengths are known to a great degree of accuracy; their values given on each photograph make it possible, by means of a simple interpolation curve, to find the value of any of the bands shown. The wave-lengths of the approximate centres of the bands are given, although the photographs themselves are of more value than tables of wave-lengths and descriptions of the bands.

It was considered essential that the strengths of the solutions, *i.e.*, the amounts of the element present in each case, should be comparable or at least accurately known. The rarity of the materials available, and the obscurity of the chemistry of some of them, made this a matter of difficulty, but after some preliminary work it was decided to take the crystalline nitrates which have the general formula of  $R(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$  as the basis of the solutions. These salts are easy to prepare and are soluble in water. As in some cases only a fraction of a gram of the element was available, it was decided to make all solutions from a weighed quantity of the

salt with ten times its weight of water. The solutions were in all cases put into a cell made from a glass cylinder, 20 mm. long, closed at the ends with plates of thin quartz.

The procedure for the production of a photograph was as follows. By adjusting the aperture-disc so that the light passed into the upper part of the slit, an exposure was made to the light from the metallic alloy, and the disc was then rotated so as to present another opening slightly overlapping the first; the cell containing the solution was fixed in front of the slit, an exposure was given for 3 minutes to the uranium spark, the disc was again shifted so as to expose another part of the slit, and the solution was removed and another exposure given to the same light for the same time; this last exposure was considered to be advisable for reasons that will appear later.

In addition to the five elements that form the subject of this paper, 1 : 10 solutions of the nitrates of the following elements were made and their absorption spectra were photographed: lanthanum, ytterbium, gadolinium, terbium, thorium, cerium, and scandium. They did not show any absorption bands in the region under examination, *i.e.*, from  $400\mu$  to the commencement of transmission, which in all cases was at about  $350\mu$ . The elements giving absorption bands are described in the order of their atomic numbers.

*Praseodymium.*—This specimen was prepared some years ago by Thompson. The nitrate gives well-defined crystals dissolving easily in water to a brilliant green solution; the dried crystals,  $\text{Pr}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$ , were used for the solution which was placed in the cell described above. The spectrum shows that it is quite free from neodymium and gives three well-defined bands at the least refrangible end; the approximate centres of the bands are  $482\mu$ ,  $468\mu$ , and  $442\mu$  (Fig. I).

*Neodymium.*—This material was obtained from the Welsbach Co. in the form of deliquescent crystals of pale rose colour; it was recrystallised by keeping the solution over sulphuric acid and gave good crystals of  $\text{Ne}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$ . The spectrum (Fig. II) shows that the material is not quite free from praseodymium, but the three bands corresponding to this element are very faint; the bands of neodymium, however, are definite, and in this region of the spectrum are represented by a very faint and narrow band midway between the two least refrangible bands of praseodymium, at  $474.5\mu$ , and a well-defined group of three bands which do not appear to have been recorded hitherto; the wave-lengths of their maxima are approximately:

$353\mu$ . Centre of the strongest part of a band having a broad wing on its least refrangible side;

1

350.5  $\mu$ . Brightest edge of a band, fading off at the most refrangible edge;

346.7  $\mu$ . Centre of the most refrangible band.

An interesting confirmation of the allocation of the faint band at 474.5  $\mu$  to neodymium is seen by reference to Fig. III, which is the absorption spectrum of a 1 : 10 solution of the nitrate of a specimen of didymium prepared, in the form of a dark brown oxide, by Cleve in 1884—some 12 months before Welsbach announced his discovery of the complex nature of the substance. It can be seen that all the bands of praseodymium and neodymium are visible, including the faint one at 474.5  $\mu$ .\*

*Samarium.*—Samarium nitrate forms yellow crystals of  $\text{Sm}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$ . The spectrum of its solution is characterised by a very strong band having sharp edges and by four other broad, but faint, bands; there is also an indication of a fifth band, but it is too faint to measure. As the spectrum as a whole did not seem to correspond to the description given by Demarcay (*Compt. rend.*, 1900, 130, 1185), other photographs of it were made using stronger solutions, but the character of the bands did not change. The measurements of the approximate centres of the bands are (Fig. IV) :

First faint band : 479  $\mu$ . Centre of dominant band : 402  $\mu$ .

Centres of other faint bands : 375  $\mu$ , 362  $\mu$ , 344  $\mu$ .

*Europium.*—This element is one of the rarest of the yttria earths. The oxide of the specimen under examination was of a faint cream tint, whereas it is said to be light pink. The spectrum shows a strong but narrow band with a very sharp edge on the more refrangible side, and one other faint but equally sharp band; the wave-lengths of the approximate centres are 393  $\mu$  and 361  $\mu$  (Fig. V).

Another specimen of this earth from an unknown source gave exactly the same spectrum.

*Erbium.*—The material from which the nitrate was prepared was a pink oxide prepared by Cleve in 1885. The wave-lengths of the absorption bands as determined by various observers vary considerably, but in this case there was one dominant band accompanied by four others that are all very faint; the wave-lengths of the approximate centres are as follows (Fig. VI) :

A strong band at 485  $\mu$ ; a very faint band at 449  $\mu$ .

\* In discussing the spectrum of neodymium, J. F. Spencer ("The Metals of the Rare Earths," 1919) states that a band with a maximum at 469  $\mu$  coincides exactly with one of the praseodymium bands and that this has led to the view that these substances contain an undiscovered element. The photographs of Cleve's old didymium and of the later praseodymium and neodymium fail to justify this view, as all the bands of the old element in this region of the spectrum are accounted for

The dominant band, sharp on the least refrangible side, at  $379\ \mu$ .

A very faint band, which is crossed by a strong uranium line (from the source of light), at  $363\ \mu$ .

A very faint line at  $365\ \mu$ .

This element is said to be slightly radioactive and a photographic experiment was therefore made: the oxide was filled into a tube closed at the end by a sheet of aluminium foil 0.04 mm. thick, which was fixed on a photographic plate so that the oxide was separated from the sensitive surface by the aluminium, and it was shut up in a dark box for 7 days. On developing, a faint but decided impression was obtained, where the oxide had rested. A similar experiment made with europia also gave an indication of radioactivity, but much more feebly.

[Received, January 27th, 1926.]

## CXCVII.—*Extinction of Methane Flames by Diluent Gases.*

By HUBERT FRANK COWARD and FRANCIS JOHN HARTWELL.

IN the course of an investigation on the influence of black-damp (a mixture of nitrogen and carbon dioxide) on the limits of inflammability of firedamp (methane) in air (Safety in Mines Research Board, Paper No. 19; London, H.M. Stationery Office, 1926), some new information has been obtained concerning the factors which determine whether or not a gas mixture is capable of self-propagation of flame. Volume for volume, carbon dioxide exceeds nitrogen in its extinctive action on flame—an effect which is generally attributed to the higher molecular heat capacity of the former. Argon, a gas of lesser heat capacity than either, proves to have less extinctive action. On the other hand, helium is much more extinctive of flame than argon, although the two have almost exactly the same heat capacities.

The limits of inflammability of methane, in various "atmospheres," composed of mixtures of air with one or other of the diluent gases, were determined in a vertical glass tube, 6 feet long and 2 inches in diameter. This tube was filled with an appropriate mixture, the lower end was then opened by sliding away a ground-glass joint and a small spirit-lamp flame was immediately passed across the aperture. The tube was sufficiently long to enable observers to judge whether a flame was self-propagating; for, if the mixture were incapable of continued self-propagation

of flame, the "cap" of flame formed above the source of ignition was extinguished within 2 feet of its passage up the tube.\*

*General Observations on the Flames.*

The flame front, as the flame passed up the tube, was in all cases nearly hemispherical in shape, sometimes with a hollow, cylindrical extension of variable length. The blue flame front was followed by a red glow in all upper-limit mixtures, an evidence of some residual chemical reaction. The speed of propagation of flame in all limit mixtures, lower or higher, was remarkably constant at 22 to 23 cm. per second, except that the speed was somewhat higher when helium was the diluent used.

The flames in certain upper-limit mixtures vibrated rapidly when within 1 or 2 feet of the top of the tube. During these vibrations the flame, on occasion, was extinguished; however, when a pad of cotton wool was held loosely over the open end of the tube during the progress of the flame, vibrations were not observed and the normal shape of flame front and speed of propagation were obtained. Furthermore, the flame vibration started at the moment when the contraction due to cooling behind the flame became equal to, or just exceeded, the expansion due to new combustion; *i.e.*, at the moment of change, at the open mouth of the tube, from an outflow of gases to an inflow of air.

These observations afford a clue to an understanding of the causes of vibration in flames travelling along tubes, and will, it is hoped, form the subject of a later communication.

*Limits of Inflammability of Methane-Air Mixtures in the Tube Used.*—The limits in the circumstances described were 5.24% methane (lower) and 14.02% (higher).† These may be taken as accurate to 0.02%. Most of the results in the following sections were determined within 0.05%.

\* In all the experiments recorded here, the gases were roughly dried by passage over calcium chloride, and contained less than 0.1% of moisture. They were at laboratory temperature up to the time of inflammation, and at laboratory pressure during the whole time of passage of the flame; the latter condition was secured by leaving the lower end of the tube open while the flame was passing up the tube. Ordinary variations in laboratory temperature and pressure have no measurable effect on the limits of methane-air mixtures (Mason and Wheeler, J., 1918, 113, 45).

† When the gases were saturated with water vapour (1.9%) at the temperature of the experiment, the limits proved to be 5.22% methane (lower) and 13.54% (higher). These are the actual proportions of the gas present in the moist mixture; expressed (as usual from gas analyses) as percentages of the water-free mixture, they become 5.33 and 13.80. These last figures may be compared with earlier determinations which are, as a rule, expressed in this manner.

*Influence of Carbon Dioxide on the Limits of Inflammability of Methane-Air Mixtures.*—The heavy curve in Fig. 1 represents the limits of inflammability of methane in atmospheres composed of pure air admixed with the indicated amounts of carbon dioxide. The limits are narrowed as the amount of diluent gas is increased, until they meet when the atmosphere contains somewhat less than 25% of carbon dioxide. The increase in the lower limit is

apparently due to the greater thermal capacity of the carbon dioxide, whilst the decrease in the higher limit is due to the combined effect of this and of the reduction in oxygen content of the atmosphere.

In the same figure are plotted results obtained by Eitner (*Habilitationsschrift*, München, 1902), Clement (*U.S. Bureau of Mines*, 1913, Technical Paper 43), and Leprince-Ringuet (*Compt. rend.*, 1914, 158, 1999). They are not strictly comparable, however,

for the conditions of experiment were somewhat different in each case. Thus Eitner's and Leprince-Ringuet's refer to experiments on the downward propagation of flame in these mixtures, and Clement's to the propagation from a point near the top of a Hempel burette, or of a steel cylinder of some 3 litres capacity. The wider

limits indicated by our experiments, in which upward propagation was observed, were therefore to be expected.

*Influence of Nitrogen on the Limits of Inflammability of Methane-Air Mixtures.*—The heavy curve of Fig. 2 represents correspondingly the limits of methane in atmospheres composed of pure air admixed with the indicated amounts of nitrogen. The extinctive effect of nitrogen is considerably less than that of carbon dioxide, for the two limits do not coincide until about 38% of added nitrogen

is present in the atmosphere, as compared with 25% of carbon dioxide. These figures are almost exactly in the inverse ratio of the mean molecular heats (at constant pressure) of the two gases between room temperature and the flame temperature. Hence the difference in extinctive action is doubtless due to the difference in heat capacities of the two diluents. The lower limit shows a small but definite rise with increase in the proportion of nitrogen. As this diluent has the same heat capacity as air up to, and beyond, the flame temperatures of these experiments, this small rise must be ascribed to the reduction of the oxygen content of the atmosphere. The effect is masked by the operation of other factors when other chemically inert diluents are used.

Fig. 2 shows also the results of Clement (*loc. cit.*), Leprince-Ringuet (*loc. cit.*), and Burgess and Wheeler (J., 1914, 105, 2596). Here, again, the results are not closely comparable with the present series, for they were obtained under different conditions; but whereas for carbon dioxide-air "atmospheres" all the previous results showed narrower limits than those now presented, one set of the nitrogen results (Burgess and Wheeler's) shows, in general, greater values for the higher limits. Now those experiments were conducted in closed vessels, wherein the pressure rose considerably (several atm.) during the inflammation, and Mason and Wheeler (J., 1918, 113, 45) have shown that increase of pressure increases markedly the higher limit of methane-air mixtures.

*Influence of Argon on the Limits of Inflammability of Methane-Air Mixtures.*—If the conclusions drawn from the experiments with atmospheres containing carbon dioxide and added nitrogen are correct, the lower limit of methane will have smaller values in atmospheres made from air and argon than in air itself, for argon has a lower heat capacity than air. Fig. 3 shows that such is the case, and that the minimum value of the lower limit is 4.40% of methane in an atmosphere composed of about 47% of argon and 53% of air, as compared with 5.24% of methane in the case of pure air. It requires nearly 51% of argon in admixture with air to produce an atmosphere which cannot form an explosive mixture with methane.

*Influence of Helium on the Limits of Inflammability of Methane-Air Mixtures.*—The heat capacity of helium is very nearly equal to that of argon and each, apparently, remains constant up to high temperatures. If, therefore, the extinctive effect of an inert gas is solely due to its thermal capacity and to its effect on the oxygen concentration of the atmosphere, the limits of methane should be identical in atmospheres composed of ordinary air mixed in one case with argon and in another case with an equal volume

of helium. Fig. 3 shows the action of helium, which, contrary to expectation, is markedly more extinctive of methane-air flames than is argon.\* From a detailed consideration of the physical differences between these two gases, we ascribe the superior extinctive action of helium to its greater thermal conductivity,† which is more than eight times that of argon, at laboratory temperatures. We have no experimental information about the temperature coefficients of the conductivities of such mixtures as we are using,

FIG. 3.

\* A mixture of composition  $\text{CH}_4 + 2\text{O}_2$  was diluted with (a) argon, (b) helium, until it was no longer inflammable. The limit mixtures contained (a) 3.95, (b) 5.00% methane. For downward propagation of flame in a tube of the same size, firing from near the open end, similar results were obtained; in an atmosphere composed of 80% of air and 20% of inert gas, the lower limits were (a) 5.50, (b) 5.75% methane when the inert gas was (a) argon, (b) helium.

† The thermometric conductivity, or diffusivity, which is equal to the thermal conductivity divided by the specific heat ( $C_p$ ) of unit volume, is the function which would have to be used in a quantitative analysis of the phenomena of flame transmission. In the present argument, the terms may be used interchangeably.

but some indication is given by Stafford's work (*Z. physikal. Chem.*, 1911, 77, 66) on the temperature coefficients of the conductivities of air and carbon dioxide separately, and Weber's work (*Ann. Physik*, 1917, 54, 481) on the conductivities of some mixed gases at laboratory temperatures. It seems highly probable that the thermal conductivity of a gas mixed with helium will be greater than that of a corresponding mixture with argon, and that this will be true at the somewhat high temperatures of the flames in limit mixtures. At first sight, it is surprising that the higher thermal conductivity of helium should be responsible for its greater extinctive action; but if the propagation of flame is due to conduction of heat, then at either zero or infinite values of the thermal conductivities flame would not be propagated. Between the two values, zero and infinity, an optimum value for the conductivity must obtain; so it is evident that the higher conductivity of the helium mixtures may well be less favourable to flame propagation in limit mixtures than the lower conductivity of the argon mixtures.

This conclusion is in good accord with, and receives support from, observations made by Coward, Cooper, and Jacobs (*J.*, 1914, 105, 1069). They found that it was much more difficult to ignite, by the electric discharge, mixtures of various gases when diluted with helium than when argon was used, and they interpreted the results in a similar manner.

#### *General Discussion.*

If, therefore, it is probable that the differences between the argon and helium curves are due to the different thermal conductivities of the two gases, it is necessary to consider how far the discovery of the influence of this factor may affect our previous conclusions as to the influence of varying heat capacities.

The thermal conductivities at 0° of the gases under consideration are (Glazebrook, "Dictionary of Applied Physics," 1922, vol. 1, p. 459)

Helium .....	$32.7 \times 10^{-3}$	Nitrogen .....	$5.14 \times 10^{-3}$
Argon .....	3.85 "	Air .....	5.22 "
Carbon dioxide .....	3.25 "		

The difference in thermal conductivity between carbon dioxide and nitrogen (1.9 units) seems far too small to account for the difference in extinctive action between these two gases, for there is about the same difference in extinctive action between helium and argon for a very much greater difference in thermal conductivity (28.9 units). We may therefore adhere to our earlier conclusion that the thermal capacity factor is predominant in determining the relative extinctive effects of two diluent gases, but we may

add that, when a gas of very different thermal conductivity is introduced, then this factor will become important.

*A Connexion between Lags on Ignition and Dilution Limits.*—When inflammable mixtures of methane and air are heated to any temperature above their ignition temperature, a distinct interval of time must elapse before inflammation is observed. The relative ease of ignition of methane-air mixtures containing the various diluents used in this research, as indicated by their relative "lags" on ignition, might be regarded as a governing factor in determining the order of the limits. Determinations of such "lags" have recently been made in the Safety in Mines Research Board Laboratories in connexion with another research which will be published shortly. At the temperature of the flames in limit mixtures (calculated to be between 1100° and 1400°) the lags, under the conditions of experiment, were too short to be measured for comparative purposes, but at 950° they were reasonably long, and are shown for 6% methane mixtures in atmospheres containing 30% of diluent. The same table also shows the limiting proportion of the diluent which is completely extinctive at normal temperature and pressure.

Diluent.	Carbon dioxide.	Nitrogen.	Helium.	Argon.
Lag (seconds) .....	0.275	0.25	0.22	0.19
Limiting proportion (%) ...	25	38	39	51

It is tempting, perhaps, to explain the relative extinctive effects as being the result of the relative lags; but it is more reasonable to regard the lags as determined largely by the same factors as determine the extinctive effects, namely, thermal capacities and thermal conductivities, because the lag is generally explained as being the period in which the gas mixture is heating itself, by partial combustion, to the temperature of rapid reaction. Other circumstances being equal, the lag must therefore be shorter in the presence, not only of inert gases of lower thermal capacity, but also of gases of lower thermal conductivity.

*The Most Inflammable Mixture of Methane and Air.*—The broken line in Fig. 3 is the locus of mixtures in which the ratio between methane and oxygen is exactly that required for complete combustion,  $\text{CH}_4 : 2\text{O}_2$ . This line runs through the "noses" of the limits curves, and therefore, from this point of view, the most inflammable of all mixtures of methane and oxygen is that which burns completely to carbon dioxide and water. This is also the mixture in which the speed of uniform movement of flame is greater than in any other mixture of methane and oxygen (Payman, J., 1920, 117, 48). On the other hand, the detonation wave is pro-

pagated more rapidly in mixtures in which the methane content exceeds that required for complete combustion (Dixon, *Phil. Trans.*, 1893, **184**, 97); in this case, the heat of reaction is evidently subordinated by those physical properties of the explosive mixture which govern the rate of transmission of a disturbance like a sound wave. Moreover, the speed of uniform movement of flame in methane-air mixtures reaches its maximum when the proportion of methane is somewhat higher than the theoretical amount for complete combustion (Wheeler, J., 1914, **105**, 2606), whilst mixtures

FIG. 4.

containing an excess of air are more readily ignited by a heated surface or by an electric spark.

*Test of the "Limits Generalisation" of Payman.*—Le Chatelier (*Ann. Mines*, 1891, **19**, 388) gave a formula which enabled the lower limit in air of a mixture of two inflammable gases to be calculated from the observed limits of the separate gases. This formula was put in more general form by Coward, Carpenter, and Payman (J., 1919, **115**, 27) and was shown to apply to lower and higher limits, in air, of mixtures of hydrogen, methane, and carbon monoxide, and of coal gas. It expressed in mathematical terms the statement that "lower-limit air mixtures, if mixed in any proportions, give rise to mixtures which are also at their lower limits."

Payman (J., 1919, 115, 1436) gave the statement a still wider form which applies to cases in which the atmosphere is not air: "All mixtures, in any proportions, of limit mixtures remain limit mixtures . . . provided that all of the limit mixtures are of the same kind, that is to say, all lower-limit or all upper-limit mixtures." This statement is tested by the present research for atmospheres which contain large quantities of carbon dioxide, excess nitrogen, argon, and helium. It holds good in each case when mixtures represented by points on the straight part of a curve (Fig. 4) \* are considered; it fails when points on the curved parts are considered, and the extent of the failure is represented by the greater or lesser curvatures at the point chosen. The generalisation is therefore fairly accurate for methane in atmospheres composed of air mixed with the inert gases named, except when applied to those mixtures the composition of which approaches the point where the lower and higher limits coincide.

### Results.

Limits of inflammability of methane in atmospheres composed of air mixed with various diluent gases, observed in a vertical tube 2 inches in diameter, upward propagation of flame, the lower end of the tube being open; gases at atmospheric temperature and pressure.

Diluent in "atmosphere"	Limits of inflammability.		Diluent in "atmo- sphere" %.	Limits of inflammability.	
	Lower.	Higher.		Lower.	Higher.
Nil.	5.24	14.02	Nitrogen.		
			19.6	5.39	—

			38.2	—	6.56
			38.5	5.83	—

\* The replotting of the experimental values on a different basis from that of Fig. 3 is necessary to exhibit the approach to a rectilinear character which tests the validity of the generalisation.

*Summary.*

1. The limits of inflammability of methane in atmospheres composed of air mixed with (a) carbon dioxide, (b) nitrogen, (c) argon, and (d) helium have been determined, and the factors which are mainly responsible for the extinction of flame have been elucidated. They are (1) the reduction of oxygen content by the diluent gas, (2) its thermal capacity, and (3) its thermal conductivity. An exact treatment of the subject would therefore demand a knowledge of the thermal conductivities of certain mixed gases up to high temperatures (say,  $1000^{\circ}$  to  $1500^{\circ}$ ). Such data are not at present available.

2. The thermal capacity effect of the diluent gas is marked in the case of argon; the lower limit of methane in the conditions described is reduced from 5.24% in air to 4.40% in an atmosphere composed of 47% of argon and 53% of air, and is further reduced to 3.95% in an atmosphere composed of argon with just sufficient oxygen to burn the methane completely.

3. The thermal conductivity effect is marked when a comparison is made between the limits in atmospheres composed of air to which has been added argon, on the one hand, or helium on the other.

4. The "limits generalisation" of Payman holds fairly accurately over the whole range of mixtures investigated, except near the point at which the lower and higher limits meet.

5. Of all mixtures of methane and oxygen, that represented by the proportions  $\text{CH}_4 + 2\text{O}_2$  is the last to become non-inflammable as inert gases (nitrogen; or nitrogen with carbon dioxide, argon, or helium) are added in increasing amount.

6. There is a parallel between the "lags" on ignition and the dilution limits of such mixtures as we have used. It is suggested that both are dependent on the same factors, in the case of any one inflammable gas.

This work has been carried out at the suggestion and under the general direction of Professor R. V. Wheeler. We desire to express our appreciation of the able manner in which Miss E. H. M. George-son and Mr. G. W. Jones, at Sheffield and Pittsburgh, respectively, have assisted us in this investigation, and to acknowledge the permission granted by the two organisations concerned to publish this work.

CXCVIII.—*Periodic Phenomena at Anodes of Copper and Silver.*

By ERNEST SYDNEY HEDGES.

THE only case of the periodic dissolution of a metal under anodic polarisation which has received systematic examination is the periodic passivity of iron. A complete series of references to this and other periodic electrochemical phenomena is to be found in a paper by Hedges and Myers (J., 1925, 127, 1013). In that paper, periodic electrochemical phenomena were classified in two groups: (a) systems which are capable of furnishing a periodic current, and (b) systems which behave periodically on electrolysis; and the experimental portion was devoted to section (a). The present work is an experimental investigation of section (b).

The reactions differ in several important respects from the experiments of Hedges and Myers (J., 1924, 125, 604; 1925, 127, 445) on the periodic dissolution of metals in various reagents in absence of applied current. For example, a metal which liberates hydrogen when dissolving in an acid may undergo electrolytic dissolution without production of any gas, or at suitable current densities oxygen may be evolved at its surface. The absence of gas evolution enables diffusion effects, supersaturation, and film formation to play important rôles, and the system may be further complicated by polarisation, overvoltage, etc.

It is not surprising, therefore, that the electrolytic periods described in the present paper should differ in some fundamental respects from the periodic phenomena in purely chemical reactions. Thus, the periods formerly described were (1) dependent on the presence of a third component, (2) dependent on a peculiar physical state of the metal, (3) increased in frequency linearly with the rate of dissolution, and (4) lengthened enormously or stopped altogether by catalytic poisons. On the other hand, the electrolytic periods now described are (1) independent of a third component, (2) independent of the state of the metal, (3) decreased in frequency with increasing rate of dissolution, and (4) unaffected by catalytic poisons.

There are reasons for supposing, however, that the fundamental causes of these manifestations of periodicity are not essentially different.

## EXPERIMENTAL.

*Apparatus.*—The electrolysis was conducted in a wide-necked glass bottle of 200 c.c. capacity, the amount of solution used in each experiment being 100 c.c. The electrodes were of pure electro-

lytic metal sheet, 4 cm.  $\times$  2 cm., and were supported by nickel rods, to which they were fastened by means of a nickel screw, a small hole being drilled near the end of each electrode. A length of only 3 cm. of electrode was immersed in order to keep the nickel well clear of the solution. The metals were approximately 0.5 mm. thick, and the effective area of each may therefore be taken as 12 sq. cm. The distance between the electrodes was 2 cm. A rubber bung, closing the reaction vessel, served to carry the electrode supports and the glass tubes for stirring the solution. Except in experiments where it was undesirable, the solutions were vigorously stirred during electrolysis by a stream of air previously freed from carbon dioxide. The reaction vessel was immersed in a thermostat at 30°, except in those experiments where other temperatures are indicated.

The source of current was a battery of twelve Edison storage cells of large capacity. The current passing through the circuit was read directly on an ammeter placed in series with the cell, and the *P.D.* between the electrodes was measured by a voltmeter of suitably high resistance placed across the electrode terminals. Both were quite dead-beat instruments. The course of the electrolysis was followed by taking readings of the voltmeter every 15 seconds, or, if necessary, every 5 seconds.

#### (1) *Copper Anode.*

*Electrolysis of some Chloride Solutions.*—When fairly strong solutions of hydrochloric acid are electrolysed between copper electrodes at low current densities, copper passes into solution at the anode as cuprous chloride. As a rule, this may be seen on the metal as a white coating which, however, does not appreciably impede the electrolysis. In the absence of atmospheric oxygen, no cupric salt is formed. At high current densities, a film which appears to be cuprous oxide forms over the metal; this film is highly resistant and the current passing falls to a low value; the electrode still dissolves, but a small portion of the current is employed in the liberation of oxygen, a few bubbles of which rise from the anode. At intermediate current densities the two effects alternate. The seat of this phenomenon is the anode, for the effect continues if platinum be substituted for the cathode, but not if the anode be changed for another metal. Further, the anode undergoes a visible periodic change.

*The Current Density-Potential Curve.*—Graph 58 (Fig. 1) shows the effect of gradual increase in current density in the electrolysis of hydrochloric acid, containing 25 c.c. of acid (*d* 1.16) in 100 c.c., using a copper anode and a platinum cathode at 20°. For values

below 60 milliamp. per sq. cm. the potential rises slowly along the line AB: cuprous chloride is formed at the anode and dissolves in the hydrochloric acid, and at the cathode copper is deposited and hydrogen evolved. At the value corresponding to B the potential oscillates in regular periods between 0.55 and 10.6 volts, and simultaneously the current fluctuates between 60 and 20

FIG. 1.

milliamp. per sq. cm. The region of regular oscillations continues as the current density is increased along BD to the value 145 milliamp. per sq. cm., the amplitude here being from 1.0 to 12.7 volts. At an intermediate point C, the values of current density and potential oscillate between points C and G. At current densities greater than 145 milliamp. per sq. cm., the potential immediately rises (the current falling) to a voltage corresponding to H, at which it remains constant. Further attempts to increase the current are

unsuccessful, for the film over the anode becomes more and more resistant and the effect is actually to decrease the current still further, along the line HI. The electrode, therefore, exists in one state along AB, in another state at H, and the area BFHD marks a region of instability where the electrode oscillates regularly between the two states.

The point B represents the critical current density required to produce periods. The value of this increases with the concentration of the hydrochloric acid and with rising temperature. The

FIG. 2.

The amplitude in Graphs 37—41 is about half of that indicated in Graph 58. This is because half the number of cells was used in these experiments. When the highly resistant film forms, the voltmeter records almost the total E.M.F. of the battery, the resistance of the rest of the circuit being relatively small.

critical current densities for a series of solutions containing from 5 to 30 c.c. of hydrochloric acid per 100 c.c. of solution electrolysed between two copper electrodes have been determined, and Graph 59 indicates a direct proportionality between critical current density and concentration.

#### *The Nature of the Phenomenon.*

The periodic changes in current and potential are accompanied by visible periodic changes at the anode. This is best described by reference to one of the waves on Graph 37 (Fig. 2). Simul-

taneously with the sudden rise in the potential (AB), there sweeps *up* the metal a very thin, dark grey film. The current slowly increases until the point C is reached. Then the potential rapidly resumes its initial low value and a white film sweeps *down* the metal. There is an interval of a fraction of a second between the drop in potential and the appearance of the white film. Careful observation shows that simultaneously with the drop in potential the smooth dark grey film breaks up into a rough red-brown film having the appearance of cuprous oxide. The transformation to the white film is almost immediate. The series of changes is repeated in each successive wave. The first film has the appearance of cupric oxide rather than cuprous, but there is doubt in assigning a composition to so thin a film. It is believed to be a form of cuprous oxide, for it changes directly into ordinary cuprous oxide and gives cuprous chloride by reaction with hydrochloric acid: further, no cupric salt is produced in the reaction. The white film is undoubtedly cuprous chloride.

It has been observed that wherever deposition of a film occurs in electrolysis, this starts at the sides and lower part of the electrode and travels up the electrode in the form of a U of diminishing concavity. This seems to be due to the concentration of current density at the corners and edges of the electrode and accounts for the manner in which the dark oxidic film travels up the anode. The downward sweep of the cuprous chloride film has been traced to the flow of hydrochloric acid down the electrode due to the downward fall of the reaction products, which is observed even when the solution is stirred. By allowing a stream of air bubbles to impinge on a point near the bottom of the anode, the reaction products can be washed upwards, and under these conditions the cuprous chloride film travels upwards also; but the oxide film could not be made to travel downwards.

The phenomenon is not affected by moderate rates of stirring, but when the solution in the vicinity of the anode is stirred very vigorously the frequency of the periods is increased or the potential may even remain constant at the low value. In the latter case, periodicity recurs on increasing the current density. Thus the phenomenon may be localised by directing a stream of air bubbles on a point about half-way up the electrode. In this case, the small area of metal affected by the rapid stirring exhibits rapid black and white flashes, while the main part of the electrode performs its slow periods unhindered. The voltmeter records curves showing short waves superimposed on the long waves.

These effects, which could be controlled by the air used for stirring, suggested that the phenomenon was due to oxidation and

probably to an oscillation of the reaction product between the cuprous and cupric states. Experiments were therefore performed in which the solutions were stirred by a stream of hydrogen bubbles. The effects of localised stirring were the same as with air and in this case no cupric salt was formed. Further, the periods were produced when the hydrochloric acid contained 1% of sulphurous acid. Separate experiments showed that a copper anode did not give periods in 1% or 5% sodium hydrogen sulphite solution alone. It may be noted that in the presence of sulphurous acid a somewhat higher critical current density was required.

Observations taken on interrupting the periods have given a clue to their nature. If the circuit be broken or the electrodes be short-circuited while the high *P.D.* exists, the cuprous chloride film immediately forms over the anode. In this case, it does not travel down the metal, but appears simultaneously over the whole area. If the circuit be completed again directly, the oxide film is reinstated immediately and the *P.D.* again rises. When an interval of 1 or 2 seconds elapses before the circuit is remade, the film does not form again for a few seconds. By breaking and making the circuit several times in succession, preferably in an unstirred solution, the cuprous chloride film does not form when the *P.D.* drops, but, instead, the oxide film turns to the red colour and the white film appears when the circuit is again made; it is quickly followed by the oxide film, the *P.D.* rising once more.

These facts suggest the following interpretation. The critical current density is such that chlorine ions are discharged more rapidly than they can be replaced by diffusion; at a certain moment, therefore, hydroxyl ions are discharged and a highly resistant oxide film forms over the metal, causing the *P.D.* to rise to a high value. This film is unstable (as will be shown independently later) and changes to a stable state of relatively low resistance, the change being indicated by the change in colour and surface of the film. This is immediately followed by reaction with the chlorine ions, which have been accumulating through diffusion, to form cuprous chloride. When the current is broken for a fraction of a second, the oxide film (which is only stable at the high potential) immediately reacts with the available chlorine ions and then rapidly forms again as these become scarce. When, however, the circuit remains open for a few seconds, the chlorine ions have time to diffuse towards the anode and, on making the circuit once more, a few seconds elapse before the oxide film forms. By repeating this process several times in rapid succession, the solution in the immediate vicinity of the anode can be so deprived of chlorine ions that breaking the circuit causes the highly resistant film to change to

the red stable state, in which form it persists for some little time; but closing the circuit causes it to react to form cuprous chloride.

Direct evidence of the instability of the highly resistant oxide film is gained by observing the effect of partially lifting the anode out of the solution when in the state represented by H in Graph 58. When this is raised 1 cm., the change to the stable state is observed to take place in the upper part of the electrode and a well-defined ridge forms about 0.5 cm. above the surface of the solution, marking the boundary between the stable and unstable forms. Each time the electrode is progressively raised, a further area remote from the solution undergoes the change and a new boundary forms, below which the grey film persists. This boundary marks the extent of the electrode which is under the influence of the high current density. The highly resistant film is stable, then, above a current density of 145 milliamp. per sq. cm., and its metastability between the values 60 and 145 milliamp. per sq. cm. is the cause of the periodicity.

Having deduced the mechanism of the process from direct experimental observation, it is necessary to show how this is supported by a study of the effect of varying the conditions of reaction.

#### *Effect of Conditions.*

(a) *Current Density.*—For any given concentration, the frequency of the periods decreases greatly with increasing current density. This is illustrated by the following values in a solution containing 25 c.c. of hydrochloric acid per 100 c.c.

Milliamp. ....	58	72	86	117
Min. ....	1.25	2.0	4.25	9

Such a result is to be expected, for the high current density (1) more rapidly exhausts the anolyte of chlorine ions, and (2) stabilises the resistant film.

(b) *Temperature.*—At a given current density, the frequency of the periods increases with rising temperature. This effect takes place in a particular way, however. The lower part of the curve (Graph 37) is unaffected and only the portion BC is shortened. On raising the temperature still higher, the amplitude AB is gradually reduced until finally the effect dies out and the potential remains constant at the low value. Periodicity can then be recovered by increasing the current density. Thus, a system at 20° under a current density of 80 milliamp. per sq. cm. gave an amplitude of 5.7 volts, the high *P.D.* lasting for 120 seconds; at 35°, the amplitude was 4.8 volts, lasting for 30 seconds; at 45°, 2.8 volts for 10 seconds; at 55°, 0.3 volt for 5 seconds. In each case, the low *P.D.* had a duration of 30 seconds.

Above  $60^{\circ}$ , no oscillation was perceptible, but by increasing the current density to 108 milliamp. per sq. cm. variations between 0.4 and 0.8 volt were recorded; at 126 milliamp. per sq. cm. the *P.D.* oscillated between 0.5 and 4.1 volts.

Thus, the effect of raising the temperature is to decrease the stability of the resistant film, and in every way it acts in an opposite sense to increasing current density: the two are mutually antagonistic.

(c) *Concentration*.—Graphs 37, 38, and 39 (Fig. 2) show that for a fixed temperature and current density (in this case  $30^{\circ}$  and 71 milliamp. per sq. cm.) the frequency of the periods increases with increasing concentration of hydrochloric acid. The rate of dissolution of the metal remains the same in the three cases. This result would be anticipated from the explanation advanced, for the anolyte is with greater difficulty depleted of its store of chlorine ions. The linear relation between the critical current density and the concentration of solution is likewise compatible. The wave-length gradually increases during the course of the electrolysis. This is due partly to decrease in concentration of the chlorine ions and partly to formation of cupric chloride through oxidation by the air-stream. Direct addition of 1% of cupric chloride was found to double the length of the waves.

(d) *Rate of Stirring*.—This factor is inconsiderable when the solution is kept in circulation without violently disturbing the solution at the anode. When the stream of bubbles is allowed to travel up the anode the frequency of the periods is increased and the critical current density raised. This is due to the rapid replenishing of the depleted chlorine ions, causing the effective concentration to be higher.

(e) *Addition of Agents*.—Addition of a reducing agent, such as sulphurous acid, served to shorten the periods and to raise the critical current density. On the other hand, oxidising agents such as hydrogen peroxide lengthened the periods. A system with a normal period of 4.25 mins. produced periods of 4.5 mins. after addition of 1 c.c. of 20-volume hydrogen peroxide, 6.5 mins. in the presence of 2 c.c. of hydrogen peroxide, and 10.5 mins. with 4 c.c. Addition of 0.5% of potassium cyanide or 0.5% of formaldehyde failed to "poison" the oscillations. The presence of 0.02% of gelatin did not affect the phenomenon. No difference could be observed between the behaviours of cold-rolled and well-annealed copper.

The periodic phenomenon takes place in solutions of other chlorides in similar circumstances and the same general effects are observed. Thus, equally well-marked periods are produced when

10% or 5% ammonium chloride is used for the solution to be electrolysed. Graph 40 (Fig. 2) illustrates the periodic dissolution of a copper anode in 5% ammonium chloride solution. Graph 41 records a similar experiment using 5% sodium chloride solution. In the latter case, the reaction product is mainly cuprous oxide, which is insoluble but does not adhere to the electrode; it soon causes the solution to become opaque, thus preventing observation. Long periods are obtained when 5% cupric chloride solution is used as the electrolyte.

#### *Electrolysis of Potassium Cyanide Solutions.*

Anodes of copper in 2.5% and 5% solutions of potassium cyanide rapidly become enveloped by a golden-green film which readily dissolves in the electrolyte on breaking the circuit. This is generally described as a basic cyanide. At certain current densities, the voltmeter needle trembles violently and occasionally executes rapid fluctuations of about 1 volt. The phenomena are much more definite in a 10% solution. At low current densities, no film forms over the anode and the copper dissolves as potassium cuprocyanide. When the current density is raised to 59 milliamp. per sq. cm. a dark grey oxide film sweeps up the metal and the *P.D.* between the electrodes rises from 1.6 to 2.7 volts. After a few seconds, the dark film gives place to a white film, presumably of cuprous cyanide, which travels down the metal, and the *P.D.* resumes its former value. The two states oscillate thereafter in regular periods.

In every respect this phenomenon is similar to the periodic electrolysis of chloride solutions, and the oxide film reacts towards interruption of the current just as in the former cases. It is therefore a logical deduction that the mechanism is precisely similar. The limits of the conditions favouring periodicity in the cyanide solutions are, however, very much narrower than in the chloride solutions. If a current density-potential curve similar to Graph 58 be constructed for a cyanide solution, the region of instability BFHD is very short and is indeed easily overshoot, the electrode often going straight from the state represented by B to that represented by H. It is only by increasing the current density cautiously that the intermediate oscillating condition can be realised in this system.

Another point differentiates the systems. On further increasing the current density to 86 milliamp. per sq. cm., a pale green film permanently covers the anode. At this stage, cuprous cyanide is being formed more quickly than it can dissolve in the potassium cyanide solution. The onset of this film is marked by a rise in

potential from 3.6 to 6.2 volts, after which a second series of oscillations ensues. These are most diverse in character, varying in amplitude from 0.1 to 6.0 volts and in wave-length from 0.1 to 5.0 seconds. Occasionally they become regular for some few minutes, after which the voltmeter needle behaves in an erratic manner, violent trembling being interspersed with sudden momentary darts up to a high value. Current densities exceeding 140 milliamp. per sq. cm. are beyond the region of periodicity in the cyanide film, but the erratic behaviour may be repeated by again lowering the current density. Since no change can be observed in the film in this second series of oscillations, there are as yet no data to afford an explanation. Analogy would suggest that the cyanide is first deposited in an unstable form at the high current density employed.

The phenomena are even better marked in 20% potassium cyanide solution. Illustrations of periodicity in the oxide film and of regular periods in the cyanide film are shown in Graphs 54 and 53 (Fig. 2), respectively. All these experiments on cyanide solutions were conducted at 20° because of the high frequency, and the solutions as a rule were not stirred in order to avoid loss of hydrogen cyanide. Control experiments in stirred solutions gave similar results, except that somewhat higher current densities were required in every case.

#### *Electrolysis of Other Solutions.*

*Sulphuric Acid.*—Investigations were carried out at intervals of 10% over the concentration range 100—10%, and also at 5, 2, and 0.5% (expressed as % by volume of acid, *d* 1.84). With concentrations above 50%, very little current would pass, the *P.D.* rapidly rising to a high value. After a time, cupric sulphate could be seen as crystals on the anode. Electrolysis followed a normal course below 10%, and at intermediate concentrations the potential rose to a high value at a certain critical current density. This was followed by a partial fall in the 40, 30, and 20% systems, but in no case was a periodic effect produced. It is probable that the highly resistant film was in this case copper sulphate. In the more dilute solutions (below 10%), some loosely adherent cupric oxide was always formed at high current densities. The 40% system was examined over a temperature range of 20° to 75°. Between these limits the critical current density increased from 58 to 138 milliamp. per sq. cm., but periodic effects were not produced.

*Nitric Acid.*—The concentrations examined were 10, 5, 2, and 0.5% (by volume of acid of *d* 1.42). In all these cases, the electrolysis pursued a steady course over the whole range of current densities. At the end of each experiment, the anode was covered

with a slimy, black deposit, probably of cupric oxide, which did not increase the resistance of the system. In one experiment with 5% nitric acid, continuous oscillations with a 30-second period between 0.8 and 1.0 volt were observed, using a current density of 36 milliamp. per sq. cm. Subsequent attempts to repeat this have failed. It is possible that the periods were due to some accidental circumstance, or that their range of existence was very narrow.

*Sodium Hydroxide.*—Solutions of concentrations graded from 8% to 0.4% were used. With the 8% solution at current densities below 5 milliamp. per sq. cm. a resistant film of cupric oxide slowly formed on the anode, the *P.D.* rising from 1.2 to 2.3 volts, at which oxygen was evolved. The film disappeared on increasing the current further and a greenish-yellow substance could be observed going into solution. Periods were not observed in any of these systems or in concentrated solutions of ammonia. A large number of mixtures of solutions of caustic soda and ammonia were also tried without success.

*Miscellaneous.*—Solutions of the following compositions were electrolysed with a copper anode over the range of current densities possible with the apparatus described and no trace of periodicity was observed. Ammonium acetate, 5 and 2.5%; sodium acetate, 8.4%; acetic acid, 12.4%; ammonium sulphate, 5, 2.5, and 1.25%; sodium nitrate, 5%; sodium hydrogen sulphite, 5 and 1%; potassium iodide, 5 and 1%; potassium chromate, 5 and 1%. With the last two substances, insoluble films immediately formed over the anode.

## (2) *Silver Anode.*

Although general considerations would lead one to anticipate that periodic phenomena might be observed at a silver anode in similar circumstances, the practical application is beset with difficulty in consequence of the insolubility of so many silver salts. Only the cyanide experiments can be repeated under precisely analogous conditions, but the insolubility of silver chloride has been overcome by the employment of ammoniacal solutions of chlorides. With these modifications, the phenomena observed are similar to the experiments with a copper anode, but, in general, the effects are much less striking; the amplitude of the oscillations is relatively small and the frequency is in all cases very high. The latter fact precludes direct experiment on the properties of the films, and it is therefore necessary at present to rely on the analogy with copper for an explanation of the phenomena. This seems a safe course in view of the similarity in every respect between the two cases.

*Electrolysis of Potassium Cyanide.*—Since, except in the strongest

solutions employed, the highest amount of current passing is small, the limits will be defined by the *P.D.* between the electrodes. With a 5% solution, the anode dissolves normally as potassium argentocyanide when the *P.D.* is less than 2.3 volts; at this value, a brownish-black film of silver oxide sweeps up the metal and the potential rises to 3.2 volts and then oscillates rapidly (about twice per second) between 3.2 and 3.0. Simultaneously, the upper part of the anode displays alternate black and white flashes—a rapid periodic dissolution of the silver oxide film by the potassium cyanide. The phenomenon is precisely similar to the case of copper, the black oxide film sweeping up and the white cyanide film rolling down, the frequency increasing with current density, concentration, and temperature. On slightly increasing the current, the alternation is so quick as to resemble a twinkling.

Similar effects were observed in solutions of concentrations 2.5, 1, 0.5, and 0.25%. The 2.5% solution gave an amplitude of 0.4 volt between the critical limits 1.7 and 2.9 volts. Below the value 1.7, no oxide film appeared and above 2.9 it existed permanently. The 1% solution gave an amplitude of 0.4 volt between the limits 1.8 and 2.7 volts. The limiting voltages for the 0.5% solution were 1.8 and 2.4, and in the case of the 0.25% solution they were 1.6 and 1.7. In the last case, the periods were as long as 30 seconds. It is seen from these figures that the extent of the unstable region decreases with progressive dilution.

These results were for unstirred solutions at 20°. In stirred solutions, the frequency was even higher. Since the low amplitude and high frequency of these periods were reminiscent of the anodic dissolution of copper in hydrochloric acid at higher temperatures, some experiments were conducted on silver in potassium cyanide solutions at 0°, and a maximum amplitude of 2.1 volts was then obtained with a 10% solution of potassium cyanide.

Experiments were also conducted in 10 and 5% ammonium thiocyanate solutions. Although above a certain current density the oxide film formed slowly, it seemed to be permanent. The 10% solution was investigated over the temperature range 20–80° in an attempt to quicken the dissolution of the film, but the experiments were not successful in producing periods.

*Electrolysis of Ammoniacal Solutions.*—When solutions of ammonium chloride were electrolysed with a silver anode, a highly resistant chloride film immediately formed. Attempts were therefore made to add just sufficient ammonia to dissolve the film as fast as it formed. Periodic effects were observed in these experiments, the anode becoming intermittently coated by a dark brown oxide film. The best result was with a solution of 50 c.c. of 10% ammonium

chloride and 50 c.c. of ammonia solution ( $d$  0.880). With a current density of 44 milliamp. per sq. cm., the *P.D.* oscillated between 3.0 and 4.1 in periods of 20 seconds. Rapid oscillations were also observed with a silver anode dissolving in a mixture of 50 c.c. of 10% ammonium sulphate solution and 50 c.c. of ammonia ( $d$  0.880).

Electrolysis of strong ammonia solutions alone might be anticipated to yield periodic phenomena on the basis of the explanation advanced here. Such solutions were tried without success, but the failure is most likely due to the fact that very little current can be made to pass. Endeavours to obviate this difficulty by adding progressively increasing amounts of caustic soda to the solution met with no success.

*Electrolysis of Sulphuric Acid.*—Solutions varying in composition from 100 to 2% were electrolysed. The anode dissolved continuously only in the most concentrated solutions, a sulphate film forming above a certain critical current density and the potential rising very sluggishly. Periods were obtained in these systems at higher temperatures. With 90% sulphuric acid at 50°, the waves shown in Graph 55 (Fig. 2) were obtained at a current density of 36 milliamp. per sq. cm., whilst Graph 56 represents 50% sulphuric acid at 75° under a current density of 17 milliamp. per sq. cm. The solutions always became cloudy, preventing observation of the state of the anode.

*Electrolysis of Other Solutions.*—In addition to those mentioned above, the following solutions gave no periodic effects: caustic soda, 8, 4, and 0.4%; nitric acid, 2, 1, and 0.5%; silver nitrate, 1.7%; acetic acid, 12.4%; potassium chromate, 9.7, 4.8, 2.4, and 0.6%; sodium thiosulphate, 3.4%; sodium hydrogen sulphite, 5%. In the last two cases, where periodicity might have been expected, the reaction followed a complex course, the main product being silver sulphide, whilst the solution developed the smell of hydrogen sulphide.

The investigation is being extended to anodes of other metals and will include the cathodic deposition of metals.

### *Summary.*

Periodic changes in current strength and in the *P.D.* between the electrodes were observed in the anodic dissolution of copper in solutions of hydrochloric acid, ammonium chloride, sodium chloride, cupric chloride, and potassium cyanide, and of silver in solutions of potassium cyanide, sulphuric acid, and ammoniacal ammonium sulphate and ammonium chloride. In every case, periodic film formation over the anode occurred. The case of copper in hydrochloric acid was the subject of a detailed examination. The pheno-

menon took place between certain limiting values of current density and the critical current density required to produce the periods was a linear function of the concentration of the electrolyte. The frequency of the periods increased with rising temperature and concentration, and decreased with rising current density. The periods were not affected by catalytic poisons. At the critical current density, an oxidic film formed over the metal and it was shown that this film was stable above a certain value of the current density; its metastability between this value and the critical current density is believed to be the cause of the phenomenon. This case appears to be typical of all the others investigated.

The author is much indebted to Dr. J. F. Spencer for his interest in these experiments and to the Chemical Society for a grant in aid of the research.

### CXCIX.—*The Existence of the Suboxides of Lead and Thallium.*

By FREDERICK AUFENAST and HENRY TERREY.

THE black substance obtained by heating lead oxalate has been interpreted as (1) a mixture of litharge and lead, or (2) lead suboxide. The work of Tanatar (*Z. anorg. Chem.*, 1901, 27, 304) on its heat of reaction with acetic acid pointed to a chemical entity, since he obtained results which indicated a heat of decomposition of lead suboxide into lead and litharge,  $\text{Pb}_2\text{O} \rightarrow \text{Pb} + \text{PbO} - 5,450$  cals. This view is supported by the work of Brislee (*J.*, 1908, 93, 154) and of Denham (*J.*, 1917, 111, 29; 1918, 113, 249; 1919, 115, 109). Evidence has also been given for the existence of subvalent lead ions by Denham (*J.*, 1908, 93, 41), Denham and Allmand (*ibid.*, p. 833), and Bell (*Trans. Faraday Soc.*, 1915, 11, 74).

The similarity of thallium and lead and of many of their salts suggests the possible existence of a thallium suboxide (compare Crookes, *Proc. Roy. Soc.*, 1862, 12, 150; Lorenz, *Z. anorg. Chem.*, 1896, 12, 439).

Investigations were first carried out to determine whether breaks could be obtained in the reduction-velocity curves such as were found by Brislee (*loc. cit.*). Thallous oxide was reduced in a stream of hydrogen and the amount of reduction was measured at regular intervals. The results showed in some cases a slight break in the curve corresponding to a compound  $\text{Tl}_4\text{O}$ , but these breaks were

not definite enough to be regarded as satisfactory evidence. Experiments were then made on the heat of solution of the products of varying composition obtained by reduction of thallic oxide, and the results are shown in Fig. 1, in which heats of solution per g. of thallium are plotted as ordinates and the extent to which the thallic oxide had lost weight on reduction as abscissæ. If a suboxide had been present, the heat of solution in 3*N*-sulphuric acid would have included a heat of decomposition of the suboxide and the graph would not have been a straight line. Within the limits of experimental error, no evidence was thus obtained for the existence

FIG. 1.

of thallium suboxide. Attempts were also made to measure the oxidation velocity of metallic thallium, but they were abandoned when it was found that the finely-divided metal was never oxidised completely although the initial velocity was very great.

Similar calorimetric experiments, in which the products of decomposition of lead oxalate were dissolved in acetic acid, gave results indicating that this supposed suboxide was a mixture of litharge and lead.

#### EXPERIMENTAL.

For the reduction velocity experiments, thallic oxide was precipitated from a thallic chloride solution by ammonia, washed, and heated to 200° in a current of oxygen to remove the last traces

of water. As thalious oxide is very deliquescent, it was decided to measure the reduction by collecting the water evolved rather than by removing the substance and determining the loss in weight. A weighed amount of thallic oxide, spread in a thin layer in a porcelain boat, was gradually heated electrically to  $150^{\circ}$  in a stream of hydrogen. After a few hours, when scarcely any more water was given off, the temperature was raised to  $185^{\circ} \pm 1^{\circ}$  and the water produced was collected in calcium chloride tubes which were weighed hourly. The complete reduction to thalious oxide, which took about 30–40 hours, was thus spread over a few days. The product was at first black, changing to a metallic grey colour.

For the heat of solution experiments a known weight of thallic oxide was reduced in a stream of hydrogen to a known composition, and the product was transferred as quickly as possible to the calorimeter, which consisted of a 100 c.c. Dewar vessel fitted with a Beckmann thermometer and a small glass stirrer and containing 25 c.c. of 3*N*-sulphuric acid. The results of these experiments are as follows :

Expt.	Wt. $\text{Tl}_2\text{O}_3$ used.	Loss %.	Wt. used for solution.	Rise in temp.	Cals. evolved.	Cals. per g. $\text{Tl}$ .
1	0.3926	6.78	0.3657	0.780°	26.86	77.29
2	0.4081	6.96	0.3797	0.809	27.86	77.21
3	0.3669	8.75	0.3242	0.404	13.91	47.36
4	0.4781	8.39	0.4257	0.693	21.44	53.30
5	0.4115	9.14	0.3655	0.400	12.38	34.73
6	0.3494	10.96	0.3029	0.067	2.07	6.81
7	0.3953	11.15	0.3394	0.025	0.77	2.28
8	0.3836	9.33	0.3151	0.325	10.06	32.66
9	0.3693	9.80	0.2848	0.266	8.20	29.51

For Expts. 1–3 and 4–9, the water-equivalent of the calorimeter and its contents was 34.43 g. and 30.94 g. respectively.

These results are shown graphically in Fig. 1, where the figures of column 3 are the abscissæ and those of column 7 the ordinates.

For the preparation of lead suboxide, about 1.5 g. of lead oxalate were heated in a porcelain boat in a vacuum at about  $275^{\circ}$ ; the gas evolved was pumped off periodically, the pressure never being allowed to exceed 1 cm. Evolution of gas ceased after about 24 hours, and the black residue gave off no carbon dioxide when treated with acids. The heat of solution in *N*-acetic acid was determined as with thallium, and after completion of the determination the liquid was filtered from undissolved lead, and the lead in the filtrate and the insoluble lead were determined by conversion into sulphate.

The results of two such experiments are given :

(Water-equivalent of calorimeter and contents = 56.2 g.)

	No. 1.	No. 2.
Weight of suboxide used (g.) .....	1.332	1.162
Amount of PbO dissolved from suboxide (%) ...	71.3	68.6
Rise in temperature .....	1.165°	0.963°
Heat of solution per g.-mol. of PbO (cals.) .....	15,370	15,140

The mean of these two experiments, *viz.*, 15,250 cals., differs only by about 350 cals. from that obtained with pure litharge, *viz.*, 15,600 cals.

These values are in agreement with those obtained by Sveda (*Chem. Listy*, 1923, 17, 47, 81, 112), but differ from those of Hersch-kowitsch (*Z. anorg. Chem.*, 1921, 115, 159) and Tanatar (*loc. cit.*).

### CC.—*The Precipitation of Cadmium Sulphide from Aqueous Solutions of Cadmium Chloride in the Presence of Hydrochloric Acid and Other Chlorides.*

By SUBRAMONIA KRISHNAMURTI.

THE object of this investigation was to determine the relation between the concentration of cadmium chloride and the minimum concentration of hydrochloric acid required to prevent the precipitation of cadmium sulphide by hydrogen sulphide at constant temperature and pressure, and to ascertain the effect of various chlorides on this relation. It will be seen that the introduction of the activity concept renders this familiar problem of analytical practice capable of much more exact theoretical treatment. The present paper forms an introduction to the study of this and allied reactions from this point of view. Amongst previous workers on the precipitation of sulphides, mention may be made of Bruner and Zawadski (*Bull. Acad. Sci. Cracow*, 1909, 267; *Z. anorg. Chem.*, 1910, 67, 454), who studied more especially the precipitation of thallos sulphide, and of Baubigny (*Compt. rend.*, 1888, 107, 1148), who investigated the concentration of free acid required to prevent the precipitation of zinc sulphide from solutions of zinc sulphate. Reference may also be made to the work of Bruni and Padoa (*Atti R. Accad. Lincei*, 1905, 14, ii, 525) and of Glixelli (*Z. anorg. Chem.*, 1907, 55, 297).

#### EXPERIMENTAL.

The apparatus used was very simple. A stream of washed and pre-heated hydrogen sulphide was bubbled through the solution contained in a suitable vessel, placed in a thermostat at 25°. The

gas escaped through an oil-trap. In order to prevent the oxidation of hydrogen sulphide, air-free water was used in making up all solutions, whilst a stream of carbon dioxide was passed through the apparatus and solution for a considerable time before the hydrogen sulphide was admitted. A pre-saturator (also in the thermostat) contained hydrochloric acid of the same concentration as that contained in the precipitation vessel. In order to obtain reproducible results, in addition to the above precautions the precipitation vessel must be cleaned very thoroughly before use. The experiments were carried out by making up a series of solutions having the same concentration of cadmium chloride and gradually increasing concentrations of hydrochloric acid. In this way, two neighbouring solutions were obtained, in one of which a precipitate just appeared whilst in the other it did not. These two solutions were then made the limiting members of a new series in which the acid concentrations were graded more closely than before, and the interval between precipitation and non-precipitation was thus more accurately determined. Proceeding in this way, it was found possible to distinguish between two solutions differing by not more than 0.1*N*. The mean of these two hydrochloric acid concentrations was taken as giving the "critical" concentration for the given solution of cadmium chloride (expressed as mols. per litre), and the results are in the first two columns of Table I.

A second series of experiments was made with solutions in which the chloride of potassium, sodium, lithium, barium, or calcium was added so as to be present in *N*-concentration. The results are in the last five columns of Table I, which show in each case the critical concentrations of hydrochloric acid corresponding to each concentration of cadmium chloride.

TABLE I.  
Limiting concentrations of HCl in the presence of

$\text{CdCl}_2$	—	<i>N</i> -KCl	<i>N</i> -NaCl	<i>N</i> -LiCl	<i>N</i> -BaCl <sub>2</sub>	<i>N</i> -CaCl <sub>2</sub>

0.50	5.55	4.80	5.00	5.15	5.25	5.35
0.60	5.60	4.85	5.05	5.20	5.30	5.40
0.70	5.65	4.90	5.10	5.25	5.35	5.45
0.80	5.70	4.95	5.10	5.25	5.35	5.50
0.90	5.75	4.95	5.15	5.30	5.40	5.55
1.00	5.75	5.00	5.20	5.30	5.40	5.60

The results contained in Table I are shown in Fig. 1. It will be seen that the critical concentration of hydrochloric acid increases very rapidly with increase of cadmium chloride concentration for the lower concentrations, whilst for the higher concentrations the variation of the hydrochloric acid concentration is comparatively small. It will also be seen that the effect of the neutral chlorides is to lower the critical concentration of hydrochloric acid corresponding to any given concentration of cadmium chloride, which

FIG. 1.

means that in the presence of these chlorides a lower concentration of hydrochloric acid suffices to prevent precipitation of cadmium sulphide, thus pointing to an activation of the acid by the neutral chloride.

*The Time Factor.*—A surprising feature of these results is the relatively high concentrations of hydrochloric acid required just to prevent precipitation. This critical concentration increases rapidly with time. Passing in hydrogen sulphide for 5 minutes and for 1 hour, respectively, gave the results shown in the two lower curves of Fig. 2. On increasing the duration of passage of the gas, the

critical concentration of hydrochloric acid steadily rose, reaching a limit after about 6 hours (see highest curve), *i.e.*, further passage of the gas produced no measurable variation in the required concentration of acid. Glxelli (*loc. cit.*) noticed a similar "period of induction" in his experiments on the precipitation of zinc sulphide. The experimental results given in Table I correspond in all cases to a duration of 6 hours for the passage of hydrogen sulphide. The

FIG. 2.

influence of this apparent supersaturation effect is shown in Table II, which gives, for a 0.1*M*-solution of cadmium chloride at 25°, the critical concentrations of hydrochloric acid corresponding to different lengths of time.

TABLE II.

Mols. HCl per litre .....	1.7	2.3	4.5
Time (min.) .....	5	60	300

*E.M.F. Measurements.*—If we apply the simple laws of chemical equilibrium to the ionic reactions occurring in such a precipitation of sulphide, then, for the points on the "precipitation curve"

(i.e., the curve separating the region of precipitation from that of non-precipitation), we have the two equations

$$[\text{Cd}^{++}] \cdot [\text{S}^{--}] = \text{const.}$$

$$[\text{H}^+]^2 \cdot [\text{S}^{--}] = K[\text{H}_2\text{S}].$$

The first equation involves, of course, the doubtful assumption that the points on the precipitation curve correspond to equilibrium with a definite crystalline cadmium sulphide present in not too fine a state of division. If we assume further that the solubility of the hydrogen sulphide and also its dissociation constant do not appreciably change with the total electrolyte content of the solution, then the right-hand member of the second equation remains constant, and division of the equations gives  $[\text{Cd}^{++}]/[\text{H}^+]^2 = \text{const.}$ , an equation which is often used in elementary treatises on the theory of inorganic analysis. For very dilute solutions, we may use the approximate form  $[\text{CdCl}_2]/[\text{HCl}]^2 = \text{const.}$  If we apply this equation to the results given in columns 1 and 2 of Table I for the dilute solutions of cadmium chloride (although the corresponding concentrations of hydrochloric acid are by no means dilute), we obtain the results shown in Table III: the quotient rises slowly.

TABLE III.

$[\text{CdCl}_2]$ .....	0.005	0.01	0.02	0.03	0.05	0.10
$[\text{HCl}]$ .....	1.50	2.05	2.75	3.20	3.80	4.50
$10^4 \times [\text{CdCl}_2]/[\text{HCl}]^2$ ...	22	25	26	29	34	49

Rewriting the former equations in terms of activities, we have

$$a_{\text{Cd}} \cdot a_{\text{S}} = L$$

$$a_{\text{H}}^2 \cdot a_{\text{S}} = K_1 a_{\text{H}_2\text{S}}$$

where  $L$  is the activity of the solid sulphide and  $K_1$  the "thermodynamic" dissociation constant of hydrogen sulphide. Since the temperature and the pressure of hydrogen sulphide in the gas phase are constant,  $a_{\text{H}_2\text{S}}$  is now strictly constant. We may also regard  $K_1$  as a constant, hence for points on the precipitation curve

$$a_{\text{H}}^2/a_{\text{Cd}} = K_1 a_{\text{H}_2\text{S}}/L = \text{const.} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

This equation will be much more exact than the former one, although it still involves the assumption that we are dealing, along the precipitation curve, with a definite "solid" cadmium sulphide of not too small a grain size, or, at all events, of constant grain size in the different experiments. It is possible to test equation (1) by measuring the *E.M.F.* of cells of the type  $\text{Cd amalgam} | \text{CdCl}_2 + \text{HCl} | \text{H}_2 \text{ gas at constant pressure}$ . A dilute cadmium amalgam of definite concentration is used instead of solid metallic cadmium, in order to

avoid irreversible evolution of hydrogen at the cadmium electrode. The *E.M.F.* of the cell is given by the equation

$$E = E_0 + RT/2F \cdot \log a_{H^2}/a_{Cd} \quad (2)$$

Hence, if we employ in the cell solutions corresponding in composition and concentration to points on the precipitation curve, *E* will be constant if equation (1) holds good for such points, since we may neglect the effect of the dissolved hydrogen sulphide. Cells of this sort were set up, with hydrogen electrodes of the usual type, and yielded constant and reproducible results after an hour. The results are in Table IV (to the nearest millivolt).

TABLE IV.

CdCl <sub>2</sub> (mol./litre)	0.005	0.01	0.02	0.05	0.08	0.10	0.20	0.30	0.50
HCl (mols./litre)	1.50	2.05	2.75	3.80	4.20	4.50	5.20	5.40	5.55
<i>E.M.F.</i> (millivolts)	481	481	481	481	482	481	482	482	480

The constancy in the *E.M.F.* indicates that the points on the observed precipitation curve do correspond to definite equilibria, and supports the view that this curve is a true border curve separating the region of precipitation from that of solution (non-precipitation).

*Neutral Salt Effect.*—The curves numbered (2) to (6) in Fig. 1 show the changes in the precipitation curve caused by the presence (in *N*-concentration) of a series of neutral chlorides. The interpretation of these neutral salt effects from the point of view of ionic activities can be seen from a consideration of the figure. At the point A on the precipitation curve of cadmium chloride (*i.e.*, without addition of any neutral chloride) we have the relation

$$a_{H^2}/a_{Cd} = K_1 a_{H_2S}/L.$$

Suppose now that the solution corresponding to point A is made *N* with respect to, *e.g.*, potassium chloride, everything else remaining the same. Since A lies above C, it is clear that A now falls in the non-precipitation region, and hence  $a_{Cd} \cdot a_S < L$ . In the mixed solution corresponding to point A, therefore,  $a_{H^2}/a_{Cd} > K_1 a_{H_2S}/L$ . The effect of the addition of potassium chloride has thus been to increase the value of the quotient  $a_{H^2}/a_{Cd}$  and this value can be brought back to the original value,  $K_1 a_{H_2S}/L$ , only by reducing the concentration of hydrochloric acid to the value corresponding to point C. Now it is well known that the addition of chlorides can increase the value of  $a_{H^+}$  in a solution of hydrochloric acid (Poma, *Z. physikal. Chem.*, 1914, 88, 671; Harned, *J. Amer. Chem. Soc.*, 1915, 37, 2460; Fales and Nelson, *ibid.*, 1915, 37, 2769; Thomas and Baldwin, *ibid.*, 1919, 41, 1981). In the present case, this action will produce

a very marked result, owing to the occurrence of  $a_{H^+}^2$  in the numerator of the quotient. It is probable that owing to complex anion formation and other causes the addition of chlorine ions (from the neutral chlorides) will *decrease* the value of  $a_{Cd}$  occurring in the denominator. We have therefore good reasons for concluding that the addition of a neutral chloride will increase the value of  $a_{H^+}^2/a_{Cd}$ .

If we ascribe the chief effect to the increase in the value of  $a_{H^+}$ , we should expect from the results of the investigations previously quoted that the effect would decrease in the order  $LiCl > NaCl > KCl$ , whereas the results in Table I would appear to give the order  $KCl > NaCl > LiCl$ .

Further discussion of this matter would not be profitable without more detailed and extensive data.

#### *Summary.*

1. The concentrations of hydrochloric acid which are just sufficient to prevent precipitation of solutions of cadmium chloride by hydrogen sulphide at  $25^\circ$  and atmospheric pressure have been determined.

2. The effects produced on these critical concentrations of hydrochloric acid by a number of neutral chlorides in *N*-concentration have been determined.

3. The cadmium chloride-hydrochloric acid "precipitation" curve has been considered from the point of view of ionic activity, and predictions based thereon have been confirmed by *E.M.F.* measurements.

4. The effects produced by the addition of neutral chlorides have been considered in the light of previous work on the influence of such salts on the hydrogen-ion activity.

5. The precipitation experiments reveal a "supersaturation" or "induction" delay in the appearance of the precipitate, an effect previously noted by Glaxelli in the precipitation of zinc sulphide.

It is intended to extend this investigation and to include allied cases.

The work described was carried out at the suggestion and under the direction of Professor F. G. Donnan, to whom the author desires to express his thanks for advice and assistance.

CHEMISTRY LABORATORIES,

UNIVERSITY COLLEGE, LONDON. [Received, April 15th, 1926.]

*CCI.—The Interaction of Hydrogen and Nitrous Oxide on the Surface of Gold.*

By WILLIAM KENNETH HUTCHISON and CYRIL NORMAN HINSHELWOOD.

IN catalytic reactions at surfaces considerable variety is found in the relations which exist between the rate of reaction and the concentrations of the several reacting substances. Examples of different kinds have been given in a number of previous papers. The most general relation, when there is one reacting substance only, is that the rate increases with concentration according to a curve of the same form as an adsorption isotherm. When there are two reacting substances, the rate may actually pass through a maximum and decrease again as the pressure of one gas increases, the decrease being due to the displacement of the other gas from the surface. But it may happen that the two reacting substances are independently adsorbed on different active parts of the surface. Saturation can then be reached with respect to each gas without displacement of the other. Examples of these two kinds of behaviour are given in J., 1925, 127, 806, 1546. For the sake of completeness in classifying the various types of heterogeneous reaction, further instances may be useful.

We have now investigated the kinetics of the interaction of hydrogen and nitrous oxide on the surface of a gold wire. The results can be interpreted by assuming that hydrogen and nitrous oxide are adsorbed on the surface independently of each other, and that interaction can take place between adjacent molecules. The reaction rate increases with increase in the pressure of nitrous oxide, and reaches a limiting value at approximately 300 mm., after which it remains constant up to the highest pressure used, *viz.*, 500 mm. The absence of any fall in the rate at the higher pressures may be taken to show that, even after saturation is reached, there is no appreciable tendency for the nitrous oxide to displace the hydrogen from the surface.

Increase of hydrogen pressure has a similar effect, except that the limiting value of the rate is not quite reached within the experimental limit of 500 mm.

A second effect was traced to the hydrogen, namely a steady decrease in the activity of the wire, especially when it was heated in mixtures containing hydrogen in excess. On a wire, the activity of which had been reduced in this way to less than one-fifth of its initial value, it was found that the influence of the nitrous oxide on the rate was more nearly proportional to its pressure, and that the

limiting or saturation value could not be reached. It is suggested that hydrogen gradually dissolves in the body of the metal—this solution being distinct from its primary adsorption on the surface—and decreases the adsorptive power towards nitrous oxide. This would result, not only in a decrease in the rate of reaction due to the smaller number of nitrous oxide molecules present on the surface, but also in a change in the actual adsorption isotherm.

The method of procedure was that already described (*loc. cit.*), the change in pressure giving a measure of the reaction

A correction was necessary for the vapour pressure of liquid water at 0° in those cases where no drying agent was present. The experimental work was complicated by the continually decreasing activity of the catalyst. Heating to dull redness in air caused a partial but only temporary recovery, for it rendered the wire very susceptible to the further action of hydrogen. The following method was therefore employed to correct for the variable activity, and to reduce the results to values which are comparable with one another. Initial rates of reaction only were observed, and in any series, the first, third, and odd-numbered experiments were performed under standard conditions of concentration of the reactants (for convenience, 100 mm. of each), and in the even-numbered experiments the initial pressure of one or other reactant was varied. The ratio of the observed initial rate in an even-numbered experiment to the mean value of the rates observed in the reference experiments on either side of it gives a value which is strictly comparable with the others in a given series, even if the state of activity of the catalyst drifts to some extent.

Owing to this gradual poisoning of the catalyst, and also on account of the complicated relation which would be required to express the velocity in terms of the concentration of both reactants, no attempt was made to evaluate velocity coefficients, nor to determine the heat of activation. The experiments were carried out in the usual manner at two temperatures with a number of different wires, and in the tables which follow it will be seen how the initial rate of reaction depends upon the initial pressure of nitrous oxide and of hydrogen. If, as seems probable, the rate is determined by the amount of adsorption or surface concentration, these figures represent also the relative degrees of saturation of the active parts of the surface with the gas in question.

*Influence of Nitrous Oxide.*—On a fresh active wire the initial rate reaches a limit at a pressure near 300 mm. and remains constant up to a pressure of at least 500 mm.

TABLE I.

Pressure of hydrogen = 100 mm.

	Pressure of N <sub>2</sub> O (mm.).						
	100.	200.	300.	400.	500.		
Relative initial rate...	1.00	1.40	1.64	1.91	1.80	Wire 1	704°
" " ...	1.00	1.18	1.34	1.37	1.38	Wire 2	
" " ...	1.00	—	1.25	—	1.26	Wire 3	
" " ...	1.00	—	1.77	—	1.89	"	880°

With a wire in a highly poisoned and inactive state, as a result of the prolonged action of hydrogen, saturation was not reached, and the rate varied considerably more extensively with the initial pressure of nitrous oxide.

TABLE II.

Pressure of hydrogen = 100 mm. (Wire poisoned.)

	Pressure of N <sub>2</sub> O (mm.).						
	100.	200.	300.	400.	500.		
Relative initial rate...	1.00	1.50	2.10	2.50	—	Wire 2	704°
" " ...	1.00	1.76	2.56	3.13	3.68	"	880°

*Influence of Hydrogen.*—The influence of the pressure of hydrogen on the rate appears to be independent of the state of the wire, as the figures of Table III show. Saturation is not reached so readily as in the case of nitrous oxide.

TABLE III.

Pressure of nitrous oxide = 100 mm.

	Pressure of H <sub>2</sub> (mm.).						
	100.	200.	300.	400.	500.		
Relative initial rate...	1.00	1.33	1.58	1.97	2.22	Wire 4	704°
" " ...	1.00	1.21	1.50	1.78	1.92		
" " ...	1.00	1.18	1.43	1.40	1.81	Wire 2 (poisoned)	880°

*Influence of Water Vapour.*—Experiments were performed in which phosphoric oxide was present either in the bulb or in a small side tube sealed to it. The rate was reduced somewhat, as compared with that observed on the same wire before the introduction of the phosphoric oxide, and a certain recovery took place when the side tube containing it was sealed off, but the change was not fundamentally important. Further, a comparison of the results contained in Tables IV and V with those already discussed shows that the adsorption isotherms remain of the same form, whether water vapour is present or not.

This reaction possesses some interest in connexion with the general classification of heterogeneous reactions, as it represents

TABLE IV.

Pressure of hydrogen = 100 mm. (Fresh wire.)

	Pressure of $N_2O$ (mm.).						
	100.	200.	300.	400.	500.		
Relative initial rate...	1.00	1.34	1.56	1.59	(1.31)	Wire 5	704°

TABLE V.

Pressure of nitrous oxide = 100 mm. (Fresh wire.)

	Pressure of $H_2$ (mm.).						
	100.	200.	300.	400.	500.		
Relative initial rate...	1.00	1.63	—	2.00	2.73	Wire 5	704°

one of the most general cases. But rather will it be in certain special circumstances, for example, with very small or very large adsorption of one reactant, that further theoretical inferences will become possible.

*Summary.*

The relation between the rate of interaction of nitrous oxide and hydrogen at the surface of a gold wire and the concentrations of the two gases has been examined at 704° and 880°. The reaction is of the type where the two gases are adsorbed independently of each other. The rate of reaction tends to a limiting value as the pressure of each gas is increased.

CCII.—*The Specific Heats of Hydrogen Cyanide. A Reply.*

By JAMES RIDDICK PARTINGTON.

A RECENT statement [(Mrs.) Ingold, this vol., p. 26] that there is no "obvious disagreement between the author's results and those of Partington and Carroll" for the ratio of the specific heats of hydrogen cyanide seems to call for correction. Whereas the value found by the last two experimenters at 20° was 1.282 (422 mm.), that of Mrs. Ingold at the lowest temperature used, 65°, was 1.310 (1 atm.), and the curve in Fig. 2 in Mrs. Ingold's former paper (J., 1922, 121, 1610) would indicate that at 20° the value should be of the order of 1.315, which is 2.3% higher than the value found by Partington and Carroll (*Phil. Mag.*, 1925, 49, 665). It is not considered that such agreement is satisfactory.

Mrs. Ingold has discussed in a very general manner the statement that "although the vapour is associated, the association is small" (Partington and Carroll, *ibid.*, p. 680). Since the critical data were not known at the time, the latter authors contented themselves with an approximate calculation, but the statement that this was "unjustified" is not confirmed by an examination of the paper. Some caution is necessary in approximate calculations, but this must not be mistaken for doubt as to the approximate validity of the results found. In reality, as Mrs. Ingold points out, the calculation of the critical constants has been very satisfactorily confirmed by the experiments of Bredig and Teichmann (*Z. Elektrochem.*, 1925, 31, 449), which appeared later, and these authors have repeated our calculations of  $c_p/c_v$  from our own and Mrs. Ingold's experiments and have shown that they are very close to those obtained with the actual experimental data for the critical constants. The regular nature of the curve in Fig. 2 in Mrs. Ingold's first paper would therefore seem to be disturbed in the manner previously pointed out by Partington and Carroll.

It would seem possible to test the assumption of a small association of hydrogen cyanide vapour by a calculation of the density on the assumption that deviations from the gas laws alone, without association, are operative, and then comparing the results with the experimental values. The method used is one which, it is stated (Ingold, this vol., p. 26), has "proved conclusively that, despite its enhanced density, the degree of association of water vapour, if not zero, is at any rate so small that the most accurate available measurements fail to show it." The densities have been calculated from the ideal value by division by

$$\lambda = 1 + \frac{9}{128}\pi\tau(1-6\tau^2)$$

in accordance with Berthelot's equation, which may be expected to apply with some accuracy at atmospheric pressure. In this expression,  $\pi$  and  $\tau$  have been calculated from the critical data of Bredig and Teichmann ( $p_c = 53.2$  atm.;  $T_c = 456.6^\circ$ ). The results in Table I indicate that, below  $100^\circ$ , the calculated densities are distinctly lower than those found by Mrs. Ingold. At  $65^\circ$ , the observed density, which lies on the smooth curve, is 2% higher than that corrected for deviations from the gas laws, although the experimental error is stated to be only 0.2%. (The two observed values at  $132^\circ$  and  $175^\circ$  lie well below the smooth curve.) This seems to indicate that, if the density measurements are as accurate as they are claimed to be, there must be some such small association of hydrogen cyanide vapour as was assumed by Partington and

Carroll, and that the opposite conclusion, arrived at by Mrs. Ingold on very general grounds, and without specific reference to hydrogen cyanide, is improbable.

In a cursory reference to Bredig and Teichmann's paper, Mrs. Ingold has not emphasised the fact that these authors show, by no fewer than five different sets of experimental data, that hydrogen cyanide is associated in the liquid state and that they express agreement with our calculations for the gas.

FIG. 1.

It is also of interest to plot the values of  $\log p/p_c$  against those of  $(T_c/T - 1)$ , in the manner used by van der Waals. Bredig and Teichmann refer to this in their paper, but do not reproduce the

TABLE I.

$t^\circ \text{C.}$	$T^\circ \text{abs.}$	$\tau.$	$\lambda.$	$\Delta \text{ obs.}$ (air=1).	$\Delta \text{ obs.}$ (O=16).	$\Delta \text{ calc.}$
65	338.1	1.3595	0.9822	0.968	14.06	13.77
96	369.1	1.2371	0.9866	0.951	13.79	13.70

curve. This curve has been constructed from the data of Bredig and Teichmann (*loc. cit.*) and of Perry and Porter (*J. Amer. Chem. Soc.*, 1926, 48, 299), the former being denoted by circles and the latter by dots on the curve. It will be seen from Fig. 1 that practi-

cally all the points lie on a straight line passing through the origin. The gradient of this line is 3.26. According to van der Waals the normal value is 3.0, whilst from the curve for water given by Nernst ("Theoretische Chemie," 8—10 Aufl., p. 248) the value 3.3 is found. It may be remarked that, in reality, the gradient depends somewhat on the molecular weight and that, although it is reasonable to compare water and hydrogen cyanide as associated substances, carbon disulphide, for which the gradient is lower than 3, should probably be chosen as a normal substance for comparison. There would seem to be very little, if any, doubt that hydrogen cyanide is associated in the liquid state.

#### *Summary.*

It is shown that the reasons advanced against the assumption of Partington and Carroll that hydrogen cyanide vapour is associated to a small extent at room temperature are inconclusive, and that when the qualitative arguments put forward on general grounds are applied quantitatively to the specific case of hydrogen cyanide they lead to conclusions exactly opposite to those arrived at by Mrs. Ingold. Attention is also drawn to the fact that all the experimental evidence, of various kinds, points to association in the liquid state.

### CCIII.—*The Laws of Aromatic Substitution. Part V.* *The Directing Effect of Electrolytically Dissociated Groups.\**

By BERNHARD FLÜRSCHHEIM and ERIC LEIGHTON HOLMES.

In previous communications of this series (*J. pr. Chem.*, 1902, 66, 321; 1905, 71, 497; 1907, 76, 165, 185) it was shown, *inter alia*, that the position in which a second substituent will enter a mono-substituted benzene ring (whether *op-*, or *m-*) can be unequivocally predicted from the affinity demand of the first substituent. In subsequent papers, a more general theory of reactivity was evolved, in which, beside the *affinity demand* (the "quantitative factor" = *q*), the *varying nature of the affinity of atoms* ("polar factor" = *p*) and their *steric effects* ("steric factor" = *s*) were taken into consideration. A review of the whole subject has recently been published in *Chemistry and Industry* (1925, 44, 246).

\* A brief preliminary communication of the ideas and the scope of the experiments contained in this paper is to be found in *Chem. and Ind.*, 1926, 45.

Whereas generally account must be taken of all three factors, there are cases, and even classes, of reactions where one or even two of them can be neglected. Thus the steric hindrance exercised by a first substituent in benzene affects substitution in the *o*-position, but its effect, and still more the difference of its effects, in the *m*- and *p*-positions are negligible. On the other hand, the polar effect of most substituents cannot be neglected in *any* position, but even here the *difference* of their influence on the *m*- and *p*-carbon atoms could be ignored in all the cases hitherto examined. This has been definitely established by numerous observations; thus, not even an accumulation of "negative" groups such as obtains in bromocyanophenylnitromethane,  $C_6H_5 \cdot CBr(CN) \cdot NO_2$ , can prevent the essentially exclusive *op*-substitution predicted from the affinity demand of the substituent (compare *J. pr. Chem.*, 1902, 66, 321).

In view of this, an observation by Noeltling and Kregczy (*Bull. Soc. chim.*, 1916, 19, 355) seemed at first sight surprising. These authors nitrated diethylbenzylamine in sulphuric acid solution and obtained 35 to 40% of the *m*-nitro-derivative. Since the affinity demand of the substituent should lead to *op*-nitration only, this experiment has now been repeated, and through the use of very accurate methods of separation the yield of the *m*-nitro-compound has been found to be even higher, *viz.*, 44% of the isomerides formed.

This result could not be ascribed to nitration of the *free base*, since the hydrolysis of such a relatively strong base in an excess of strong sulphuric acid would be negligible. Neither could it be due to nitration of the *salt*, which should occur only in the *o*- and *p*-positions. Reference to the work of Walden and others having shown that salts possess a high degree of electrolytic dissociation in strong sulphuric acid, even at high concentrations, the question whether *m*-nitration of the *electrolytic ion* would be in accordance with the theory was next considered. Concerning the relative polar effects of different atoms, it had already been pointed out (*J.*, 1909, 95, 719) that an electric charge may be regarded as the most polar element. The meaning of this statement may be briefly explained.

Discarding all speculations concerning the origin and nature of chemical affinity, what we really *know* about it appears to be this: 1. Chemical affinity, like gravitational and magnetic forces, is *some* function of an atom. 2. Although atoms contain positive and negative electrical charges, there is no compelling reason for assuming that chemical force, any more than gravitational or magnetic force, is electrostatic. 3. The behaviour of atoms, not only towards electrical charges, but also *towards one another*, proves that chemical affinity varies in different atoms both in *amount* and in *kind*. The difference in kind is most pronounced between the

atoms of the elements situated at the opposite ends of a period in the periodic table and *gradually* diminishes with the number of intervening members of the period. The more two atoms differ as to the kind of their affinity, the greater is the difference in their tendencies to combine, either with a third atom located towards either end of a period, or with an electrical charge of a given sign.

We may conclude that the variation in kind exhibited by chemical affinity implies a *gradual transition in polarity*, involving a change of sign at a given point in a period. *This gradual transition, if extended far beyond the terminal members of a period, would lead to polarity in its extreme form—electropolarity.* In other words, *whilst electropolarity exists only in two extreme kinds of opposite sign, chemical polarity, gradually varying in kind, bridges a limited central region in the wide gap between the two electropolar extremes.* Thus, in view of the strong affinity of fluorine for an electron as well as for lithium, the corresponding period might be written :

polar attraction between two members of opposite sign, and polar repulsion \* between a given member and a more polar one of the same sign, running parallel with their distance apart within the period. This is what is meant by the polar factor *p* or “polar effect,” or, to use the term recently introduced by Lapworth, by “general polarity.”

The polar attraction by a negative charge, and the polar repulsion by a positive charge, of a halogen atom, nitro-group, etc., therefore considerably exceed the corresponding effects of an electrically neutral atom or group on these atoms or groups. Accordingly, since the polarity of such a charge is transmitted to different nuclear carbon atoms in different degrees ascertainable from the theory itself (J., 1910, 97, 85), a positive charge tends to direct an entering nitro-group, etc., to the least affected nuclear carbon atom, whereas a negative charge tends to direct it to the most affected carbon atom. In the benzoic anion and the diethylbenzylammonium kation, for instance, the nuclear atoms are affected in the order *o*->*p*->*m*- (on account of the direct neutralisation of residual affinity between the *p*-atoms which results in the *direct* transmission of the polar effect from the substituted atom to the *p*-atom) (see *loc. cit.*), so that the overpowering *p* of the electrical charge must favour substitution in the order *o*->*p*->*m*- in the benzoic anion and *m*->*p*->*o*- in the diethylbenzylammonium kation. Besides, it must have an acceler-

\* “Repulsion” is used in a relative sense only, to denote a reduced potential at corresponding points in the field of mutual attraction of the atoms. The affinity of neon, whilst much smaller in amount than that of fluorine, must be even more polar in kind.

ating effect in the anion and a retarding effect in the kation, as compared with the corresponding neutral compound.\*

This is exactly what has been found to occur. Electrolytically dissociated sodium benzoate is chlorinated by hypochlorous acid (Lossen, D.R.-P. 146, 174) with remarkable ease and in the order  $o \rightarrow p \rightarrow m$ -, whereas benzoic acid itself is brominated, by hypobromous acid, slowly and in the meta-position (Stark, *Ber.*, 1910, 43, 473). Electrolytically dissociated benzyldiethylammonium hydrogen sulphate is nitrated in the meta-position and more slowly than the undissociated salt, since  $m$ -substitution in an approximately normal solution amounts to 44% only, although the degree of dissociation of binary salts in strong sulphuric acid at a corresponding concentration is of the order of 80 or 90%.

The theoretical support thus afforded for the assumption that the observed *meta*-nitration is due to the electrolytic ion has been supplemented by direct experimental proof. The assumption requires that increased electrolytic dissociation should lead to increased *meta*-substitution, and *vice versa*. This has been found to be the case. At double the dilution, 52% of the  $m$ -nitro-derivative was formed, the increase being in approximate agreement with the value calculated from the increase in dissociation required by Sugden's cubic root law on the basis of *exclusive m*-nitration of the ion and *exclusive op*-nitration of the undissociated salt (see experimental part); any appreciable *op*-substitution in the ion and/or  $m$ -substitution in the salt would, according to Sugden's law and still more according to other dilution laws, have caused the increase in the amount of  $m$ -nitration to be correspondingly below the experimental result. Similarly, the introduction of a common ion by saturation of the nitrating solution with ammonium sulphate resulted in lowering the amount of *meta*-compound formed to 34%. In this case, only an approximate calculation is feasible, but it shows the decrease to be of the right order. If the dissociation of the sulphuric acid solvent itself (to which Dr. Sugden has kindly called the authors' attention) produced a common ion, then the change in  $m$ -nitration with varying concentration would be even greater than required by Sugden's law.

Complications such as have now been dealt with, where the uniquely strong  $p$  of an electrical charge conflicts with and outweighs  $q$ , can occur only where the charge is carried by an atom separated from the nucleus by *one* intervening atom. When the charged

\* This effect of the polar factor on the *velocity* of aromatic substitution has repeatedly been emphasised by one of the authors (*e.g.*, *Ber.*, 1906, 39, 2016; *J. pr. Chem.*, 1907, 76, 200), and its electronic equivalent recently by Robinson (this vol., p. 410) and co-workers.

atom is directly attached to the nucleus,  $p$  and  $q$  support each other. When the charged atom and the nucleus are separated by two or more atoms, the polar factor even of an electrical charge may be presumed to become negligible, at least as regards its effect on  $m$ - versus  $p$ -substitution.

The present results appear to supply a conclusive solution of the problem of  $m$ -nitration in solutions of benzylammonium salts and to be in complete agreement with the theory advanced by one of the authors. Apart from this they seem to show, for the first time, a way in which the changes of the "degree of dissociation" can be ascertained without interference from disturbing factors such as variations in viscosity, ionic mobility, and solvation. The results also furnish, perhaps not a final proof, but at least a strong argument against the theory of the complete dissociation of strong electrolytes and of the intramolecular ionisation of undissociated ammonium salts. On these views, the undissociated salt in solution would have to be replaced by its two ions in more or less close proximity. But in this case, the charge on the kation would be substantially nearer to the benzene ring than would the charge on the anion, and though it is perhaps not entirely impossible, it is at least highly improbable that the latter charge could seriously interfere with the transmission to the ring of the pronounced polar effect of the first charge. What appears quite certain, however, is that it could not do so in the case of Robinson's mechanism of transmission. Robinson, who has adopted the electronists' view that an ammonium group is ionised even in the undissociated salt (J., 1922, 121, 430), attributes *meta*-substitution to a "Lewis" electron shift towards the ammonium group caused by its positive charge (*Chem. and Ind.*, 1925, 44, 563; this vol., p. 410). But such a shift would occur both in the electrolytically dissociated and in the undissociated state, since in the latter the attraction of the electron by the positive charge would, according to Coulomb's law, be compensated by the repulsion of the more distant anionic charge only to a fractional extent (less than one-quarter). It would be less compensated than a positive charge on carbon in carboxyl, carbonyl, trichloromethyl, or on nitrogen in a nitro-group (since the acid radical is generally recognised to be at a greater distance from ammonium nitrogen than oxygen is from carbon or nitrogen, or than chlorine is from carbon), all these being cases where Robinson (*loc. cit.*) attributes *meta*-substitution to such a positive charge, thus obviously assuming it to be insufficiently compensated. Contrary to the experimental results, Robinson's theory would therefore require *meta*-substitution in the undissociated as well as in the dissociated portion, especially since his alternative (conjugation) cannot be applied in this case.

Neglect of the polar and steric factors in classes of reactions where—as has repeatedly been emphasised—they must not be neglected, has recently led several authors to erroneous objections, which will be dealt with in a subsequent communication.

#### EXPERIMENTAL.

Three series of nitrations of diethylbenzylamine were carried out. The first of these served to establish the best method of separating the isomerides formed. The second series (nitrations 1 to 5 in the table) gave the approximate results obtained by that method, whereas in the final series (nitrations 7 to 10) quantitative values were obtained by the determination of that portion of the *m*-nitro-compound which could not be separated as such.

The nitrations were carried out by Noelting and Kregczy's method (*loc. cit.*), but at  $-10^{\circ}$  to  $0^{\circ}$  instead of  $-5^{\circ}$  to  $+5^{\circ}$ . Nitric acid (Kahlbaum, "*d* 1.52") was used, except in No. 5, where ordinary fuming nitric acid served both as nitrating agent and as solvent. In Nos. 8 and 10, the nitrated mixture was kept at room temperature for  $1\frac{1}{2}$  hours, and 4 hours, respectively, instead of the usual 1 hour. To prevent any volatilisation of the nitro-bases formed, the benzene extract containing them was treated with picric acid before evaporation to dryness. The yield of crude nitro-bases was always close to 97.0% of the theoretical, and the picric acid added (2.60, 4.0, 6.71, 7.10, 2.60, 3.417, 6.48, 4.286, and 4.480 g., respectively, in nitrations 1 to 5 and 7 to 10) was either 97% of the theoretical or slightly more. The freezing-point method being untrustworthy in the presence of even small amounts of impurities, and fractional distillation of the free bases having failed, there only remained the following method, involving the use of an analytical balance throughout and weeks of work for each nitration of the final series:

The bulk of the relatively insoluble picrate of the *m*-isomeride was obtained pure by prolonged fractional recrystallisation from alcohol (see Noelting and Kregczy); this was preferably preceded by fractional extraction with small amounts of the solvent. This fractionation was carried especially far in Nos. 1, 8, and 10. In Nos. 2, 3, and 5, the pure picrate of the *p*-nitro-compound was also isolated, by further recrystallisation from glacial acetic acid, to the extent of 1.60, 2.30, and 1.09 g., respectively. The purity of the picrate of the *m*-nitro-compound was established by its correct and constant melting point, by the melting point of a mixture with a sample prepared from *m*-nitrobenzyl chloride and diethylamine, and by its oxidation to *m*-nitrobenzoic acid. The purity of the picrate of the *p*-compound, where isolated, was established by its correct

and constant melting point, and by the melting point of a mixture with synthetic material. The pure picrate, m. p.  $122^{\circ}$ , of the *o*-nitro-compound could only be obtained synthetically (Noelting and Kregczy give  $117^{\circ}$ ). The *picrate* of diethylbenzylamine itself crystallises in stout, yellow prisms, m. p.  $120^{\circ}$ . In the final series, the picrate of the *m*-nitro-compound left behind in the *op*-mixture was thus determined : 1 part of the picrate mixture was boiled under reflux with 120 parts of water and 2 parts of potassium permanganate. At intervals of 30 minutes three further additions of 2 parts of permanganate were made, then another after 40 minutes, whereafter boiling was continued for 3 hours. After the excess of permanganate had been destroyed by alcohol, the nitrobenzoic acids were extracted in the usual way, except that any portion held back by manganese dioxide was freed by dissolving the latter in sulphurous acid. The *m*-nitrobenzoic acid was exhaustively separated from its isomerides by fractionation of the barium salts (the relatively insoluble *m*-salt crystallising in its characteristic needles), then of the free acids, then again of the barium salts, and so on as often as was necessary. Traces of benzoic acid, only found in Nos. 8 and 9, were determined by the loss in weight of the acid mixture when heated below  $100^{\circ}$  to constant weight, the sublimed benzoic acid being subsequently identified. Experiment 6 was carried out to ascertain whether the proportions of the isomeric nitrobenzoic acids obtained by oxidation (whereby about 80% of the theoretical quantity was recovered as crude acids) corresponded exactly with the proportions of the isomeric picrates oxidised. This was found to be the case. Corroboration was obtained by oxidising 2 g. of the picrate of the *o*-nitro-compound under identical conditions, whereby 0.579 g. of pure *o*-nitrobenzoic acid was obtained (76% of the theoretical), whereas 2.50 g. of the *m*-isomeride gave 0.76 g. of acid (79.6%); also by boiling 2 g. of *o*-nitrobenzoic acid in 240 c.c. of water with 1.5 g. of potassium hydrogen carbonate and 4 g. of potassium permanganate during 3 hours, whereby 1.789 g. (89.5%) of the unchanged acid was recovered. This proves that, in the particular method employed, undue further oxidation of *o*-, as compared with *m*- and *p*-nitrobenzoic acids, does not occur.

The yields of *m*-compound were calculated in Nos. 1, 7, 8, and 10 on the total separated picrates obtained, less a correction for any excess of picrate (0 to 0.1 g.) used beyond the normal equivalent of 97% of the theoretical quantity, and also for any traces of benzoic acid found and calculated as the picrate of the unnitrated amine. In Nos. 2, 3 and 5, where the picrates of the *op*-mixture had been worked up further for the *p*-compound before its weight was taken, and in No. 9, where this mixture was inadvertently oxidised before

8	4.678	25	1.9	12.13	3.92	$\left\{ \begin{array}{l} 3.28 \\ 2.46 \end{array} \right.$	0.010 impure 0.008 impure	0.932 0.698	0.026 0.030	33.83 $\pm$ 0.35 34.30 $\pm$ 0.37
9	3.058	39.7	1.3	7.95	3.042	?	$\left\{ \begin{array}{l} 0.266 \text{ pure} \\ 0.01 \text{ impure} \end{array} \right.$	1.046	0	51.89 $\pm$ 0.23
10	3.277	42.2	1.4	8.433	3.937	2.24	$\left\{ \begin{array}{l} 0.069 \text{ pure} \\ 0.007 \text{ impure} \end{array} \right.$	0.490	0	53.51 $\pm$ 0.33

its weight had been *accurately* taken, the yield of *m*-compound was calculated on the normal yield of separated picrates amounting to 94% of the theoretical. The proportion of *m*-acid in the separated nitrobenzoic acids gave the percentage of *m*-picrate in the inseparable portion of the picrates.

The  $\pm$  corrections in the last column of the table are due to adding one-half of the small fraction of impure *m*-nitro-acid to the pure for calculation of the yield. In Nos. 9 and 10 the concentration of the amine in the sulphuric acid was accurately one-half of that obtaining in No. 7. The ammonium sulphate added in Nos. 2, 3, 4, and 8 was in excess of the amount soluble at the nitration temperature. The amount dissolved can be calculated from the following experiment: 15 c.c. of the sulphuric acid and 2.523 g. of the amine gave 17.5 c.c. of solution and 17.3 c.c. at 0°. 6.2 G. of ammonium sulphate gave a clear solution in the above liquid of 20.4 c.c. at 0°; a further 0.2 g. produced a distinct cloudiness (total volume 20.5 c.c.).

The average *m*-nitration in Nos. 9 and 10 is 52.7%. For an average degree of dissociation of 90% in nitration No. 7, Sugden's cubic root dilution law requires a yield of 50.3% of the *m*-compound in Nos. 9 and 10, whereas for 80% and 70% dissociation in No. 7, 51% and 51.9% of the *m*-compound should be obtained in Nos. 9 and 10. Walden's dilution law ( $1-\alpha = K/v^{0.45}$ ) (quoted in Walden, "Leitvermögen der Lösungen," III, 59) requires 52.5, 53.3, and 54.3%, respectively.

The authors desire to express their indebtedness to the Department of Scientific and Industrial Research for a grant to one of them (E. L. H.) which has enabled him to contribute the experimental portion of this work; also to Sir W. Bragg and the Royal Institution for placing at their disposal the facilities of the Davy Faraday Laboratory, where the work was carried out.

[Received, March 12th, 1926.]

#### CCIV.—*Properties of Conjugated Compounds. Part I. Conjugative Associations in Extended "Conjugated" Systems.*

By ERNEST HAROLD FARMER and JOHN ROSS.

IN extended conjugated systems of the type  $\text{CH:CH:CH:CH:C:O}$ , the characteristic mode of terminal hydrogen addition is usually regarded as due to the conjugative coherence of all the individual saturated elements of the chain. Many reactivities of these

structures, however, appear to be dependent on a state of partial association in which the complex  $\text{CH}_2\text{CH}:\text{C}:\text{O}$  acts as a conjugated unit, the whole behaving as a substituted ethylene or as a  $\beta$ -substituted acrylic acid. As a means of estimating the extent of conjugative association in extended systems, an attempt has been made to examine the degree to which the behaviour of the acrylic "unit" is modified by inclusion in systems of the type in question. Since one of the most important properties of the complex is a normal capacity for change from one conjugated form to another ( $\text{CH}_2\text{CH}:\text{C}:\text{O} \rightleftharpoons :\text{C}:\text{CH}:\text{OH}$ )—a change impossible in extended systems unless the olefinic chain is branched—observations have been made in this respect, certain *cyclohexenylidenecyanoacetic* esters containing the essential structure  $\text{C} \begin{smallmatrix} \text{C}=\text{C} \\ \text{C}-\text{C} \end{smallmatrix} \text{C}=\text{C}:\text{C}=\text{O}$  being employed for the purpose.

It was shown by Knoevenagel and Mottek (*Ber.*, 1904, 37, 4464), in their investigation of the reactivity of ketones, that 1-methyl- $\Delta^1$ -*cyclohexen*-3-one reacts with ethyl cyanoacetate in the presence of piperidine, giving ethyl methyl*cyclohexenylidenecyanoacetate* (I). In accordance with the assigned constitution, this substance could be broken down by hydrolysis with caustic alkali into the original ketone and malonic acid; apparently, however, it was unsuitable for our experiments owing to the ease with which it was stated to undergo an astonishing intramolecular change. Thus, according to these authors, hydrolysis with sodium carbonate yielded an acidic compound to be represented by some such formula as (II) or (III), or one of their enolised equivalents.

Further, the silver salt of the substance yielded with methyl iodide a mixture of isomeric esters or ethers for the isomerism of which it was difficult to account. The formulæ assigned were necessitated solely by the analytical results; there was nothing in the behaviour of the substance itself to suggest the presence of the aromatic nucleus which these formulæ imply. Consequently, in reviewing the evidence, the suspicion arose that the acidic compound was a nitrogenous substance, and, if formula (I) were correct, was actually the normal hydrolysis product (IV). Repetition of Knoevenagel

and Mottek's work confirmed this view, thus rendering possible the study of the methylcyclohexenyldenecyanoacetic esters.

The ethyl ester was very readily obtained and was converted by alcoholic alkali into an acid agreeing with formula (IV) analytically, and in melting point and general properties with Knoevenagel and Mottek's supposed dicyclic compound. This rather intractable acid did not appear homogeneous, but could not be separated into components by fractional crystallisation. Esterification, however, yielded the two isomeric methyl esters mentioned above.

Formula (IV) at once suggests the possibility of geometrical isomerism about the extracyclic double bond, and the two isomerides found might be regarded as the maleinoid and fumaroid forms (V and VI). This being so, these two solid methyl esters should be directly obtainable by the condensation of methyl cyanoacetate with the ketone. When this was done, the excellent yield of the two methyl esters obtained left no doubt as to their monocyclic constitution.

As the isomerides or tautomerides concerned in mobility of the  $\alpha\beta$ - $\beta\gamma$  type are usually brought into equilibrium in the presence of alkalis or sodium alkyl oxides, the two methyl methylcyclohexenyldenecyanoacetates were separately treated with alcoholic sodium methoxide. In each case, a similar mixture of three esters was obtained from the product. Two of these were the esters (V) and (VI), and the third must be regarded as the methyl methylcyclohexadienylcyanoacetate (VII). Subsequently this was shown to yield a similar mixture of three isomerides on treatment with sodium methoxide. Since in all three mixtures the proportions of the

components appeared identical, there is little doubt that an equilibrium holds. Caustic alkali exerted a similar influence during the

hydrolysis of these esters, as was shown by the melting point of the acid mixture obtained and by the nature of the mixture of esters obtained on re-esterification; further, upon repetition of these processes with larger amounts of the ethyl ester first obtained, the third methyl ester was isolated in this case also.

Each of the three esters gave a distinctive dibromide and each could be methylated precisely as the various *cyclopentenyl*- and *cyclohexenyl*-cyanoacetic esters and their tautomerides (Harding and Haworth, J., 1910, 97, 490; Birch and Kon, J., 1923, 123, 2440), the product in all cases being one and the same methyl derivative (VIII).

In attempts to prepare the cyanoacetamides of the isomeric esters by means of aqueous ammonia, each gave rise to a dicyanoacetamide (IX) and the ammonium salt of the imide (X), both being identical with the compounds directly obtainable from the ketone and cyanoacetic ester by the Guareschi synthesis. Such syntheses resulting from the reversion of a portion of the cyclic ester into its generators, with the subsequent addition of the liberated cyanoacetic ester (or amide) to the undecomposed portion, have recently been observed in other series (private communication by Miss W. Kilroy).

Among the small portions of ester recovered in these reactions, isomerides other than the original one were obtained. Interconversion of the esters could be secured only by the use of an alkaline equilibrating agent; thus the passage from a fumaroid to a maleinoid form was only possible by way of the third (*cyclohexadienyl*-) form, and in the original condensation of the ketone and methyl cyanoacetate two and only two forms were obtained.

In estimating the effect of conjugative association on the incorporation of the group  $\text{CH}:\text{CH}:\text{C}:\text{O}$  in a larger unit, it is convenient to compare the results obtained above with the evidence furnished by substances containing no double bonds other than those of the acrylic system. Among the latter, considerable, and at present inexplicable, variations occur in the speed of attainment and in the position of equilibrium. In some cases, the  $\alpha\beta$ - and  $\beta\gamma$ -forms are readily isolable and undergo appreciable interconversion only in the presence of a reagent like sodium alkyl oxide; in the limiting cases, isomerisation is so rapid (even in absence of a reagent) and the position of equilibrium favours so strongly one form or the other

that the separation of individuals has been impossible.\* In the cyclohexenylidene esters described above, the acrylic group seems to be preserved as a definite unit. Change of the  $\alpha\beta$ - $\beta\gamma$  type, which might conceivably have been suppressed, is here of normal and intermediate character; and in so far as this is the case there is no positive evidence of any considerable tendency for the extended system, of which the acrylic group is a part, to act persistently as a completely conjugated unit.

#### EXPERIMENTAL.

*Condensation of Methyl Cyanoacetate with 1-Methyl- $\Delta^1$ -cyclohexen-3-one.*—A mixture of the ketone (110 g.), the ester (100 g.), and piperidine (10 c.c.) was heated at 120—125° for 6 hours. The cooled product, upon the surface of which a thin aqueous layer had formed, was diluted with ether and thoroughly washed, first with dilute sulphuric acid and then with dilute sodium carbonate solution. The dried ethereal solution was distilled, finally at a very low pressure (the amount of undecomposed material passing over at 1 mm. was double that at 10 mm.); the fraction, b. p. 165—175°/2 mm., solidified on cooling (yield 70%).

A considerable portion of this solid dissolved in boiling petroleum (b. p. 40—60°). The solution deposited one isomeride of *methyl 1-methyl- $\Delta^1$ -cyclohexenylidene-3-cyanoacetate* in large, needle-shaped prisms, m. p. 74°; these were sometimes colourless, but often had a deep yellow colour which was removed by boiling in petroleum solution with animal charcoal (Found: C, 68.95; H, 6.9; N, 7.5.  $C_{11}H_{13}O_2N$  requires C, 69.05; H, 6.85; N, 7.3%).

The petroleum mother-liquor, after concentration and cooling, deposited flat, colourless prisms, m. p. 60°. This substance, isomeric with that described above (the two are regarded as isomerides of the fumaroid-maleinoid type), represented about 6% of the ester mixture (Found: C, 69.05; H, 6.9; N, 7.45%).

The portion of the ester mixture undissolved by boiling petroleum crystallised from methyl alcohol-petroleum in colourless, hexagonal prisms, m. p. 88°. The nature of this stable, highly nitrogenous substance, which is readily obtainable from the cyanoacetic ester and piperidine alone, has not been determined (Found: C, 63.1; H, 8.0; N, 17.7%).

\* The strictly comparable cyclohexylidene- and cyclopentylidene-cyanoacetic esters are liquids (Birch, Kon, and Norris, J., 1923, 123, 1368) and from the details published it is evident that both the position of equilibrium and the isolability of the separate forms are uncertain. In the present case, equilibrium is attained when the material is divided between the cyclohexylidene and the cyclohexenylidene form in the approximate ratio of 3 : 10.

*Condensation of Ethyl Cyanoacetate with 1-Methyl- $\Delta^1$ -cyclohexen-3-one.*—This condensation, effected by Knoevenagel and Mottek's method (*loc. cit.*), produced an oil from which, by distillation at 1 mm. pressure and refractionation, a mixture of esters, b. p.  $190^{\circ}/16$  mm., which solidified on cooling, was obtained. The main part of this mixture melted at  $58^{\circ}$  after recrystallisation from light petroleum. This substance, doubtless one form of ethyl methylcyclohexenylidenecyanoacetate, was used for the repetition of Knoevenagel and Mottek's experiments (Found: C, 70.0; H, 7.5; N, 7.05. Calc. for  $C_{12}H_{15}O_2N$ : C, 70.2; H, 7.4; N, 6.85%).

*Equilibration by Alcoholic Caustic Alkali.*—*Hydrolysis of methylcyclohexenylidenecyanoacetic esters.* The ethyl ester was not appreciably hydrolysed on boiling for 12 hours with 15% hydrochloric acid and was only slowly affected by boiling with sodium carbonate solution in the manner described by Knoevenagel and Mottek. Since prolonged treatment with caustic alkali caused degradation, the ester was boiled for 30 minutes with 10% aqueous-alcoholic caustic potash (alcohol: water = 3:1). The deep brown solution so obtained was cooled, and the hydrolysis product separated by the usual methods into neutral and acidic portions. The acidic portion was a very sticky, brown solid which was recrystallised several times from benzene, decolorised by animal charcoal, and recrystallised from acetone. This acid, which was not homogeneous in crystalline form, melted at  $149^{\circ}$  (Found: C, 67.6; H, 6.3; N, 7.9; *M*, monobasic, 174. Calc. for  $C_{10}H_{11}O_2N$ : C, 67.8; H, 6.25; N, 7.9%; *M*, 177.1). The ammonium salt was obtained, from the acid and ammonia in ether, as a colourless, crystalline precipitate, which was dried in a vacuum. The silver salt was precipitated as a pale yellow powder from an aqueous solution of the ammonium salt by silver nitrate.

*Separation of the isomeric esters.* The mixture of methyl esters, b. p.  $180$ — $185^{\circ}/17$  mm., obtained by boiling the silver salt with alcoholic methyl iodide was crystallised from petroleum. The characteristic, needle-like crystals of methyl methylcyclohexenylidenecyanoacetate, m. p.  $74^{\circ}$ , separated first; then, after concentration, the geometrical isomeride, m. p.  $60^{\circ}$ , was obtained in large, hexagonal plates. (Both of these were shown by analysis and by direct comparison to be identical with the respective esters described above.) Finally, when the mother-liquor had been evaporated almost to dryness, crystals of methyl 1-methyl- $\Delta^{1:3}$ -cyclohexadienyl-3-cyanoacetate were obtained. These, after recrystallising several times from strongly-cooled methyl alcohol-petroleum, were obtained in colourless needles, m. p.  $42^{\circ}$  (Found: C, 69.1; H, 7.0; N, 7.5.  $C_{11}H_{13}O_2N$  requires C, 69.05; H, 6.9; N, 7.35%).

The proportions in which the three esters were obtained were (m. p.  $74^{\circ}$ ) : (m. p.  $60^{\circ}$ ) : (m. p.  $42^{\circ}$ ) = 4 : 1 : 1.6.

*Equilibration by Sodium Alkylloxide.*—A mixture of the ester, m. p.  $74^{\circ}$  (3 g.) and sodium methoxide (1 mol.) in cold methyl alcohol was kept for one hour and then poured into water. The mixture of solid esters (2 g.) obtained by extracting the product with ether yielded, on fractional crystallisation, the three isomeric esters in the approximate proportions 4.2 : 1 : 1.5. Nearly a third of the material suffered hydrolysis during the process.

Similar results were obtained with the other two isomerides.

*Methylation of the Isomeric Esters.*—An equilibrated mixture obtained as described above was heated on a water-bath with an excess of methyl iodide for 30 minutes. The cooled solution was poured into ice-water, and the product extracted with ether. The extract was washed in turn with dilute acid and sodium carbonate solution and dried. Evaporation of the ether yielded an oil two-thirds of which distilled at  $160$ — $165^{\circ}/10$  mm. On redistillation it was obtained as a colourless, mobile liquid, b. p.  $160^{\circ}/11$  mm. This substance, from its analysis and ready conversion into the corresponding acetonitrile, must be regarded as *methyl 1-methyl- $\Delta^{1:3}$ -cyclohexadienyl-3- $\alpha$ -cyanopropionate* (VIII) (Found : C, 69.95; H, 7.5; N, 7.3.  $C_{12}H_{15}O_2N$  requires C, 70.2; H, 7.4; N, 6.9%).

*Bromination of the Isomeric Methyl Methylcyclohexenylidenecyanoacetates.*—The esters, m. p.  $74^{\circ}$  and  $60^{\circ}$ , yielded, on bromination (1 mol.) in cold chloroform, *dibromides* which crystallised from alcohol-petroleum in large, colourless prisms, m. p.  $77^{\circ}$  (Found : Br, 45.2%), and fine needles, m. p.  $65^{\circ}$  (Found : Br, 45.3.  $C_{11}H_{13}O_2NBr$  requires Br, 45.5%) respectively. The ester, m. p.  $42^{\circ}$ , similarly yielded a yellow, oily dibromide (Found : Br, 44.8%).

These dibromides readily lost hydrogen bromide on treatment with diethylamine, but the products were all liquid and could not be satisfactorily reduced by any of the reagents employed.

*Decarboxylation of the Cyano-esters.*—Decarboxylation of (VIII) by Birch and Kon's method (*loc. cit.*, p. 1374) gave, in good yield, *1-methyl- $\Delta^{1:3}$ -cyclohexadienyl-3-propionitrile* as a colourless, mobile liquid, b. p.  $126^{\circ}/11$  mm. (Found : C, 81.9; H, 9.0; N, 9.0.  $C_{10}H_{13}N$  requires C, 81.6; H, 8.9; N, 9.5%).

The purified hydrolysis product of methyl (or ethyl) methylcyclohexenylidenecyanoacetate (p. 1575) yielded, on heating with water at  $180^{\circ}$  or on boiling for 30 minutes with 15% hydrochloric acid, a light, neutral oil which, after extraction, drying, and distillation, was obtained as a colourless, mobile, highly refractive liquid, b. p.  $105$ — $110$  mm. (Found : C, 80.8; H, 8.3; N, 10.2.  $C_9H_{11}N$  requires C, 81.1; H, 8.3; N, 10.5%).

*Action of Ammonia upon the Three Isomeric Esters.*—The methyl ester, m. p.  $74^{\circ}$  (3 g.), gradually dissolved in concentrated aqueous ammonia, and after 12 hours large crystals, m. p.  $273^{\circ}$ , of 1-methyl- $\Delta^1$ -cyclohexene-3 : 3-dicyanoacetamide (IX) were deposited. A second crop consisted of this substance and the ammonium salt of the cyanimide (X). The latter had m. p.  $188^{\circ}$  (Found : C, 60.1; H, 6.4; N, 21.3.  $C_{13}H_{16}O_2N_4$  requires C, 59.95; H, 6.2; N, 21.5%) and yielded, on acidification of its aqueous solution, the free imide, a white, crystalline powder, m. p.  $195^{\circ}$  (Found : N, 17.1.  $C_{13}H_{13}O_2N_3$  requires N, 17.3%). The dicyanoacetamide, which was insoluble in all the ordinary solvents, was washed in turn with boiling alcohol and boiling water and then had m. p.  $275^{\circ}$  (Found : C, 59.85; H, 6.2; N, 21.4.  $C_{13}H_{16}O_2N_4$  requires C, 59.95; H, 6.2; N, 21.5%). The yields of the condensation products corresponded with the explanation of their formation given in the introduction.

The esters, m. p.  $60^{\circ}$  and m. p.  $42^{\circ}$ , also gave on similar treatment the same two compounds (m. p.  $188^{\circ}$  and m. p.  $275^{\circ}$ ). The quantities of the cyclic imide and dicyanoacetamide produced varied in the different experiments, but the total amount was constant.

*Condensation of Methyl Methylcyclohexenylidenecyanoacetate with Methyl Cyanoacetate.*—To a solution of the ester, m. p.  $74^{\circ}$  (5 g.) and methyl cyanoacetate (2.5 g.) in cold alcohol, ammoniacal alcohol (10 c.c., saturated at  $-10^{\circ}$ ) was added, and the mixture kept at  $0^{\circ}$  for 2 days, much crystalline matter separating. The ammonium salt of the cyclic imide and the dicyanoacetamide described above were thus obtained in 68% yield.

*Condensation of Methylcyclohexenone and Ethyl Cyanoacetate.*—A mixture of methylcyclohexenone (4 g.), ethyl cyanoacetate (8.5 g.), and ammoniacal alcohol (18 c.c., saturated at  $-10^{\circ}$ ) was kept at  $0^{\circ}$  in a closed bottle. The crystals deposited after 1 day consisted almost entirely of cyanoacetamide, but after 3 days 5.5 g. of the almost pure ammonium salt of the imide (X) were obtained.

The authors desire to express their thanks to the Government Grant Committee of the Royal Society (E. H. F.) and to the Chemical Society (J. R.) for grants towards the cost of the investigation, and to Professor J. F. Thorpe for his interest in the work.

CCV.—*The Isomerism of the Styryl Alkyl Ketones.*  
*Part III. Methoxy-2- and 4-hydroxystyryl Alkyl Ketones.*

By ALEXANDER MCGOOKIN and DONALD JAMES SINCLAIR.

IN order to confirm the results of the investigations on the isomerism and behaviour towards alkali of the hydroxystyryl alkyl ketones (J., 1924, 125, 2099; 1925, 127, 2539) various derivatives of 2-hydroxystyryl methyl ketone and analogous compounds have been prepared and examined.

5-Methoxy-2-hydroxystyryl methyl ketone (Heilbron and Whitworth, J., 1923, 123, 238), like the 2-hydroxy-compound, exists in a yellow and a colourless form of identical m. p. and is partly converted into the red sodium salt of 5 : 5'-dimethoxy-2 : 2'-dihydroxydistyryl ketone in alkaline solution. This change occurs instantly with the yellow isomeride, but only very slowly with the colourless modification; the colourless form of 2-hydroxystyryl methyl ketone also develops the usual red colour in similar circumstances.

The colourless form of 4-methoxy-2-hydroxystyryl methyl ketone has been isolated; it is stable in air and resembles the colourless form of 2-hydroxystyryl methyl ketone in properties. The yellow form (Heilbron and Whitworth, *loc. cit.*) has not been obtained pure and is under investigation.

The yellow crystalline condensation product, m. p. 83°, of 3-methoxysalicylaldehyde and acetone obtained by Heilbron and Whitworth (*loc. cit.*), and regarded by them as  $\beta$ -hydroxy- $\beta$ -3-methoxy-2-hydroxyphenylethyl methyl ketone, has also been described by Nomura and Nozawa (*Sci. Rep. Tôhoku Imp. Univ.*, 1918, 7, 79), who consider it a hydrate of 3-methoxy-2-hydroxystyryl methyl ketone. Further examination indicates that it is a hydrate rather than an aldol. In addition to the benzoyl derivative of 3-methoxy-2-hydroxystyryl methyl ketone already obtained from it by Heilbron and Whitworth (*loc. cit.*) an *acetyl* derivative of the unsaturated ketone has been prepared. Both compounds, on hydrolysis, yield the hydrated substance. Moreover, condensation of this compound with 3-methoxysalicylaldehyde produces the symmetrical distyryl ketone. Again, crystallisation of the hydrated substance from dry benzene yields, as a second crop, colourless needles which, on removal of the solvent, immediately absorb water to form the original yellow compound of m. p. 83°. 3-Methoxy-2-hydroxystyryl methyl ketone, however, could not be isolated. From the compound of m. p. 83°, by crystallisation from an anhydrous solvent, Nomura and Nozawa (*loc. cit.*) obtained

an unsaturated ketone of m. p. 77—77·5°. This m. p. for 3-methoxy-2-hydroxystyryl methyl ketone is anomalous in three respects : (i) all ketones of this type melt at about 130°; (ii) removal of water from an aldol or a hydrate invariably causes a rise in m. p.; (iii) the symmetrical distyryl ketone has a normal m. p.

In Part I the compound of m. p. 83° was assumed to have the aldol structure, and the fact that it could not be isomerised was taken as evidence of the geometric nature of the isomerism of this class of ketones. In view of the present observations this evidence cannot be taken as conclusive.

The yellow form of 3-methoxy-4-hydroxystyryl methyl ketone (Francesconi, *Gazzetta*, 1908, 38, ii, 70; McGookin and Heilbron, J., 1924, 125, 2104) is peculiar in being exceedingly stable, resisting isomerisation except by extreme methods. When, however, concentrated alkali is added to its alkaline solution, the salt precipitated is that of the colourless form. Hence it is assumed that the salts of both isomerides are in equilibrium in alkaline solution.

The yellow form of 3-methoxy-4-hydroxystyryl methyl ketone changes on fusion into the colourless modification of the same m. p.—a similar change doubtless accounts for the identity of the m. p.'s of each pair of isomerides throughout this series of ketones. Both forms of this substance resemble those of 2-hydroxystyryl methyl ketone by dissolving in alkali, the yellow form to yield a red solution and the colourless isomeride to give a yellow solution which assumes a red colour on standing. In both instances the red colour is due to the sodium salt of 3 : 3'-dimethoxy-4 : 4'-dihydroxydistyryl ketone. Hence styryl methyl ketones are capable of condensing to a slight extent with 4-hydroxyaldehydes in the presence of alkalis (compare Buck and Heilbron, J., 1922, 121, 1095).

#### EXPERIMENTAL.

**5-Methoxy-2-hydroxystyryl Methyl Ketone.**—The colourless modification was obtained, by boiling the yellow isomeride (Heilbron and Whitworth, *loc. cit.*) with water containing a trace of acid, in needles, m. p. 124°, soluble in alcohol or benzene. It dissolves in alkali to a yellow solution which develops a deep red colour after 12 hours (Found : C, 68·5; H, 6·3.  $C_{11}H_{12}O_3$  requires C, 68·7; H, 6·3%).

**5 : 5'-Dimethoxy-2 : 2'-dihydroxydistyryl Ketone.**—When 40% sodium hydroxide (10 c.c.) was added to a solution of the yellow isomeride of 5-methoxy-2-hydroxystyryl methyl ketone (2 g.) in 20% sodium hydroxide (30 c.c.), lustrous, green needles separated. An aqueous solution of these, on acidification, gave the distyryl ketone (1·2 g.), which crystallised from alcohol in orange needles,

m. p. 158°, soluble in acetone but almost insoluble in benzene (Found: C, 69.6; H, 5.6.  $C_{19}H_{18}O_5$  requires C, 69.9; H, 5.5%).

**4-Methoxy-2-hydroxystyryl Methyl Ketone.**—The following is the best modification of Heilbron and Whitworth's method. To a solution of 4-methoxysalicylaldehyde (9 g.) and acetone (16 g.) in alcohol (100 c.c.), sodium hydroxide (200 c.c. of 20%) was added. After 3 days the red mixture was diluted with water (1000 c.c.), cooled to 0°, and almost neutralised with dilute sulphuric acid (rise of temperature or excess of acid caused the production of tar). The product (10 g.) was crystallised from benzene and from chloroform-hexane and obtained in colourless needles, m. p. 131°. It was readily soluble in alkali to a yellow solution which developed a deep red colour after 12 hours.

**4:4'-Dimethoxy-2:2'-dihydroxydistyryl Ketone.**—A mixture of 2 mols. of 4-methoxysalicylaldehyde (10 g.), 1 mol. of acetone (2 g.), and alcohol (40 c.c.) was treated with sodium hydroxide (250 c.c. of 20%) and warmed on the water-bath for 10 minutes. The deep red solution deposited, after 12 hours, lustrous green needles of the sodium salt of the distyryl ketone. From an aqueous solution of this, almost neutralised at 0°, the ketone was precipitated as a yellow solid. It crystallised from cold aqueous alcohol in brown plates, m. p. 170°, soluble in alcohol, but almost insoluble in benzene. It is unstable and produces a red solution with an intense green fluorescence when warmed in alcohol (Found: C, 69.6; H, 5.6.  $C_{19}H_{18}O_5$  requires C, 69.9; H, 5.5%).

**3-Methoxy-2-hydroxystyryl Methyl Ketone Hydrate (?)**.—This compound (Heilbron and Whitworth, *loc. cit.*) formed yellow plates, m. p. 83°, from aqueous alcohol. It crystallised from dry benzene in similar yellow plates, but the second crop of crystals consisted of colourless, hygroscopic needles. These dissolved in alkali to form an orange-red solution which developed the usual deep red colour on standing.

**3-Methoxy-2-acetoxystyryl Methyl Ketone.**—The hydrated compound (10 g.) was boiled for an hour with acetic anhydride (150 c.c.), the hot solution poured into an excess of water, and almost neutralised with sodium carbonate. The precipitate produced (10 g.) crystallised from alcohol in colourless needles, m. p. 91°, soluble in benzene or hot water (Found: C, 66.4; H, 6.1.  $C_{13}H_{14}O_4$  requires C, 66.6; H, 6.0%).

**3:3'-Dimethoxy-2:2'-dihydroxydistyryl Ketone.**—The sodium salt that separated after 24 hours from a solution of 3-methoxysalicylaldehyde (50 g.) in acetone (80 g.) and sodium hydroxide (600 c.c. of 2.5%) to which 10% sodium hydroxide (240 c.c.) had been added was dissolved in water and acidified. The ketone precipitated

crystallised from aqueous alcohol in orange needles, m. p.  $182^{\circ}$  (Found: C, 69.6; H, 5.5.  $C_{19}H_{18}O_5$  requires C, 69.9; H, 5.5%).

**3-Methoxy-4-hydroxystyryl Methyl Ketone.**—A solution of vanillin (50 g.) in acetone (120 c.c.) and alcohol (50 c.c.) was treated with sodium hydroxide (100 c.c. of 20%) and kept for 12 hours. Long, yellow needles of the *sodium* salt of the colourless isomeride were produced; the *ketone* obtained from these crystallised from aqueous alcohol in colourless needles, m. p.  $129^{\circ}$ , soluble in acetone or benzene. It dissolved in alkali to a yellow solution which turned red after 12 hours.

**3:3'-Dimethoxy-4:4'-dihydroxydistyryl Ketone.\***—(a) On boiling, a solution of the preceding colourless isomeride (25 g.) in sodium hydroxide (200 c.c. of 20%) became deep red and acetone was evolved. When the evolution of this had ceased, after 15 minutes, the solution was cooled, and sodium hydroxide (40%) added until a precipitate formed. Lustrous green needles of the *sodium* salt of the distyryl ketone slowly separated. The *ketone* obtained from these crystallised from chloroform in pale yellow needles, m. p.  $142^{\circ}$  (Found: C, 69.6; H, 5.6.  $C_{19}H_{18}O_5$  requires C, 69.9; H, 5.5%).

This compound was very soluble in alcohol or acetone, moderately easily soluble in chloroform, but almost insoluble in benzene. It forms an orange-red *hydrate*, m. p.  $121^{\circ}$ , containing one molecule of water when crystallised from an aqueous solvent (Found: C, 65.8; H, 5.9.  $C_{19}H_{18}O_5 \cdot H_2O$  requires C, 66.2; H, 5.8%). The hydrate loses water when heated in a steam-oven or crystallised from a non-aqueous solvent.

(b) A better yield (15 g.) of the distyryl ketone was obtained by gradually adding concentrated hydrochloric acid (50 c.c.) to a solution of vanillin (25 g.) in acetone (90 c.c.) cooled in a freezing mixture. A dark violet-red coloration was observed and from the mixture, kept at  $0^{\circ}$  for 4 days, green-black crystals separated. These were filtered off, washed well with ether, and decomposed by dissolution in excess of sodium hydroxide (10%). The free distyryl ketone was obtained from this solution as before.

UNIVERSITY OF LIVERPOOL.

\* This compound has recently been prepared by Nomura and Hotta (*Sci. Rep. Tōhoku Imp. Univ.*, 1925, 14, 119).

CCVI.—*The Halogenation of Phenols.*

By FREDERICK GEORGE SOPER and GILBERT FREEMAN SMITH.

THE iodination of phenols has been investigated by Cofman (J., 1919, 115, 1040), who concluded that the active iodinating agent was hypoiodous acid, free iodine having apparently no direct iodinating effect. Similar views were held on the mechanism of bromination (Baines, J., 1922, 121, 2810), but recently Francis (J. Amer. Chem. Soc., 1925, 47, 2340) has shown that bromine is a more active brominating agent than hypobromous acid. Both Cofman and Francis are of the opinion that probably the only active halogenating agent is the positive halogen ion. This conclusion can be tested using halogens and hypohalous acids, since, although the actual degrees of ionisation of these substances into positive halogen ions (Stieglitz, J. Amer. Chem. Soc., 1901, 23, 796) are not known—except in the case of hypoiodous acid (Murray, J., 1925, 127, 882)—their relative ionisations may be calculated from other data. For, assuming the existence of such equilibria as

then

$$\frac{K_{\text{HOCl}}}{K_{\text{Cl}_2}} = \frac{[\text{OH}'][\text{Cl}']}{[\text{HOCl}]} \bigg/ \frac{[\text{Cl}'][\text{Cl}']}{[\text{Cl}_2]} = \frac{[\text{Cl}_2][\text{OH}'][\text{H}']}{[\text{Cl}']^2[\text{HOCl}][\text{H}']} = \frac{K_w}{K_s},$$

where  $K_s$  is the hydrolysis constant of chlorine (Jakowkin, Z. physikal. Chem., 1899, 29, 613) and equals  $4.84 \times 10^{-4}$ . Similar expressions hold for bromine and for iodine, the hydrolysis constants being  $5.2 \times 10^{-9}$  and  $3 \times 10^{-13}$  respectively (Bray and Connolly, J. Amer. Chem. Soc., 1911, 33, 1485; Bray, *ibid.*, 1910, 32, 932). On substituting these values in the above expression, the ionisation constants of chlorine and hypochlorous acid will be in the ratio  $4.5 \times 10^{10}$  to 1; and one would expect that their chlorinating efficiencies would be in the same ratio. The corresponding values for bromine and iodine and their hypohalous acids are  $5 \times 10^5$  and 30 respectively. Thus, whilst hypochlorous acid would have little chlorinating effect in comparison with free chlorine, we should expect the effects of iodine and hypoiodous acid to be of the same order of magnitude.

In order to test this theory of halogenation by positive halogen ion, the chlorination of phenols has been studied, using hypochlorous acid and chlorine as chlorinating agents. The much greater stability of hypochlorous acid (as compared with hypobromous and hypoiodous acids) has allowed of a sharp differentiation between the mechanisms of substitution of phenols by these two chlorinating agents.

The mechanism of the interaction with hypochlorous acid was investigated by the isolation method. The reaction speed is approximately proportional to the phenol and hypochlorous acid concentrations, and is greatly affected by the alkalinity or acidity of the mixture. In acid and in dilute alkaline solutions (hydroxyl-ion concentration in the neighbourhood of  $10^{-7}$ ) the reaction speed increases in direct proportion to the hydroxyl-ion concentration until it becomes too rapid for measurement. In more strongly alkaline solution (hydroxyl-ion concentration about  $10^{-2}$ ), the speed decreases to measurable dimensions, and is now inversely proportional to the hydroxyl-ion concentration.

These facts can be interpreted in two ways. Interaction may take place either between the phenol molecule and the hypochlorite ion or between hypochlorous acid and the phenoxide ion, the reaction speed being given by the alternative equations

$$v = k_2'[\text{OCl}'][\text{PhOH}] \quad \dots \quad (1)$$

$$v = k_2[\text{HOCl}][\text{PhO}'] \quad \dots \quad (2)$$

On both hypotheses addition of alkali, by causing increased ionisation, would first increase and then decrease the speed as was observed. The alternative hypotheses cannot, however, be differentiated by studying the reaction between a simple phenol and hypochlorous acid, since it follows from the ionic equilibria of hypochlorous acid and a phenol that

$$[\text{OCl}'][\text{PhOH}]/[\text{HOCl}][\text{PhO}'] = K_a'/K_a'' = \text{constant},$$

where  $K_a'$  and  $K_a''$  are the respective ionisation constants. It is obvious that any test of the first explanation will be equally satisfactory when applied to the second explanation, if it is based on the constancy of  $k_2$  or  $k_2'$ .

It is shown later from other evidence that the mechanism involves the phenoxide ion and hypochlorous acid. The constant  $k_2$ , rather than  $k_2'$ , is therefore calculated in the following preliminary proof of the correctness of the suggested mechanism of the reaction.

The calculation of the velocity coefficient in the presence of excess of alkali involves the hydrolysis constant of sodium hypochlorite (Soper, J., 1924, 125, 2227), since the hypochlorous acid and the phenol are present almost entirely as ions, sodium hypochlorite and phenoxide in the presence of  $N/10$ -hydroxyl-ion being hydrolysed only to the extent of 0.1 and 0.001% respectively.

$$\begin{aligned} dx/dt &= k_2[\text{HOCl}][\text{PhO}'] = k_2K_h'/[\text{OH}'] \cdot [\text{OCl}'][\text{PhO}'] \\ &= k_2K_h'/[\text{OH}'] \cdot (b-x)(a-x) \end{aligned}$$

or

$$k_2K_h' = \frac{1}{i(a-b)} \ln \frac{b(a-x)}{a(b-x)}$$

where  $K_h'$  represents the hydrolysis constant of the hypochlorite.

The terms  $a - x$  and  $b - x$  in this equation represent the activities of the hypochlorite and phenoxide ions which are some fraction of the concentrations of sodium hypochlorite and phenoxide, respectively, dependent on the ionic strength (Lewis and Randall, "Thermodynamics," 1924) of the mixture. In the absence of data on the activities of these ions, we have taken them as equal to the concentrations of their respective salts. The effective concentration of the hydroxyl ion was taken as the product of the concentration of free base and its appropriate activity coefficient. The results obtained at 25.0° with *p*-cresol and alkaline hypochlorite are in Table I, where time is shown in minutes.

TABLE I.

[HOCl] = $10^{-3}$ ; [p-cresol] = $2 \times 10^{-3}$ ; [NaOH] = 0.019; $\gamma[\text{OH}'] = 0.01424$ .			[HOCl] = $10^{-3}$ ; [p-cresol] = $2 \times 10^{-3}$ ; [NaOH] = 0.038; $\gamma[\text{OH}'] = 0.02904$ .		
Time.	$[\text{OCl}'] \times 10^4$ . $k_2 \times 10^{-5}$ .		Time.	$[\text{OCl}'] \times 10^4$ . $k_2 \times 10^{-5}$ .	
0	8.28	—	0	8.90	—
4.03	5.51	8.59	3.40	7.44	8.39

17.15	1.48	10.5	21.03	3.07	9.60
			27.23	2.24	10.1

Another experiment, in which  $[\text{HOCl}] = 10^{-3}$ ;  $[\text{p-cresol}] = 10^{-2}$ ;  $[\text{NaOH}] = 10^{-1}$ ;  $\gamma[\text{OH}'] = 0.0712$ , gave values of  $k_2 \times 10^{-5}$  which gradually decreased from 9.37 to 8.70.

The velocity coefficient can also be calculated from measurements of the reaction speed in water. The ionisation constants of hypochlorous acid (Soper, *loc. cit.*) and of *p*-cresol (Boyd, J., 1915, 107, 1538) are  $1.0 \times 10^{-8}$  and  $0.67 \times 10^{-10}$ , respectively. The hydrogen-ion concentration will therefore be governed by the hypochlorous acid, and in *M*/1000-solution will be  $3.1 \times 10^{-6}$ , but will increase slightly in concentrated solutions of *p*-cresol. During the reaction, hypochlorous acid disappears, and it might be anticipated that the acidity of the mixture would diminish. Actually indicators show that at the conclusion of the reaction the acidity has slightly increased. This is probably due to a very slight reduction of the hypochlorous acid, for even traces of hydrochloric acid would materially affect the hydrogen-ion concentration. In the calculations which follow, the hydrogen-ion concentration has been regarded as constant.

In aqueous solution both hypochlorous acid and *p*-cresol are mainly un-ionised. The concentration of the phenoxide-ion will be

determined by the acidity of the solution and the ionisation constant of the cresol, thus

$$[\text{R}\cdot\text{O}'] = K_a''[\text{R}\cdot\text{OH}]/[\text{H}'].$$

The velocity is given by

$$dx/dt = k_2[\text{R}\cdot\text{O}'][\text{HOCl}] = k_2[\text{HOCl}] \cdot K_a''[\text{R}\cdot\text{OH}]/[\text{H}'] = \frac{k_2 K_a''(b-x)(a-x)}{[\text{H}']}$$

$$\text{or} \quad \frac{k_2 K_a''}{[\text{H}']} = k = \frac{1}{t(a-b)} \ln \frac{b(a-x)}{a(b-x)}.$$

Mixtures were used in which the hypochlorous acid was  $M/1000$ , and the *p*-cresol concentration varied from  $10^{-3} M$  to  $4 \times 10^{-2} M$ . Table II shows one experiment in detail, and Table III summarises all the experiments.

The higher value for the velocity coefficient when equimolar quantities of hypochlorous acid and cresol interact is due to the chlorination of the chlorocresol formed. The average value for the velocity coefficient in aqueous solution when excess of the cresol is present may be taken as  $5 \times 10^5$ , as compared with the value  $10 \times 10^5$  in alkaline solution. The lower value obtained in water is probably to be attributed partly to the fact that activities are not accurately represented by concentrations, partly to some uncertainty in the ionisation constants concerned, and partly to the effect of the presence of other substances on the degrees of ionisation.

The addition of acids, with the exception of hydrochloric acid, decreased the observed speed. The effect of hydrochloric acid doubtless depends on the formation of chlorine, and is dealt with in Section 2.

The comparison of velocity coefficients calculated from the observed speeds in aqueous and in strongly alkaline solution is a stringent test of the mechanism, as it involves concentrations of the reacting species which differ by several thousand times in the two cases. This test has been repeated for other phenols. The results are summarised in Table IV.

The agreement between the velocity coefficients calculated over such exceptionally wide ranges of concentration is satisfactory and shows that the mechanism proposed is of general character; moreover, it eliminates the possibility of concurrent interaction of the hypochlorite ion with the phenoxide ion.

In order to differentiate between the two possible mechanisms of chlorination of a phenol by hypochlorous acid, the chlorination of salicylic acid has been studied. Here the alternative mechanisms become

In this case, unlike that of a simple phenol, the expression representing  $k_2/k_2'$  is not constant, but is inversely proportional to the hydroxyl-ion concentration. It is therefore possible, by examination of the speed of reaction in media of different hydroxyl-ion concentrations, to differentiate between the two theories, for on one mechanism only will velocity coefficients be obtained which are independent of the alkalinity of the medium.

The second ionisation constant of salicylic acid (Senter and Bulle, J., 1912, 101, 2532) is approximately  $1 \times 10^{-13}$ . In *N*/10-hydroxyl ion the disodium salt is 50% hydrolysed, and in *N*-hydroxyl ion 9% hydrolysed. If the interaction involves the hypochlorite ion, then the speed, on change of the alkalinity from *N*/10 to *N*, will be decreased 55 times,\* whilst if the phenoxide ion is involved the

\* The ratio of undissociated acid to monosodium salt is decreased 10 times and the monosodium salt concentration is decreased 5.5 times, giving a total decrease in the concentration of the undissociated acid of 55 times. The hypochlorite-ion concentration remains unaltered. The calculation is approximate, as the activities are not known.

corresponding decrease will be certainly less than 10 times (due to a 10-fold decrease in the un-ionised hypochlorous acid) since the concentration of the phenoxide ion has been increased 1.8 times, giving a net decrease of 5.5 times. Actually the observed decrease is 2.7 times, which is in favour of the phenoxide-ion theory.

Further confirmation of the theory that the reaction involves the phenoxide ion is obtained from the behaviour in the initial stages of the reaction. The phenomenon is particularly clearly defined with *p*-nitrophenol, but is of general occurrence. If sodium hypochlorite is mixed with the phenol, the reaction proceeds smoothly without initial disturbance. If, however, sodium phenoxide be mixed with hypochlorous acid, as much as 35% of the hypochlorous acid may disappear before a portion of the solution can be removed for titration. The reaction after the initial disturbance is normal. The initial fall of titre in the one case is obviously due to the high concentrations of hypochlorous acid and phenoxide ion. An example of this effect is given in Table VI.

TABLE VI.

HOCl ( $10^{-3}$ ) added to <i>p</i> -nitrophenol ( $10^{-2}$ ) and NaOH ( $1.5 \times 10^{-2}$ ).		<i>p</i> -Nitrophenol ( $10^{-2}$ ) added to HOCl ( $10^{-3}$ ) and NaOH ( $1.5 \times 10^{-2}$ ).

## 2. Chlorination of Phenols and Phenolic Ethers by Chlorine.

The presence of small traces of hydrochloric acid has a great effect on the speed of interaction of hypochlorous acid and a phenol. The speed is independent of the concentration and nature of the phenol, and is dependent on the hypochlorous acid concentration and the square of the hydrochloric acid concentration, thus:

$$v = k_1[\text{H}^+][\text{Cl}^-][\text{HOCl}] = k_1[\text{HCl}]^2[\text{HOCl}] \quad (5)$$

It is obvious that the speed measured is that of the formation of chlorine from hydrochloric and hypochlorous acids,\* the chlorine immediately reacting with the phenolic substance present. Using *p*-nitrophenol, a slower speed is observed, but on increasing its concentration the same limiting speed is obtained. Chlorine, therefore, chlorinates a phenol more rapidly than does hypochlorous acid. Some of the observed results obtained at 25.0° are in Table VII.

TABLE VII.

[HCl] =  $2 \times 10^{-4}$ ; [HOCl] =  $10^{-3}$ .

Substance.	<i>p</i> -Cresol.	Phenol.	Phenetole.	Anisole.	<i>p</i> -Nitrophenol.
Conc. to give limiting speed .....	$< 2 \times 10^{-3}$	$< 2 \times 10^{-3}$	$4 \times 10^{-3}$	$10^{-2}$	$10^{-2}$
$k \times 10^{-3}$ .....	2.17	2.14	2.16	2.14	2.06

The velocity coefficient is unimolecular, since the concentration of the hydrochloric acid is constant, each molecule of chlorine which reacts with the phenol giving one molecule of hydrochloric acid, which in turn forms chlorine.

### 3. The Action of Hypochlorous Acid on Phenolic Ethers.

In dilute alkali, in which the existence of chlorine is excluded, no fall in titre of the mixture of ether and hypochlorous acid is observed. In water, however, a slow reaction occurs, the rate of which is only slightly dependent on the concentration of the ether present, and is thus probably due to chlorine. It is concluded that there is no detectable interaction between hypochlorous acid and the ether. By purification of the hypochlorous acid, as described in the experimental section, it was found that only a 2% loss of titre in 4 hours was experienced in a mixture of aqueous anisic acid and hypochlorous acid at 25°. This behaviour supports the theory that hypochlorous acid reacts with the phenoxide ion. Anisole, phenetole, and anisic acid cannot form the phenoxide ion, and therefore do not react.

The behaviour of chlorine is significant. It can chlorinate the ether as well as the phenol, so that the chlorination of phenolic

\* This velocity of formation of chlorine allows of the calculation of the speed of hydrolysis of chlorine, which is generally regarded as extremely rapid: The hydrolysis constant  $[\text{HOCl}][\text{H}^+][\text{Cl}^-]/[\text{Cl}_2]$  is  $4.84 \times 10^{-4}$  (Jakowkin, *loc. cit.*), and equals the ratio of the velocity coefficient of hydrolysis ( $k'$ ) to that of formation of chlorine by the reversible reaction ( $k$ )

Thus  $k'/k = 4.84 \times 10^{-4}$ , whence  $k' = 1.06 \times 10^{-3}$ . The speed of hydrolysis of chlorine is therefore relatively slow.

substances does not necessarily involve the phenoxide ion. This does not exclude the possibility of reaction between chlorine and the phenoxide ion in a solution of a phenol.

#### 4. Reactivity and Constitution.

The velocity coefficients of chlorination by hypochlorite of a number of phenols have been measured at 25.0°, chiefly in alkaline solution because control of the hydroxyl-ion concentration is facilitated. The results are in Table VIII.

TABLE VIII.

	$k_2$ .	$K_a''$ .	$k_2 K_a''$ .
Phenol .....	$3.3 \times 10^5$	$1.1 \times 10^{-10}$	$3.63 \times 10^{-5}$
o-Cresol .....	$1.25 \times 10^6$	$0.63 \times 10^{-10}$	$7.88 \times 10^{-5}$
m-Cresol .....	$4.4 \times 10^6$	$0.98 \times 10^{-10}$	$42.00 \times 10^{-5}$
p-Cresol .....	$9.0 \times 10^5$	$0.67 \times 10^{-10}$	$6.0 \times 10^{-5}$
o-Chlorophenol .....	$5.9 \times 10^4$	$7.7 \times 10^{-10}$	$4.55 \times 10^{-5}$
p-Chlorophenol .....	$4.90 \times 10^4$	$4.1 \times 10^{-10}$	$2.0 \times 10^{-5}$
3-Chloro-p-cresol .....	$1.67 \times 10^5$		
o-Nitrophenol .....	$1.01 \times 10^3$	$7.5 \times 10^{-8}$	$7.58 \times 10^{-5}$
m-Nitrophenol .....	$5.89 \times 10^3$	$1.0 \times 10^{-8}$	$5.89 \times 10^{-5}$
p-Nitrophenol .....	$6.84 \times 10^3$	$9.6 \times 10^{-8}$	$6.57 \times 10^{-5}$
1:3:4-Xylenol .....	$2.02 \times 10^6$		

The velocity coefficients differ considerably from one another, but the products of the velocity coefficient and the ionisation constant of the phenols are grouped in a noteworthy manner about the value  $7 \times 10^{-5}$ . It appears that the reactivity of the phenoxide ion is proportional to its affinity for hydrogen ion. Those ions derived from phenols of high ionisation constant are least reactive. These results may be compared with those of Boyd and Thomas (J., 1919, 115, 1239), who found a similar relation between the rates of interaction of phenoxide ions with olefine oxides.

#### 5. Discussion.

1. Since the speed of interaction of a phenol and hypochlorous acid is proportional to the product of the concentrations of the un-ionised acid and the phenoxide ion, the halogenating agent cannot be the positive halogen ion, for its concentration is proportional to the hypohalous acid concentration divided by that of the hydroxyl ion, *i.e.*,  $[Cl^+] = K[HOCl]/[OH^-]$ . The idea must also be abandoned in the case of chlorine, as its speed of chlorinating acetanilide, for example (Orton and King, J., 1911, 109, 1369), is independent of the excess of chlorine ions present. It appears that the molecules of chlorine or of hypochlorous acid react as whole molecules, and that therefore an intermediate complex must exist as a transient stage of the reaction.

2. It is probable that the theory of the reactivity of the phenoxide ion which has been proved for the interaction of hypochlorous acid and phenols also applies to the similar reactions involving hypobromous and hypoiodous acids. The conclusion of Vortmann (*Ber.*, 1923, 56, 234) that the alkali hypoiodite is the effective iodinating agent is based on evidence which also supports the mechanism involving the phenoxide ion. We find that the speed of iodination is decreased in strong alkaline solution, which can be explained by the great decrease in the concentration of the un-ionised hypoiodous acid.

3. Hypochlorous acid does not react with phenolic ethers, since they do not form the phenoxide ion, but chlorine interacts easily with both phenols and ethers. It is probable, however, that the interaction of chlorine with the phenol involves both the highly reactive phenoxide ion and the un-ionised phenol. Any alteration in the degree of ionisation of the phenol might be expected to alter the proportions of the isomeric products formed. Thus Arnall (*J.*, 1924, 125, 811) found that the proportions of *o*-, *m*-, and *p*-nitrophenols formed on nitration varied with the concentration of nitric acid present. This observation is consistent with the present theory of the reactivity of the phenoxide ion, the concentration of which varies with the acidity of the medium. The slower speed of bromination by bromine water in strong acid solution attributed by Francis (*loc. cit.*) to a decrease in the concentration of "nascent" bromine is also naturally explained on the present theory by the decrease in concentration of the phenoxide ion, the bromination of which is probably faster than that of the un-ionised molecule.

#### EXPERIMENTAL.

*Method of Titration.*—The course of a reaction was followed by estimation of the iodine liberated by the hypochlorous acid from acidified potassium iodide. The titration of iodine in the presence of a phenol must be carried out in acid solution in order to prevent interaction of the iodine and phenol. The consequent presence of free hydriodic acid, which is easily oxidised, is a source of error in the titration. The difficulty was overcome by using oxygen-free solutions and carrying out the titration in an atmosphere of nitrogen (compare Soper, *J.*, 1924, 125, 1899). Perfectly sharp end-points, with *N*/500-thiosulphate, were obtained in this way, even in the presence of 3*N*-sulphuric acid.

*Preparation and Purification of Hypochlorous Acid.*—The hypochlorous acid was prepared by passing chlorine into water containing yellow mercuric oxide in suspension, or by distillation of a

bleaching powder solution through which carbon dioxide was passed. Both specimens of hypochlorous acid behaved in the same way after purification. Two methods of purification were used: (a) repeated distillation of the hypochlorous acid from yellow mercuric oxide under reduced pressure; (b) simply shaking the hypochlorous acid with yellow mercuric oxide and after some time filtering off the oxychloride. The latter method was the one finally adopted, since the distillation method gave a hypochlorous acid which, on addition of sulphuric acid, formed traces of chlorine, the presence of which was manifested by the greater rate of reaction with phenol.

*Purity of Phenols.*—Kahlbaum specimens were purified either by several crystallisations from suitable solvents or by distillation, preferably under reduced pressure. Two distillations were usually found sufficient to give a pure phenol, the reactivity of which was unaltered by further distillation.

*Water.*—A high grade of conductivity water was used throughout. In such water a sample of hypochlorous acid showed no fall of titre in 60 hours.

#### *Summary.*

1. The interaction of phenols with hypochlorous acid in aqueous and in alkaline solution has been shown to involve the phenoxide ion and the un-ionised hypochlorous acid.

2. The reactivity of the ion with hypochlorous acid is least when the phenol from which it is derived is most strongly acidic. The reactivity of the ions of the simple phenols is roughly proportional to their affinity for hydrogen ions.

3. The chlorination of phenols and phenolic ethers by chlorine is a much faster reaction than the rate of formation of chlorine from a mixture of hydrochloric and hypochlorous acids, the velocity coefficient of which is  $2.2 \times 10^6$  at  $25^\circ$ . The calculated velocity coefficient of the hydrolysis of chlorine at this temperature is  $1.06 \times 10^3$ .

4. The mechanism of halogenation of phenols is discussed.

In conclusion, we wish to acknowledge the helpful criticism of Professor K. J. P. Orton, F.R.S.

UNIVERSITY COLLEGE OF NORTH WALES,  
BANGOR.

[Received, February 24th, 1926.]

CCVII.—*Compounds of Tervalent Molybdenum. Part IV. Bromides.*

By WILLIAM WARDLAW and ARTHUR JACOB IMMINES HARDING.

By electrolytic reduction of molybdenum trioxide dissolved in hydrochloric acid, solutions of tervalent molybdenum are obtained which, on addition of alkali chlorides, yield complex salts of the types  $[\text{MoCl}_6]\text{R}_3$  and  $[\text{MoCl}_5, \text{H}_2\text{O}]\text{R}_3$ . Although the trichloride has not yet been isolated from such solutions, when the concentration of molybdenum is high, the oxychloride,  $\text{MoOCl}_4 \cdot 4\text{H}_2\text{O}$ , can be obtained (J., 1924, 125, 2370). From the reduced bromide solutions, Rosenheim and Braun (*Z. anorg. Chem.*, 1905, 46, 311) have prepared two complex salts  $[\text{MoBr}_6](\text{C}_5\text{H}_5\text{N})_3$  and

In all these cases, the co-ordination number is 6. Moreover, the different halogen complexes containing molybdenum in other stages of oxidation exhibit this co-ordination number, for in such compounds an oxygen atom occupies only one co-ordination position: *e.g.*,  $[\text{MoO}_2\text{Cl}_4]\text{R}_2$ ,  $[\text{MoO}_2\text{Br}_4](\text{C}_5\text{H}_5\text{N})_3$ ,  $[\text{MoOX}_5]\text{R}_2$  where  $\text{X} = \text{Cl}, \text{Br}, \text{or F}$ .

On the Bohr theory of atomic structure, molybdenum, like chromium, iron, cobalt, nickel, rhodium, osmium and platinum, which all form well-defined compounds of co-ordination number 6, is a member of one of the groups of elements the planetary electrons of which are undergoing reorganisation. It shows, therefore, variable valency and marked colour in its compounds. The *maximum* co-ordination number of molybdenum is not, however, 6. A co-ordination number of 8 is seen in the complex salt  $\text{R}_4\text{Mo}(\text{CN})_8$ . This is in accordance with Sidgwick's rule that the maximum co-valency number or co-ordination number is that of the maximum sub-group next to the largest completed group in the atom. Molybdenum, atomic number 42, has its 3-quanta orbits completed and the numbers of electrons in the 4-quanta sub-groups are 2, 2, 4, 4, 6, 6, 8. So far, 6 represents the maximum co-ordination number for tervalent molybdenum and further evidence for this is afforded by the results of the present investigation, whereby, from a reduced solution of molybdenum trioxide in hydrobromic acid, a fawn-coloured oxybromide  $[\text{MoOBr}_4 \cdot 4\text{H}_2\text{O}]$  and red salts of the general formulæ  $\text{R}_3[\text{MoBr}_6]$  and  $\text{R}_2[\text{MoBr}_5, \text{H}_2\text{O}]$  have been isolated.

## EXPERIMENTAL.

*Molybdenyl Monobromide.*—The most satisfactory method for the preparation of constant-boiling hydrobromic acid is that outlined

by Scott (J., 1900, 77, 648), in which bromine is covered with water and reduced by sulphur dioxide and the resulting homogeneous liquid is distilled, the fraction boiling at 124—126° being collected and re-distilled.

In preparing his electrolyte, Rosenheim (*loc. cit.*) dissolved the dihydrate of molybdenum trioxide in the hydrobromic acid. However, the trioxide itself will dissolve in the hot acid. 25 G. of molybdenum trioxide and 350 c.c. of the hydrobromic acid were heated under reflux for 3 to 6 hours, the final solution being golden-brown in colour. The filtered solution was electrolysed in a diaphragm cell with smooth platinum electrodes (J., 1923, 123, 169), a current of 3.5 amps. being used, until the cathode solution was reddish-brown. This solution was transferred to an air-free flask and concentrated at 70° under diminished pressure to 80—100 c.c. The liquid was then transferred to a small cell and re-electrolysed to ensure that the molybdenum was tervalent. The electrolysis was continued until a sample of the liquid added to air-free acetone gave a flocculent fawn precipitate of molybdenyl bromide. (If the electrolysis is continued beyond this stage, the product is hydrolysed and much darker than the true compound.) The cathode solution was now forced by pressure of carbon dioxide into air-free acetone, and the solid which separated was filtered off and washed with acetone. All these operations were performed in an atmosphere of carbon dioxide, air being rigidly excluded. The solid was transferred to a desiccator which was then evacuated.

*Valency of the Compound.*—This was determined as for the oxychloride (*loc. cit.*). Direct titration with standard permanganate required, for 1 g. of solid, 118.90 c.c. After oxidation and passage through the reductor a solution containing 1 g. of the substance required 118.40 c.c. The molybdenum is therefore tervalent, for the latter titration represents the oxidation of the tervalent molybdenum, produced by reduction, to the sexavalent condition.

*Analysis.*—The molybdenum was precipitated as sulphide and ignited to trioxide (J., 1924, 125, 1911). The bromide in the filtrate and washings was weighed as silver bromide (Found: Mo, 37.5, 37.7; Br, 31.1, 31.3; Mo:Br = 1:1; 1:1.  $\text{MoOBr}_3 \cdot 5\text{H}_2\text{O}$  requires Mo, 37.7; Br, 31.35%). In all probability the normal hydrate is  $\text{MoOBr}_3 \cdot 4\text{H}_2\text{O}$ .

#### *Properties and Reactions of Molybdenyl Monobromide.*

The dried solid is light fawn in colour and does not deliquesce in the air, although it gradually undergoes atmospheric oxidation. It is readily soluble in water or hydrobromic acid, its solubility in water being greater than that of the oxychloride. It is insoluble

in acetone or dry ether, slightly soluble in cold absolute alcohol and more soluble on warming. The substance has pronounced reducing properties. Silver nitrate is reduced to the metal, whilst with lead acetate acidified with acetic acid no precipitate of lead bromide is obtained. This test seems to indicate that molybdenyl bromide is not a binary electrolyte.

*Molecular Weight Determinations.*—The molecular weight was determined by depression of the freezing point of air-free water.

G. of $\text{MoOBr}_4 \cdot 4\text{H}_2\text{O}$ per 10 g. of water ...	0.1235	0.0640	0.0698
" Apparent " mol. wt. ....	218.8	218.2	220.1

If the salt has the formula  $[\text{MoOBr}_4 \cdot 4\text{H}_2\text{O}]$ , the molecular weight is 263.9, whereas if it is formulated as  $[\text{MoO}]\text{Br}_4 \cdot 4\text{H}_2\text{O}$  in dilute aqueous solution, if ionisation is complete, its "apparent" molecular weight should be 131.9. The above results furnish strong evidence in favour of its formulation as the co-ordination compound  $[\text{MoOBr}_4 \cdot 4\text{H}_2\text{O}]$ , although they also indicate that the substance undergoes gradual hydrolysis in accordance with the equation

This view receives support from the fact that the molecular weights determined with solutions of the solid, after standing some hours in ice-cold water, were considerably less than those quoted above, whilst after longer periods the hydroxide of molybdenum gradually separated.

Conductivity measurements at  $1^\circ$  showed this continuous hydrolysis, which was accelerated by the presence of the electrodes (compare Duff, J., 1923, 123, 572). For  $v = 24$  litres per mole

$\mu$ .....	66.8	68.2	75.2	76.1	76.9	77.6	77.8	78.2	78.2
Time (mins.) ...	2	3	4	5	6	7	8	9	10

In more dilute solutions, the rate of hydrolysis was increased. The fact that the conductivity alters with time and that it approaches the value for a binary electrolyte like potassium chloride, for which the data at  $1^\circ$  are

$v$ (litres per mole) .....	8	16	32
$\mu$ .....	72.2	75.2	77.3

supports the formula  $[\text{MoOBr}_4 \cdot 4\text{H}_2\text{O}]$  for the new compound. Many cases could be cited to show that ionisation of co-ordination compounds occurs with replacement of the co-ordinated halogen atom by a molecule of the solvent.

#### *Salts of the Types $\text{R}_3[\text{MoBr}_6]$ and $\text{R}_2[\text{MoBr}_5 \cdot \text{H}_2\text{O}]$ .*

By the addition of alkali bromide to a reduced bromide solution containing tervalent molybdenum, two salts have so far been pre-

pared conforming to the above types. The isolation of the oxy-bromide from a reduced molybdenum solution shows that a further possibility of complex salt formation may arise, namely, salts of the type  $\text{MoOBr}_x\text{KBr}$ . Although such a salt has not been isolated, the corresponding chlorine derivative  $[\text{MoOCl}_2\cdot 3\text{H}_2\text{O}]\text{K}$  has been obtained (unpublished research). The preparation of these three classes of salts depends on the following factors: (a) Molybdenum concentration, (b) relative amount of alkali bromide present, (c) amount of "free" acid. By suitable adjustment of these factors we have isolated  $\text{K}_3\text{MoBr}_8$ ,  $\text{K}_2\text{MoBr}_5$ ,  $\text{Cs}_2\text{MoBr}_5\cdot\text{H}_2\text{O}$ , and an impure rubidium salt of the last type.

*Preparation of Tripotassium Molybdenum Hexabromide.*—200 C.c. of the bromide solution containing tervalent molybdenum, to which was added a saturated aqueous solution of 10 g. of potassium bromide, were concentrated at  $65\text{--}70^\circ$  under diminished pressure to about 100 c.c. Air-free alcohol was then admitted to the flask, and the excess of potassium bromide precipitated. After filtration in an atmosphere of carbon dioxide, the filtrate was concentrated to 40 c.c. On addition of absolute alcohol a crystalline, light red solid was obtained which was filtered off and dried (Found: Mo, 13.9; Br, 69.0; K, 16.9.  $\text{K}_3\text{MoBr}_8$  requires Mo, 13.9; Br, 69.2; K, 16.9%). A valency determination showed the molybdenum in this salt to be tervalent.

*Preparation of Dipotassium Molybdenum Pentabromide.*—100 C.c. of the solution containing tervalent molybdenum and 20 c.c. of potassium bromide solution (containing 1.5 g.) were placed in an air-free flask and concentrated at  $65\text{--}70^\circ$  under diminished pressure until nearly dry. At this stage, air-free alcohol was admitted and a crystalline, brick-red salt separated which, after filtration and drying in an evacuated desiccator, was shown to contain tervalent molybdenum (Found: Mo, 16.7; Br, 69.5; K, 13.8.  $\text{K}_2\text{MoBr}_5$  requires Mo, 16.7; Br, 69.6; K, 13.6%).

This salt is obviously of the same type as the ammonium salt first obtained by Rosenheim and Braun (*loc. cit.*) and later by Foerster and Fricke (*Z. angew. Chem.*, 1921, 36, 2, 458). The former investigators formulated the dark garnet-red crystals as  $(\text{NH}_4)_2\text{MoBr}_5\cdot 2\text{H}_2\text{O}$ , whilst Foerster and Fricke considered them to be  $(\text{NH}_4)_2[\text{MoBr}_5\cdot\text{H}_2\text{O}]$ . By double decomposition with caesium bromide a solution of the potassium salt yielded the very insoluble  $\text{Cs}_2\text{MoBr}_5\cdot\text{H}_2\text{O}$  (Found: Mo, 12.3; Mo:Br = 1:5. Calc.: Mo, 12.3%).

A rubidium salt was prepared by a similar method to that used for the potassium derivative, but it could not be obtained pure.

*Properties of the Complex Salts.*

All these soluble complex salts give deep red solutions with water, in which both potassium salts are very soluble, the rubidium salt is sparingly soluble, and the caesium compound insoluble. The aqueous solutions gradually turn brown, then turbid, and finally yield a dark brown precipitate. This decomposition is accelerated by warming. The salts reduce copper sulphate solution to cuprous bromide, whilst silver nitrate solution is reduced to the metal.

The authors desire to thank Messrs. Brunner Mond and Co. for a grant in aid of this investigation and Professor G. T. Morgan, F.R.S., for his continuous interest.

### CCVIII.—*The Dehydration of Glycols derived from $\alpha$ -Naphthylglycollic Acid.*

By ALEX. MCKENZIE and WALTER SAMUEL DENNLER.

THE present investigation arose from previous work on the deamination of 2-hydroxy-1 : 2-diphenyl-2- $\alpha$ -naphthylethylamine (I) and on the dehydration of  $\alpha$ -naphthylhydrobenzoin (II) (McKenzie and Richardson, J., 1923, 123, 79; McKenzie and Roger, J., 1924, 125, 844; McKenzie and Dennler, *ibid.*, p. 2105; Tiffeneau and Orékhov, *Compt. rend.*, 1924, 178, 1619). It appeared likely that 1- $\alpha$ -naphthyl-2 : 2-diphenylethylene glycol (III), which is isomeric with (II), would behave very differently when acted on by sulphuric acid. By arrangement with Professor Tiffeneau, it is now shown in the present paper that this is the case.

The products resulting from the elimination of water from (II) have already been shown to depend on the experimental conditions. With cold concentrated sulphuric acid, both  $\alpha$ -naphthyldeoxybenzoin (IV) and diphenylacetoneaphthone (V) were formed, whereas with hot dilute sulphuric acid the products were  $\alpha$ -naphthyldeoxybenzoin

(IV), diphenyl- $\alpha$ -naphthylacetaldehyde (VI), and diphenyl- $\alpha$ -naphthylethylene oxide (VII).

Whilst the formation of both (IV) and (V) from (II) may be interpreted on the basis of semipinacolonic transposition,

it should be noted that Danilov (*J. Russ. Phys. Chem. Soc.*, 1919, 51, 97) has shown that triphenylacetaldehyde undergoes molecular rearrangement into phenyldeoxybenzoin even under the influence of hot dilute sulphuric acid, thus:  $\text{CPh}_3\cdot\text{CHO} \rightarrow \text{CHPh}_2\cdot\text{COPh}$ . Similarly, Orékhov and Tiffeneau (*Compt. rend.*, 1926, 182, 67) have shown that substituted acetaldehydes undergo transformation into the same ketones as are formed by the direct dehydration of the corresponding glycols, e.g., a mixture of ethyldeoxybenzoin and diphenylbutanone is obtained either from diphenylethylacetaldehyde or from ethylhydrobenzoin:

In the light of these results, it would appear quite probable that, in the formation of (IV) and (V) from (II), the intermediate product might be (VI). The proportion of (IV) and (V) in the mixture resulting from the dehydration of (II) with cold concentrated sulphuric acid varies according to the experimental conditions, and it might not be easy to arrive at this proportion experimentally, more particularly since the ketones melt at practically the same temperature. The recent work of Luce (*Compt. rend.*, 1925, 180, 145), however, would indicate that the migrational aptitude of  $\alpha$ -naphthyl is greater than that of phenyl, and one would argue that, in the mixture of ketones referred to, (IV) should preponderate.

1- $\alpha$ -Naphthyl-2:2-diphenylethylene glycol was prepared by the action of magnesium phenyl bromide on methyl  $\alpha$ -naphthylglycolate. It gave the same ketone, namely, diphenylacetone naphthone (V), irrespective as to whether cold concentrated sulphuric acid or hot

dilute sulphuric acid was used as the dehydrating agent, and its behaviour is thus quite different from that of the isomeric glycol (II). The change, which is best depicted as a vinyl dehydration, involves no transposition of phenyl:

Since phenyl has undoubtedly a stronger saturation capacity than  $\alpha$ -naphthyl, the sum of the saturation capacities of the two phenyls will be greater than that of  $\alpha$ -naphthyl plus hydrogen. The alternative explanation,

which involves migration of hydrogen in preference to  $\alpha$ -naphthyl, is regarded as unsatisfactory.

The researches of both Meerwein and Tiffeneau have demonstrated that phenyl has a strong saturation capacity, and a comparison of the results obtained by dehydrating (II) and (III) will show that the saturation capacity of phenyl is greater than that of  $\alpha$ -naphthyl. Obviously, the dehydration of (III) is not a semipinacolinic change; if it were, the product would be (IV) and not (V). Of the two hydroxyls, the tertiary is the more loosely bound, because the saturation capacity of the two phenyl groups more than balances the saturation capacity of  $\alpha$ -naphthyl plus hydrogen.

1- $\alpha$ -Naphthyl-2:2-dimethylethylene glycol was prepared from methyl  $\alpha$ -naphthylglycolate and magnesium methyl iodide. Its behaviour on dehydration is similar to that of (III):

This result was anticipated, since methyl has a strong saturation capacity.

The behaviour of (III) and (II) on dehydration has a parallel in two other cases which may be quoted. Thus, diphenylpropylene glycol gives diphenylacetone both with hot dilute and with cold concentrated sulphuric acid:

The isomeric methylhydrobenzoin, however, behaves differently :

(For literature, see McKenzie and Roger, *loc. cit.*)

Again, *as*-benzylidiphenylethylene glycol may be contrasted with the isomeric benzylhydrobenzoin :

(Orékhov, *Bull. Soc. chim.*, 1919, **25**, 107).

Here the same ketone is produced by two different mechanisms, migration of phenyl taking place in the one case and not in the other.

The ketones formed from 1- $\alpha$ -naphthyl-2:2-diphenylethylene glycol and 1- $\alpha$ -naphthyl-2:2-dimethylethylene glycol, respectively, cannot exist in optically active modifications. To obtain such a ketone from a glycol derived from optically active  $\alpha$ -naphthylglycollic acid, it would be necessary for semipinacolinic change to occur during the dehydration of the glycol instead of the vinyl dehydration as in the two other cases, and even then optical activity might not persist. Accordingly, since Tiffeneau and Lévy (*Bull. Soc. chim.*, 1923, **33**, 759) have shown that benzyl has a greater migrational aptitude than methyl and also has a weaker saturation capacity, the examination of the dehydration of 1- $\alpha$ -naphthyl-2:2-dibenzylethylene glycol (VIII), prepared by the action of magnesium benzyl chloride on methyl  $\alpha$ -naphthylglycollate, was undertaken. The change is apparently semipinacolinic :

#### EXPERIMENTAL.

*Preparation of  $\alpha$ -Naphthylglycollic Acid.*—(1) From  $\alpha$ -naphthoic acid. Boessneck's method (*Ber.*, 1883, **16**, 639) was modified as

follows:  $\alpha$ -Naphthoic acid (40 g.)  $\rightarrow$  acid chloride (37 g.), b. p. 170—172°/15 mm.,  $\rightarrow$   $\alpha$ -naphthoyl cyanide (27 g.), m. p. 100°,  $\rightarrow$   $\alpha$ -naphthoylformamide (24 g.), m. p. 151—153°,  $\rightarrow$   $\alpha$ -naphthoylformic acid (15 g.), m. p. 110—111°. The latter acid was reduced by aluminium turnings and an excess of caustic potash, the excess of aluminium removed, and the hydroxy-acid obtained by acidification by hydrochloric acid and extraction with ether. It crystallised from benzene in rectangular needles, m. p. 80—82°, and was then dried in a vacuum. Yield: 14 g.; m. p. 98.5—99.5° (Found: C, 71.2; H, 5.0. Calc.: C, 71.3; H, 5.0%). Boessneck does not quote the melting point of his acid, but Brandis (*Ber.*, 1889, 22, 2148), who obtained the acid from  $\alpha$ -naphthaldehyde by the cyanohydrin method, gives m. p. 80—81°.

(2) *From naphthalene.*  $\alpha$ -Naphthyl methyl ketone (14 g.), prepared from naphthalene by the Friedel and Crafts reaction (Caille, *Compt. rend.*, 1911, 153, 393), was brominated (Schweitzer, *Ber.*, 1891, 24, 549). Caustic potash (25 g. in 250 c.c. of water) was added to the dibromide and, after a fortnight, the acid obtained by acidification and extraction with ether was crystallised from benzene (yield of dry acid, 5 g.; m. p. 98—99°. Schweitzer gives m. p. 91—93°).

(3) *From chloral* (compare Hébert, *Bull. Soc. chim.*, 1920, 27, 45). The Grignard reagent prepared from 150 g. of  $\alpha$ -bromonaphthalene (1 mol.) was cooled to -12°, and an ethereal solution of 98 g. of anhydrous chloral (1 mol.) gradually added (90 min.). The action was very vigorous, the ether assumed a blood-red tint, and a solid separated. The mixture remained at 0° over-night, and was then decomposed by ice and dilute acetic acid. The oil resulting from the ethereal solution was mixed with an excess of sodium carbonate, and, after hydrolysis of the trichloro-alcohol and removal of the naphthalene by steam, the aqueous solution was acidified by concentrated hydrochloric acid, and the hydroxy-acid extracted with ether (yield: 70 g.). The acid after crystallisation from benzene and drying in a vacuum melted at 98—99°. Its silver salt gave Ag, 35.0 (Calc.: Ag, 35.0%).

Of those three methods, the third was in our experience the most practicable.

$\alpha$ -Naphthylglycollic acid gives a blue coloration when a trace is added to cold concentrated sulphuric acid. Its methyl ester is sparingly soluble in light petroleum, from which it separates in needles, m. p. 79°, as given by Schweitzer (*loc. cit.*) (Found: C, 72.2; H, 5.6. Calc.: C, 72.2; H, 5.6%). When heated under pressure at 100° with aqueous ammonia ( $d$  0.88), the ester was converted into  $\alpha$ -naphthylglycollamide,  $C_{10}H_7\cdot CH(OH)\cdot CO\cdot NH_2$ , which crystallises

from acetone-light petroleum in rhombic plates, m. p. 134—135° (Found: C, 71.8; H, 5.7.  $C_{12}H_{11}O_2N$  requires C, 71.7; H, 5.5%). An attempt to prepare the ketol,  $C_{10}H_7\cdot CH(OH)\cdot CO\cdot C_6H_5$ , by the action of an excess of magnesium phenyl bromide on the acid amide led to the regeneration of the latter.

*Action of Grignard Reagents on Methyl  $\alpha$ -Naphthylglycollate.*

*Action of Magnesium Phenyl Bromide.*—An ethereal solution of 5 g. of the ester (1 mol.) was added during 45 minutes to the Grignard reagent prepared from 16 g. of bromobenzene ( $4\frac{1}{2}$  mols.). A solid separated during the heating (9 hours). The product was decomposed with ice and ammonium chloride and, after the usual manipulation, diphenyl was removed by light petroleum. The 1- $\alpha$ -naphthyl-2:2-diphenylethylene glycol (III) obtained crystallised from light petroleum (b. p. 60—100°), in which it was sparingly soluble, in rectangular needles, m. p. 126—127° (yield 6.1 g.). It gives a bright green coloration with concentrated sulphuric acid. For analysis, it was dried in a vacuum at 80° (Found: C, 84.6; H, 6.0.  $C_{24}H_{20}O_2$  requires C, 84.7; H, 5.9%).

*Action of Magnesium Methyl Iodide.*—The conditions were similar to the preceding (15 g. of the ester [1 mol.]; Grignard reagent prepared from 60 g. of methyl iodide [6 mols.]; decomposition with ice, ammonium chloride and ammonia). The crude product was crystallised twice from light petroleum, 1- $\alpha$ -naphthyl-2:2-dimethylethylene glycol,  $C_{10}H_7\cdot CH(OH)\cdot CMe_2\cdot OH$ , being obtained (11 g.) in clumps of rectangular prisms, m. p. 81.5—82° (Found: C, 78.0; H, 7.5.  $C_{14}H_{16}O_2$  requires C, 77.8; H, 7.5%). It gives a reddish-brown coloration with concentrated sulphuric acid.

*Action of Magnesium Benzyl Chloride.*—An ethereal solution of 14 g. of the ester (1 mol.) was added during 90 minutes to the Grignard reagent prepared from 40 g. of benzyl chloride ( $4\frac{1}{2}$  mols.). A solid separated during the heating (10 hours). The product was decomposed with ice and dilute sulphuric acid, and dibenzyl removed by light petroleum. The 1- $\alpha$ -naphthyl-2:2-dibenzylethylene glycol (VIII) obtained crystallised from rectified spirit in rectangular plates (17 g.), m. p. 174—175° (Found: C, 84.8; H, 6.7.  $C_{26}H_{24}O_2$  requires C, 84.8; H, 6.6%). It gives a purple coloration with concentrated sulphuric acid.

*Dehydration of Glycols derived from Methyl  $\alpha$ -Naphthylglycollate.*

*Dehydration of the Diphenyl Glycol.*—(a) *With concentrated sulphuric acid.* 2 G. of finely-powdered 1- $\alpha$ -naphthyl-2:2-diphenylethylene glycol were triturated in instalments with 30 c.c. of concentrated sulphuric acid during 2 hours. The bright green color-

ation which appeared at first changed gradually to a greenish-brown. The mixture was added to 100 g. of ice, and the ethereal extract dried with sodium sulphate. The resulting oil gradually solidified, and the solid crystallised from rectified spirit in glistening rhombic plates, m. p. 108—109°. The compound (0.9 g.) was identified as diphenylacetone naphthone by its colour reaction with concentrated sulphuric acid, and by the non-depression of melting point when mixed with a specimen of the ketone prepared by the dehydration of  $\alpha$ -naphthylhydrobenzoin with concentrated sulphuric acid (McKenzie and Roger, *loc. cit.*).

(b) *With dilute sulphuric acid.* A mixture of the glycol (2 g.), water (16 c.c.), and concentrated sulphuric acid (20 g.) was boiled for 2 hours under reflux. The mixture was cooled, diluted with water, and the oil extracted with ether. The product was crystallised from ethyl alcohol, and diphenylacetone naphthone (1.5 g.), identified as above, was isolated.

*Dehydration of the Dimethyl Glycol.*—(a) *With concentrated sulphuric acid.* 7 G. of 1- $\alpha$ -naphthyl-2:2-dimethylethylene glycol were dehydrated with 100 c.c. of concentrated sulphuric acid. 2 G. of a golden-yellow oil, b. p. 295—298°, were collected.

(b) *With dilute sulphuric acid.* 10 G. of the glycol were boiled for 2½ hours with a mixture of 100 g. of concentrated sulphuric acid and 100 c.c. of water. The resulting oil was fractionated, and the portion boiling at 304—306°/758 mm. was collected. It did not reduce Fehling's solution, nor did it restore the colour to Schiff's reagent. Yield 6 g. (Found: C, 85.3; H, 7.0. Calc. for  $C_{14}H_{14}O$ : C, 84.8; H, 7.1%). This was isopropyl  $\alpha$ -naphthyl ketone, which according to Rousset (*Bull. Soc. chim.*, 1896, 15, 66) has b. p. 308—310°. The scission of the oil with alcoholic potash gave a solution of potassium salt from which  $\alpha$ -naphthoic acid was isolated, and the oil from the dehydration with concentrated sulphuric acid underwent a similar decomposition.

*Dehydration of the Dibenzyl Glycol.*—(a) *With concentrated sulphuric acid.* 10 G. of 1- $\alpha$ -naphthyl-2:2-dibenzylethylene glycol were gradually added (1 hour) with constant trituration to 220 g. of concentrated sulphuric acid. A purple coloration was noted. After being kept for 2 hours at the ordinary temperature, the mixture was poured into 500 g. of ice; the purple coloration then disappeared and the temperature fell quickly to -2°. When the ice had melted, the oil was extracted with ether, the ether expelled, and the residue (7 g.) distilled under diminished pressure. The compound,  $C_{26}H_{22}O$ , was a golden-yellow oil, b. p. 275°/15 mm. For analysis, it was dried in a vacuum (Found: C, 89.3; H, 6.3.  $C_{26}H_{22}O$  requires C, 89.2; H, 6.2%). It solidified after several days,

and was then crystallised from rectified spirit, from which it separated in rhombic plates, m. p. 58—59°. With concentrated sulphuric acid, it gave a light brown coloration which disappeared quickly.

(b) *With dilute sulphuric acid.* A mixture of the glycol (15 g.), water (125 c.c.), and concentrated sulphuric acid (120 g.) was boiled for about 2½ hours under reflux, and the oil extracted with ether. The product was an oil (13.5 g.), b. p. 276°/15 mm., which gradually solidified; m. p. 58—59°.

The substance is probably benzyl- $\alpha$ -naphthylmethyl benzyl ketone,  $\text{CH}_2\text{Ph}\cdot\text{CO}\cdot\text{CH}(\text{C}_{10}\text{H}_7)\cdot\text{CH}_2\text{Ph}$ , but the evidence for its constitution is not quite convincing. It formed no oxime with hydroxylamine, and it is very stable towards alcoholic soda; thus, when 2.5 g. were heated at 100—140° for 24 hours with a solution of 6 g. of caustic soda in ethyl alcohol, the original substance was recovered. It gave, however, benzoic acid when it was oxidised in glacial acetic acid solution with chromic anhydride. The first product of the oxidation was presumably phenylacetic acid; it was found that the latter does give benzoic acid when oxidised under similar conditions to those adopted for the compound.

The thanks of the authors are due to the Department of Scientific and Industrial Research for a maintenance grant awarded to one of them (W. S. D.).

## CCIX.—*The Complexity of the Solid State. Part IV. The Behaviour of Pure Sulphur Trioxide. Part III.*

By ANDREAS SMITS and PIETER SCHOENMAKER.

### *Investigations with X-Rays.*

As shown in our last publication (this vol., p. 1120), it is possible by partial distillation to obtain the intensively dried, high-melting, asbestos-like form in a condition having an abnormally low vapour pressure and an initial melting point which is 33° higher than the unary melting point. It appears, indeed, that this form of sulphur trioxide behaves as a mixed crystal; the most volatile pseudo-component can be distilled off, so that the residue is a substance having the above abnormal properties.\*

\* Only the states of aggregation of a single substance in inner equilibrium will be called "modifications"; the states not in inner equilibrium will be termed "forms" of the substance.

For the X-ray investigation of the different states of the high-melting, asbestos-like form we used the simple apparatus of high-melting Jena glass shown in Fig. 1. The bulb, A, is sealed to B along with a vessel, C, and three very thin-walled capillary tubes, D, E, and F (diameter 0.008 to 0.01 mm.). Bulb A is partly filled with freshly-distilled phosphorus pentoxide and then with intensively dried sulphur trioxide, as described in our first communication (J., 1924, 125, 2557). The apparatus is then evacuated and the tube

FIG. 1.

B is sealed off at G.

The capillary tubes were filled one after another with the high-melting, asbestos-like form by the method of condensation and evaporation. In order to obtain a form with an abnormally low vapour pressure, a part of the contents was distilled off rapidly and the capillaries were subsequently sealed off.

The Röntgenogram was then taken, using  $\text{CuK}_\alpha$ -rays. We obtained a film of 15 lines, the strongest of which are given in the following table:

Distances (mm.).....	8.9	11.6	13.2	16.4
$10^\circ \times \sin^2 \theta/2$ .....	32	54	70	106

( $\theta$  is the angle between the incident and refracted beams; the intensities of the lines mentioned here were very strong.)

The same capillary was now heated at  $50^\circ$  for 48 hours and, since our experiments had shown that under these conditions the low vapour pressure of the high-melting, asbestos-like form (which had been disturbed by evaporation) increased strongly, it was expected that the Röntgenogram taken after this heating process would show a great difference. *It was, however, unchanged. Hence, either the X-ray method was unable to detect the change which had taken place in the solid, or the X-rays had already effected the establishment of the inner equilibrium during the first exposure, so that the state of the solid before and after the heating was in reality the same.*

#### X-Rays effect the Establishment of the Inner Equilibrium.

To decide between the alternatives mentioned above, the following apparatus (Fig. 2) was constructed. As in other cases, pure phosphorus pentoxide was first distilled into vessel A, and then intensively dried sulphur trioxide. A T-piece with septum S was then connected with an exceedingly small glass spring indicator,

G, the little vessel of which was provided with a very thin-walled capillary, C, as used in X-ray analysis. The storage apparatus containing the sulphur trioxide was first evacuated and sealed; then the glass spring indicator with its capillary and the T-piece with its breaker were heated to redness in a current of dried air, the breaker-tube was sealed off at D, and this part of the apparatus was evacuated by stopcock K.

Capillary N being sealed off, a part of the sulphur trioxide was distilled into B and this vessel also was sealed off. Septum S was then broken and the capillary C filled with the high-melting, asbestos-like form, by the method of alternate condensation and evaporation.

FIG. 2.

In order to get a highly-disturbed state of this form, a portion was distilled off in the way described above, and then the capillary M was sealed off. The vapour pressure at the ordinary temperature was only 1 cm. Hg, proving that we had indeed a strongly-disturbed state of the high-melting, asbestos-like form.

We now placed the apparatus in front of our X-ray tube, protecting it by asbestos plates from access of heat. The X-rays were allowed to penetrate only the capillary containing the sulphur trioxide. As soon as this capillary was exposed to the X-rays the pressure in the indicator began to rise, showing that X-rays rapidly effect a transformation in the direction of inner equilibrium. In order to determine the final pressure, observations were continued over a period with the following results :

Time of exposure (hrs.) .....	0	1	4	8	10	13
Vapour pressure (mm. Hg) ...	10.8	22.2	43.1	46.1	46.3	46.3
Temperature .....	18.0°	18.0°	18.0°	18.8°	19.7°	19.7°

Consequently the final vapour pressure is 46.3 mm. Hg at 19.7°. As shown previously (this vol., p. 1116), the vapour-pressure line for the high-melting, asbestos-like form in inner equilibrium is given by the equation  $T \ln P = -Q/R + CT$ , where  $C = 32.0$ . Now, giving  $Q/R$  the mean, *i.e.*, 8243 cal., of the three values obtained (8246, 8236 and 8246 cal.), we find, for  $T = 292.7^\circ$  (*i.e.*, 19.7° C.),  $P = 46.45$  mm. Hg.

The agreement of this figure with the final value shown in the foregoing table proves that X-rays do indeed effect the establishment of inner equilibrium. It appears, therefore, that the X-ray diagrams showed no difference because, on exposure to X-rays, the substance was transformed into the state of inner equilibrium. This very interesting result shows that it is impossible to study the disturbed states of sulphur trioxide more closely by means of X-rays.

*X-Rays bring about the Transformation of the Metastable into the Stable Modification.*

Finally we investigated the X-ray diagrams of the two metastable modifications of sulphur trioxide—the ice-like form and the low-melting, asbestos-like form. Not only were the films obtained identical, but the X-ray diagram in each case was that of the high-melting, asbestos-like form considered above.

Hence X-rays, besides effecting the establishment of the inner equilibrium of sulphur trioxide, transform the metastable states into the stable state, *i.e.*, the high-melting, asbestos-like modification. *The only X-ray diagram obtainable is accordingly that of the stable modification in inner equilibrium.*

*Summary.*

On distillation of a portion of the intensively dried, high-melting, asbestos-like form, different states having abnormally low vapour pressures and abnormally high initial melting points were obtained, thus showing that the intensively dried, high-melting, asbestos-like form behaves as a mixture of pseudo-components which have very different vapour pressures and melting points.

At the ordinary temperature these states do not alter, but at 50° changes take place in the direction of the inner equilibrium. On studying the unchanged state and that changed at 50°, by means of X-rays, a very interesting result was obtained: the Röntgenograms in these two cases were identical.

Using an apparatus which enabled us to determine the vapour pressure during the exposure to X-rays, we found the explanation of the interesting phenomenon mentioned above to lie in the fact

that the X-rays effect a very rapid increase of the vapour pressure, proving that X-rays cause a rapid change in the direction of the inner equilibrium. Calculation showed that the final vapour pressure was exactly that of the high-melting, asbestos-like form in inner equilibrium.

X-Rays bring about not only the establishment of the inner equilibrium, but also the transformation of the metastable modifications into the stable form. The films obtained by exposing the ice-like form and the low-melting, asbestos-like form to X-rays are thus identical with the film of the high-melting, asbestos-like modification.

THE UNIVERSITY, AMSTERDAM.

### CCX.—*The Photolysis of Acetaldehyde and of Acetone.*

By EDMUND JOHN BOWEN and HAROLD GARFIT WATTS.

It was shown by Berthelot and Gaudechon (*Compt. rend.*, 1913, **156**, 68, 233) that acetaldehyde is partly polymerised in ultra-violet light and partly decomposed into methane and carbon monoxide; also (*ibid.*, 1910, **151**, 478) that acetone is decomposed into ethane and carbon monoxide. In aqueous solutions acetone is said to be photolysed to methane and acetic acid.

The following experiments were made to compare the number of molecules chemically changed with the number of molecules activated, *i.e.*, with the number of quanta absorbed. No work of this kind on gaseous aldehydes and ketones seems to have been done, although Volmar (*Compt. rend.*, 1924, **178**, 697), apparently without experimental evidence, assumed that these reactions obeyed the Einstein-Stark law.

#### *Experiments with Acetaldehyde Vapour.*

The apparatus is shown diagrammatically in the figure. A mercury vapour lamp made by the Thermal Syndicate was contained in a box fitted with quartz condensing lenses so that approximately parallel light fell on the fused quartz reaction bulb A, which was filled with acetaldehyde vapour by lowering the mercury reservoir B, evacuating with two mercury vapour pumps in series, and then connecting with the liquid aldehyde in D through the tap. The reservoir B was then raised so that mercury rose in the limbs of the U-tube C, and the tap on the right hand limb opened to the atmosphere. The amount of photochemical change was measured by pressure changes in the left hand limb, which was heated electrically to prevent condensation of liquid.

For the measurement of the energy of the ultra-violet light, use was made of the "ultra-violet radiometer" of Anderson and Robinson (*J. Amer. Chem. Soc.*, 1925, 47, 718) which is based upon the decomposition of oxalic acid in uranyl sulphate solutions. There is a serious discrepancy in the results of different investigators of this reaction. Anderson and Robinson state that in ultra-violet light 1 molecule of oxalic acid is decomposed for every 25 quanta absorbed; Boll (*Compt. rend.*, 1913, 156, 1891) states that 50 molecules of oxalic acid are decomposed for each quantum absorbed; whilst Büchi (*Z. physikal. Chem.*, 1924, 111, 269) finds that the reaction obeys the Einstein-Stark law. We therefore

FIG. 1.

made direct measurements of the photochemical efficiency of this reaction.

The mercury vapour lamp with quartz condensing lenses was set up with a 5 cm. water-filter, and the light passed through a stop on to a cell with fused-on ends of plane-polished quartz containing the uranyl sulphate (0.01*M*) and oxalic acid (0.1*N*) solutions. The oxalic acid decomposed was estimated with *N*/20-potassium permanganate solution, and

the total energy of the light measured with a Moll thermopile calibrated against a Hefner lamp (Gerlach, *Physikal. Z.*, 1913, 14, 577). The amount of light absorbed was obtained from the difference in readings of the galvanometer connected to the thermopile when the quartz cell contained water or the solution. The results were as follows :

Galvanometer readings (1 division =  $1.4 \times 10^{-4}$  cal./sec.) :

Total energy of lamp falling on cell = 50 divisions.

Quartz cell filled with water = 30.5 "

" " " " solution = 17.5 "

Thus, cal. absorbed by solution per sec. =  $2.8 \times 10^{-3}$ .

Taking the Hg line 3130 Å. as the mean wave-length absorbed, 1 gram-molecular quantum = 85,000 cal.; therefore the number of gram-molecular quanta absorbed per sec. =  $3.3 \times 10^{-8}$ . In these experiments, each of 1 hour's exposure, the amount of oxalic

acid decomposed per second was  $3.0$ ,  $3.35$ , and  $3.5 \times 10^{-8}$  g.-mol., respectively. From these results it appears that it may safely be assumed, in agreement with Büchi, that for each quantum of ultra-violet light absorbed one molecule of oxalic acid is decomposed.

The absorption of the aldehyde vapour was then measured by the difference in the photochemical change taking place in the uranyl sulphate-oxalic acid solution in the plane-walled quartz vessel E when the bulb A was empty and when it was filled with aldehyde vapour; also, by placing the vessel E in the place of A, the total amount of ultra-violet light could be measured.

Acetaldehyde undergoes two photochemical changes:

- (1) Photolysis,  $\text{CH}_3\cdot\text{CHO} = \text{CH}_4 + \text{CO}$ .
- (2) Polymerisation,  $3\text{CH}_3\cdot\text{CHO} = \text{paraldehyde} + \text{metaldehyde}$ , etc.

The first series of measurements was made with a little liquid aldehyde in the bulb, *i.e.*, with saturated vapour, only the vapour being exposed to the light. If  $x$  molecules are changed according to reaction (1), the pressure change will be proportional to  $2x$ , the second reaction giving condensation products which do not affect the pressure appreciably. The results were:

Volume of reaction vessel = 125 c.c.

Pressure *increases* in cm. Hg after 1 hour's exposure. =  $\begin{cases} 0.59, 0.665, 0.55, 0.685. \\ \text{Mean} = 0.62. \end{cases}$

Thus,  $2x = 125 \times 0.62/3600 \times 76 \times 23400 = 1.2 \times 10^{-8}$  g.-mol./sec. or  $x = 0.6 \times 10^{-8}$  g.-mol./sec.

A second series of experiments was made with unsaturated vapour; a diminution in pressure then took place showing that more molecules are polymerised than photolysed. If  $y$  is the number of molecules activated for the reaction

the diminution in pressure is proportional to  $(3y - x)$ . The results were:

Pressure *decreases* in cm. Hg. after 1 hour's exposure. =  $\begin{cases} 3.5, 3.9, 3.3, 3.8, 2.8, 2.4. \\ \text{Mean } 3.5. \end{cases}$

Thus,  $3y - x = 125 \times 3.5/3600 \times 76 \times 23400 = 6.85 \times 10^{-8}$  g.-mol./sec., whence  $y = 2.48 \times 10^{-8}$  g.-mol./sec.

Total number of g.-mols. activated per second for photolysis and polymerisation =  $x + y = 3.08 \times 10^{-8}$ .

Number of gram-molecular quanta absorbed per second by aldehyde vapour (obtained from oxalic acid-uranyl sulphate solution titrations) =  $1.42 \times 10^{-8}$ .

Allowing for the inaccuracy of the measurements and the complexity of the decomposition products of acetaldehyde, the results indicate that two molecules are chemically activated for each quantum absorbed.

*Experiments with Acetone Vapour.*

The same apparatus was used except that an air-bath was placed round the reaction bulb to keep the acetone as an unsaturated vapour at about 750 mm. and 60°. The amount of light absorbed was taken to be equal to that measured in the experiments on aqueous solutions of acetone described below, as, the concentrations of acetone being equal, it has been shown that the extinction coefficients of gaseous and of dissolved acetone are not very different (Porter and Iddings, *J. Amer. Chem. Soc.*, 1926, 48, 40). The results were:

Vol. of bulb (c.c.).	Exposure (mins.).	Press. change (cm. Hg).	No. of g.-mols. acetone decomp. per sec.
125	245	2.42	$1.34 \times 10^{-8}$
80	160	3.63	} $1.81 \times 10^{-8}$ (mean)
80	135	3.35	

Number of gram-molecular quanta absorbed per sec. =  $1.0 \times 10^{-8}$ .

Other experiments were made at room temperature in an apparatus consisting of two bulbs filled with acetone vapour connected by a U-tube containing liquid acetone. The apparatus was immersed in a thermostat before and after exposing one bulb (of quartz) to the lamp, and the photochemical change determined by the change in level of the liquid in the U-tube. The energy in the light absorbed was directly measured with the oxalic acid-uranyl sulphate solution. The results were:

Exposure = 1 hour. Volume of bulb = 125 c.c.

Pressure change (cm. Hg) = 0.212, 0.176, 0.141, 0.159, 0.247.

Taking the average as 0.187 cm. Hg, the number of g.-mol. of acetone decomposed per second is  $2 \times 10^{-9}$ . The mean of several oxalic acid titrations gave the number of gram-molecular quanta per second =  $4.85 \times 10^{-9}$ . The number of molecules chemically changed is very close to the number of quanta absorbed.

The accuracy of these low-pressure measurements was not so great as that of the high-pressure ones, so that it is not certain whether the diminution in quantum sensitivity is real or due to experimental errors.

A further series of experiments was made with hot acetone vapour, oxalic acid-uranyl sulphate solutions being used to measure the absorption.

The results were: Volume of bulb = 125 c.c. Exposure = 60

minutes. Pressure change (cm. Hg.) = 0.60, 0.82, 0.815, 0.77, 0.71, 0.80, 0.60, 0.90.

Taking the mean as 0.75, the number of g.-mol. of acetone decomposed per second =  $1.5 \times 10^{-8}$ .

The mean of several oxalic acid titrations gave the number of gram-molecular quanta absorbed per second =  $0.867 \times 10^{-8}$ .

It seems that about two molecules of acetone are decomposed for each quantum absorbed.

*Experiments with Aqueous Solutions of Acetone.*

It is stated by Henri (*Compt. rend.*, 1913, 156, 1012) that about 1300 molecules of acetone are hydrolysed for each quantum of ultra-violet light absorbed. He appears to have used an open quartz cell to contain the solution, and must have lost acetone by evaporation. In our experiments, solutions of acetone were exposed in a closed plane-walled quartz cell to an approximately parallel beam of ultra-violet light, and the number of quanta absorbed measured with the oxalic acid-uranyl sulphate solution. When the acetone solution was titrated iodimetrically, the photochemical change was too small to be measurable, although if the reaction followed the Einstein-Stark law it should have been recognisable. The acetic acid formed was therefore estimated with very dilute baryta solution, and the following mean results were obtained :

Conc. of acetone solution %.	G.-mols. acetic acid formed per sec.	G.-molecular quanta absorbed per sec.
0.3	$5.7 \times 10^{-10}$	$1.0 \times 10^{-8}$
15	$2.88 \times 10^{-9}$	$1.9 \times 10^{-8}$

Here the number of g.-mols. of acetic acid formed is less than one-fifth of the number of quanta absorbed. It is possible that formation of other products occurs, but these could not be discovered or estimated, and the results must be taken to be in serious disagreement with those of Henri.

These measurements emphasise the need for reinvestigation of older results on the ratio of the number of molecules reacting to the number of quanta absorbed in photochemical reactions. Correcting the tables of such reactions examined from this point of view which were presented to the Faraday Society in October, 1925 (Allmand, Dhar, and Mukerji), we now find that in 65% of the cases the number of molecules reacting is, within a factor of about 3, equal to the number of molecules physically activated, indicating fairly simple mechanisms in all these examples. In 20% of the cases, chiefly those involving halogen molecules, the number of molecules changed is many times the number of quanta absorbed, indicating "chain" mechanisms. It is characteristic

of this class of reaction that "inhibitors" produce their large effect by interfering with the "chains." In 15% of the cases, the number of molecules reacting is much less than the number of quanta absorbed, and in some of these cases, again involving the halogens, we find long lives of activated molecules (Briers, Chapman, and Walters, this vol., p. 562; Eggert, *Physikal. Z.*, 1925, 26, 865), and reaction rates varying with the square root of the light absorbed (Bodenstein and Lütkemeyer, *Z. physikal. Chem.*, 1924, 114, 208; Berthoud and Bellenot, *J. Chim. phys.*, 1924, 21, 308), all indicating a primary dissociation of the halogen molecule, followed by extensive slow recombination of the atoms produced, only an occasional atom entering into the observed chemical change. There is need for much work to elucidate the complexities of these last two classes of reactions. It is significant, however, that the first class of reactions should be the largest; here apparently every molecule physically activated takes part in chemical change, showing that under these conditions, when a molecule is activated, its chemical reactivity on collision is not affected by its orientation.

[Received, May 15th, 1926.]

## CCXI.—The Constitution of the Condensation Product of $\beta$ -Phenylhydroxylamine and Acetone.

By FRANCIS HARROLD BANFIELD and JOSEPH KENYON.

A CONCENTRATED solution of  $\beta$ -phenylhydroxylamine in acetone deposits, after about two weeks, large, rhombic crystals which melt at 136°. To this compound Bamberger and Rudolf, who first described it (*Ber.*, 1907, 40, 2237), gave the constitution  $\text{Me}_2\text{C} \begin{array}{c} \diagup \text{NPh} \\ \diagdown \text{O} \end{array}$  by analogy with  $\text{PhCH} \begin{array}{c} \diagup \text{NPh} \\ \diagdown \text{O} \end{array}$ ,\* at that time regarded as the constitution of the condensation product of  $\beta$ -phenylhydroxylamine and benzaldehyde. Beckmann and Scheiber (*Annalen*, 1907, 355, 235) showed, by molecular-weight determinations, that the empirical formula must be doubled, and prepared analogous

\* Bamberger subsequently (*Ber.*, 1922, 55, 3376; 1924, 57, 2082) replaced this formula by  $\text{PhCH:NPh:O}$  in accordance with the modern formulation of azoxy-compounds, and support for the new constitution is afforded by the formation of the additive compound  $\begin{array}{c} \text{CHPh:NPh} \\ | \\ \text{NPh-CO} \end{array} \begin{array}{c} \diagup \text{O} \\ \diagdown \end{array}$  with phenylcarbimide.

compounds from acetone and  $\beta$ - *p*- and *m*- (but not *o*-) tolyl- and  $\beta$ -( $\alpha$ -naphthyl)-hydroxylamines. They did not succeed, however, in preparing condensation compounds when acetone was replaced by its homologues. Scheiber and Wolf (*Annalen*, 1908, 357, 25), who studied the reaction products of acetone and these  $\beta$ -aryl-hydroxylamines in some detail, suggested that the condensation is due to loss of water following direct combination of the two reagents; *e.g.*,

They did not, however, prepare any crystalline derivatives or well-defined decomposition products in support of either of these formulæ.

Although, as stated by Scheiber and Wolf (*loc. cit.*), the condensation product of  $\beta$ -phenylhydroxylamine and acetone is very susceptible to acidic reagents, yet it is possible by working under carefully regulated conditions to prepare a number of its crystalline derivatives and other definitely characterised products. The formation of these is in no way accounted for by the formulæ given above.

The maximum yield of the condensation product—68%—is obtained by the interaction, at the ordinary temperature, of dry  $\beta$ -phenylhydroxylamine and acetone during a period of two to three months. Reaction at a higher temperature results in rapid decomposition of the  $\beta$ -phenylhydroxylamine, and the effect of adding calcium chloride or sodium sulphate to the reaction mixture to combine with the liberated water is to diminish the yield of the condensation product.

The filtrate after removal of the condensation product consists of two layers: (a) water, (b) an acetone solution of azoxybenzene and aniline. The latter two substances are the normal decomposition products of  $\beta$ -phenylhydroxylamine and can be isolated in amounts almost sufficient to account for the portion of the  $\beta$ -phenylhydroxylamine which does not condense with acetone. The probable course of the reaction between acetone and  $\beta$ -phenylhydroxylamine may therefore be represented by the equation  $2\text{Me}_2\text{CO} + 2\text{PhNH}\cdot\text{OH} = \text{C}_{13}\text{H}_{22}\text{O}_2\text{N}_2 + 2\text{H}_2\text{O}$ .

The condensation product decomposes slowly in solution at the ordinary temperature; when a solution in 96% alcohol is boiled for 24 hours, complete decomposition into mesityl oxide, aniline, and azoxybenzene occurs.

The condensation product reacts readily at the ordinary temperature with acetic anhydride to yield a crystalline *monoacetyl*

derivative,  $C_{20}H_{24}O_3N_2$ , and in pyridine solution with benzoyl chloride to give a crystalline *monobenzoyl* derivative,  $C_{25}H_{26}O_3N_2$ . These results alone suffice to show the incorrectness of the formulæ mentioned above, since none of them contains a reactive hydrogen atom which would be likely to undergo displacement by an acyl group. The acyl derivatives are readily and quantitatively converted into the original condensation product on hydrolysis and therefore are very probably derivatives of it and not of some transformation compound.

The introduction of an acyl group into the molecule of the condensation product renders it resistant to permanganate and other oxidising agents and to dilute acids—including acetic acid—which attack it readily. The acyl group evidently protects a very reactive portion of the molecule, and since it can be removed by warming for a few minutes with alcoholic potash, there is a strong presumption that the group so protected is a hydroxyl group. Additional evidence for the presence of a hydroxyl group is afforded by the production at the ordinary temperature of a *potassium* derivative,  $C_{18}H_{21}O_2N_2K$ , which reacts with benzoic anhydride to give the benzoyl derivative described above. That the hydroxyl group is attached to nitrogen is rendered probable by the ease with which this potassium derivative is quantitatively oxidised by air to a red compound,  $C_{18}H_{21}O_2N_2$  (see p. 1622).

*Action of Dilute Hydrochloric Acid on the Condensation Product.*—The finely-powdered material is readily decomposed by dilute hydrochloric acid, the principal product being a liquid base,  $C_{12}H_{16}ONCl$ ; small quantities of azobenzene,  $\beta$ -phenylhydroxylamine and *p*-chloroaniline and a trace of mesityl oxide are also produced. This base differs in composition from the original compound by  $C_6H_6ONCl$ , and this fact and the nature of the by-products indicate that one of the  $\beta$ -phenylhydroxylamine residues has been detached from the compound during the reaction. Moreover, the acquisition of a chlorine atom under such mild treatment is in harmony with the view that a hydroxyl group attached to a nitrogen atom has been replaced by a chlorine atom:  $\cdot NPh\cdot OH + HCl \rightarrow \cdot NPhCl$ . The chloro-base thus produced does not, however, liberate iodine from an acidified solution of potassium iodide, so it is necessary to assume that the chlorine atom has already migrated into the benzene nucleus. This view is confirmed by the behaviour of the chloro-base, which decomposes into *p*-chloroaniline and mesityl oxide in molecular proportions on heating and gives equivalent quantities of *p*-chloroacetanilide and mesityl oxide by interaction with acetic anhydride. Moreover, it reacts with nitrous acid to give a yellow crystalline *nitrosoamine* (m. p. 75–76°)—a result

which further supports the view that the chlorine atom has wandered \* from the nitrogen atom to the nucleus.

The production of mesityl oxide and *p*-chloroaniline in equivalent proportions accounts entirely for the molecule of the chloro-base— $C_{12}H_{16}ONCl = C_6H_{10}O + C_6H_6NCl$ —and several attempts have been made, though unsuccessfully, to synthesise it from these two compounds.

The chloro-base readily yields a crystalline *semicarbazone* ( $C_{13}H_{19}ON_4Cl$ ), the oxygen atom thus being shown to be ketonic, and by its reduction with sodium and alcohol sodium chloride and aniline are obtained in equivalent quantities together with *p*-chloroaniline and methylisobutylcarbinol. There can be little doubt, therefore, that the constitution of the chloro-base is represented by formula (I), and its modes of decomposition by heat and by acetic anhydride by the scheme :

Its formation from the original compound can be represented by the equation :

The constitution of the chloro-base as  $\beta$ -*p*-chloroanilino- $\beta$ -methyl-pentan- $\delta$ -one has been established by its synthesis from  $\beta$ -phenylhydroxylamine and mesityl oxide by the following reactions :

The compound (II) is too unstable to be isolated; its *sodium* derivative, however, has been prepared by the interaction of mesityl oxide and the sodium derivative of  $\beta$ -phenylhydroxylamine.

The complete and facile scission, by the action of dilute hydrochloric acid, of a molecule of  $\beta$ -phenylhydroxylamine from the original condensation product renders it probable that the latter is  $\beta$ -phenyl-

\* The mechanism of the formation of *p*-chloroaniline from  $\beta$ -phenylhydroxylamine and hydrochloric acid is represented by Bamberger (*Ber.*, 1900, 33, 3600; 1901, 34, 61) as follows :

and by Löb (*Ber.*, 1896, 29, 1894) as

The experimental results recorded above are clearly opposed to Bamberger's view and in agreement with Löb's.

*hydroxylamino-β-methylpentan-δ-oneoxime N-phenyl ether* (III), or *β-phenylhydroxylamino-β-methylpentane-δ-phenylimine oxide* (IV), and its interaction with hydrochloric acid may be represented thus :

This view of the constitution of the condensation product is supported by the following additional reactions. The condensation product is rapidly decomposed by hot concentrated hydrochloric acid, giving mesityl oxide (20.5%), *p*-chloroaniline (33%) and azoxybenzene (16%) together with a small amount of a substance of very high boiling point. A similar decomposition is effected by steam, the principal products being azoxybenzene, mesityl oxide, and tarry material which has not been identified. When heated with an alcoholic solution of zinc chloride, the condensation product decomposes into *p*-phenetidine, azoxybenzene, *p*-chloroaniline, aniline and mesityl oxide. A similar scission of the molecule is brought about by the prolonged action of cold dilute sulphuric acid, the products being *p*-aminophenol, mesityl oxide and azoxybenzene; these can be isolated in amounts which account for 80% of the original material.

In marked contrast to the above-mentioned hydrolytic agents, hydrogen chloride converts the condensation product in dry ethereal solution into its *monohydrochloride*, a white solid which is decomposed by water into its components. This compound resembles β-phenylhydroxylamine hydrochloride in its behaviour and its constitution is probably

*Reduction of the Condensation Product.*—The condensation product is unaffected in moist ethereal solution by aluminium amalgam. It is, however, readily reduced in absolute alcoholic solution by sodium; aniline, azobenzene, and methylisobutylcarbinol are formed, but the main product is a secondary base,  $\text{C}_{12}\text{H}_{19}\text{ON}$ , from which a *chloroplatinate*, a yellow, crystalline *nitrosoamine*, and a *diacetyl* derivative have been prepared. Since one of the acetyl groups in this derivative is much more easily removed by hydrolysis than the other, it is probable that the secondary base contains a

hydroxyl group. Two formulæ for this compound suggest themselves :

of which the former is the more probable, as it implies a decomposition of the condensation product similar to that brought about by hydrolytic agents. The alternative formula is improbable, since a compound of this structure would tend to be dehydrated by an excess of an acetylating agent.

Several unsuccessful attempts were made to synthesise the secondary base from aniline and mesityl oxide. The only definite compound which could be isolated appeared to be produced by the condensation of one molecule of mesityl oxide with two molecules of aniline.

*Action of Oxidising Agents on the Condensation Product.*—When the finely powdered condensation product is agitated with a solution of potassium permanganate, potassium ferricyanide, sodium hypobromite, or ammoniacal silver oxide, or is exposed, suspended in faintly alkaline water, to the air for several weeks, it is oxidised to a bright red, crystalline compound. The most convenient procedure, however, is by the use of ammoniacal silver oxide as described in the experimental section. The oxidised compound, which is easily obtained pure in a yield of 98% of the theoretical amount, is produced by the action of one-half molecular quantity of silver oxide, it thus being shown that only one atom of hydrogen is removed from each molecule of the condensation product. Its molecular weight is of the same order of magnitude (about 300) as that of the unoxidised compound and therefore there has been no condensation between two molecules of the latter with the elimination of hydrogen. Moreover, the two compounds are almost identical in composition and therefore no oxygen has entered the original substance. That no change other than oxidation occurs during the reaction is shown by the quantitative regeneration of the original compound by the action of aluminium amalgam on a cold moist ethereal solution of the red oxidation compound.

The oxidised and the unoxidised compound differ in several important properties. The former does not react with acetic anhydride or with benzoyl chloride in pyridine solution at the ordinary temperature, the absence of a hydroxyl group being thus indicated. This view is supported by the marked difference in the behaviour of cold dilute hydrochloric acid towards the two compounds; whereas the oxidised compound is unaffected by this reagent (and other cold dilute mineral acids), the unoxidised one

undergoes an immediate change involving the substitution of one atom of chlorine for one atom of hydrogen and one of oxygen—a type of reaction to which  $\beta$ -arylhydroxylamines are peculiarly susceptible. It is therefore probable that the oxidation process involves the reaction

and leads to the production of a compound which contains a quadri-valent nitrogen atom.

Additional support for this view is furnished by the following experimental evidence: (a) one of the hydrolytic products of the action of dilute hydrochloric acid on the original condensation compound is  $\beta$ -phenylhydroxylamine (see p. 1623), whilst the oxidised compound in dry ethereal solution combines with hydrogen chloride to give a derivative the decomposition of which by water yields 50% of the unoxidised compound and 10% of nitrosobenzene (i.e., oxidised  $\beta$ -phenylhydroxylamine); (b) the oxidised compound is immediately decomposed by steam, giving a mixture of products from which the original unoxidised compound (22%) and nitrosobenzene (13%) can be isolated; (c) when the oxidised compound is gently heated under diminished pressure, it decomposes and nitrosobenzene sublimes from the reaction products.

Since both the unoxidised and the oxidised compound yield under the action of hot dilute mineral acids, or even of hot water, considerable quantities of mesityl oxide, the structural similarity of the aliphatic portions of the two molecules is confirmed. The oxidation process may therefore be expressed by the equation

and the decomposition of the two compounds by the equations

The experimental results so far recorded do not enable a decision to be made between the oxime-ether and the nitron formulations of the condensation compound. The following results are in harmony with the first view, but since the evidence is of a negative

character the question is not considered settled. Attempts are being made to obtain further evidence on this point.

The condensation product forms an additive compound with phenylcarbimide (1 mol.)—a result which is not obtained with either its acetyl derivative or its oxidation product. All the experimental evidence points to these two derivatives having the same molecular structure as the parent compound with the sole modification that a  $>\text{N}\cdot\text{OH}$  group has been converted in the one case into  $>\text{N}\cdot\text{O}\cdot\text{CO}\cdot\text{CH}_3$  and in the other into  $>\text{N}\cdot\text{O}$ . It is highly probable, therefore, that phenylcarbimide reacts with the  $>\text{N}\cdot\text{OH}$  part of the condensation product to give a compound

which is analogous to  $\beta$ -carbanilino- $\beta$ -phenylhydroxylamine,  $\text{NHPh}\cdot\text{CO}\cdot\text{N}(\text{OH})\text{Ph}$ , produced by the interaction of phenylcarbimide and  $\beta$ -phenylhydroxylamine (Beckmann, *J. pr. Chem.*, 1897, 56, 71).

It follows also that there is present in the condensation product no other group capable of reacting with phenylcarbimide.

Evidence for the view that the condensation products of  $\beta$ -phenylhydroxylamine with acetone and with benzaldehyde differ in structure is the fact that the latter product is unaffected by cold concentrated hydrochloric acid or 65% sulphuric acid, reagents which hydrolyse the acetone compound with the greatest readiness.

One of the very few recorded cases of organic compounds which contain quadrivalent nitrogen is diphenylnitric oxide, which Wieland and Offenbächer (*Ber.*, 1914, 47, 2111) obtained by the oxidation of  $\beta\beta$ -diphenylhydroxylamine with silver oxide:

Diphenylnitric oxide is described as an intensely red substance which decomposes on keeping; liberates iodine from an acidified solution of potassium iodide; is reduced by phenylhydrazine to the original  $\beta\beta$ -diphenylhydroxylamine and by stronger reducing agents to diphenylamine; and is converted by the action of dilute hydrochloric acid, by simultaneous oxidation and reduction, into diphenylamine and quinoneanil oxide—a change which sometimes occurs spontaneously in ethereal solution (Wieland and Roth, *Ber.*, 1920, 53, 215):

There are, therefore, many points of similarity between diphenylnitric oxide and the red compound formed by the oxidation of the

condensation product of  $\beta$ -phenylhydroxylamine and acetone, in which the presence of a quadrivalent nitrogen atom has been suggested.

The formulation of the oxidation of diphenylhydroxylamine to diphenylnitric oxide as in equation (1) is in conflict with the electronic theory. The reaction is, however, of some interest, since the oxygen atom which takes part in the reaction gains two electrons and acquires them from two molecules of the hydroxylamine. Obviously, therefore, each molecule of diphenylhydroxylamine loses one electron, and the product of oxidation has, according to the electronic theory, the formula

and can be contrasted with diphenylhydroxylamine which has "ionised":

The particular type of N—O compound formed by the oxidation of the condensation product of acetone and phenylhydroxylamine belongs, therefore, to the small class of substances whose molecules contain an uneven number of electrons—the so-called "odd electron molecules"—of which nitrogen dioxide is the most typical example; others are nitric oxide, triphenylmethyl, and chlorine dioxide. Lewis states that "odd electronic compounds" with the exception of nitric oxide absorb light in the visible part of the spectrum and are generally intensely coloured. They are very reactive and attach themselves to a great variety of substances; they tend to react in such a manner that one molecule gains an electron while another loses one (simultaneous oxidation and reduction). The red oxidation product thus appears to possess the properties of an odd electron compound, and, indeed, its method of preparation combined with the determination of its molecular weight proves that it is such a substance.

#### EXPERIMENTAL.

*Preparation of the Condensation Product.*— $\beta$ -Phenylhydroxylamine, prepared by Kamm's method ("Organic Syntheses," IV, 57) in 60% yield, was dissolved in rather more than its own weight of dry acetone, and the filtered solution was kept for several days at room temperature; the condensation product then began to

crystallise. Thereafter the mixture was kept, with daily agitation, in the ice-chest for 3 months, until no further separation occurred. The yield of the condensation product varied from 40—68% (calculated on the amount of  $\beta$ -phenylhydroxylamine), the better yields being obtained when carefully dried  $\beta$ -phenylhydroxylamine was used. The condensation product, after being washed with cold acetone, in which it was only slightly soluble, was obtained almost colourless. It crystallised from ethyl alcohol in hard, glassy rhombs, m. p.  $136^{\circ}$  (slight decomp.). In a typical experiment, 5704 g. of  $\beta$ -phenylhydroxylamine dissolved in acetone (6830 c.c.) gave, after several weeks, 3719 g. of the condensation product (yield 49%).

The reaction mixture, when left undisturbed and "unseeded," deposits the condensation product in large, colourless, transparent, glassy rhombs which remain colourless and retain the same melting point ( $136^{\circ}$ ) for several years. The small crystals obtained by frequent agitation of the solution slowly develop, during several months, a pale yellow colour and a slight odour: this is probably due to their retaining a small quantity of the mother-liquor.

Earlier workers state that this compound melts with decomposition. The amount of decomposition, however, is very small, for a molten sample will resolidify and then melt at a temperature only a few degrees below the original melting point; after one crystallisation from alcohol, it melts at  $136^{\circ}$ .

*The Acetyl Derivative.*—(a) To the deep brownish-orange solution obtained by shaking the finely powdered condensation product (10 g.) with pure acetic anhydride (10 c.c.) below  $35^{\circ}$ , ice is gradually added; the whole then sets to a crystalline mass. The washed and dried product (12 g.) melts at  $95$ — $97^{\circ}$ .

(b) To a solution of the condensation product (45 g.) in pyridine (60 c.c.) acetic anhydride is added (23 c.c.) at such a rate that the temperature does not rise above  $45^{\circ}$ . After a few minutes, crushed ice is added, and the crude acetyl derivative washed and dried as before (yield, about 54 g.).

The *acetyl* derivative separates from ethyl acetate, acetone, or aqueous alcohol in radiating clusters of prismatic needles, m. p.  $99$ — $101^{\circ}$ . When it is added to warm benzene a cloudy solution is produced which becomes clear on the addition of calcium chloride. This solution, when diluted with warm light petroleum, deposits stout needles. These melt at  $105$ — $106^{\circ}$  (without decomp.), but at about  $140^{\circ}$  vigorous decomposition sets in and tarry products are formed (Found in material crystallised from alcohol: C, 66.95; H, 7.2; N, 7.7;  $\text{CH}_3\cdot\text{CO}$ , 12.6.  $\text{C}_{20}\text{H}_{24}\text{O}_3\text{N}_2\cdot\text{H}_2\text{O}$  requires C, 67.0; H, 7.3; N, 7.8;  $\text{CH}_3\cdot\text{CO}$ , 12.0%. Found in material crystallised

from benzene: C, 71.0; H, 7.1; *M*, cryoscopic in benzene, 310.  $C_{20}H_{24}O_3N_2$  requires C, 70.6; H, 7.1%; *M*, 340).

The acetyl derivative was recovered unchanged after 1 g. had been heated with acetic anhydride (3 c.c.) at 100° for 10 minutes.

*The Benzoyl Derivative.*—(a) A solution of the condensation product (12 g.) and benzoyl chloride (6 g.) in pyridine (50 c.c.) is, after several hours, mixed with crushed ice. The washed and dried crystalline product, m. p. 90–95°, is obtained in almost quantitative yield.

(b) A suspension of the potassium derivative of the condensation product (see below) in pure dry ether is shaken with benzoic anhydride (1 mol.) for 15 minutes, the gelatinous precipitate of potassium benzoate filtered off and washed with dry ether, and the filtrate concentrated; the benzoyl derivative is thus obtained as an orange oil which solidifies completely on inoculation.

The *benzoyl* derivative crystallises from aqueous alcohol in rosettes of glistening, prismatic needles, m. p. 96–98°, containing  $1H_2O$  (Found: C, 71.0; H, 6.9; N, 6.6.  $C_{25}H_{26}O_3N_2 \cdot H_2O$  requires C, 71.4; H, 6.7; N, 6.7%) and from benzene or light petroleum in anhydrous, prismatic needles, m. p. 98–99° (Found: C, 74.6; H, 6.4.  $C_{25}H_{26}O_3N_2$  requires C, 74.6; H, 6.4%).

*Hydrolysis.* To a solution of the benzoyl derivative (1.1 g.) in warm alcohol (10 c.c.), sodium hydroxide (0.2 g.) was added, followed, after 10 minutes, by water. The crystalline product, m. p. 135–136°, weighed 0.62 g. (calc., 0.78 g.) and from the concentrated acidified filtrate 0.25 g. of benzoic acid was obtained (calc., 0.32 g.).

The *potassium* derivative is prepared by adding a benzene solution of the condensation product to rather less than one atomic proportion of finely powdered potassium. The latter dissolves, hydrogen is evolved, the liquid darkens, and a white gelatinous precipitate forms. This is filtered off, washed quickly with dry benzene several times, and dried in a vacuum (Found: K, 11.7, 11.8.  $C_{18}H_{21}O_2N_2K$  requires K, 11.3%). When left for several days in a dry atmosphere, the substance (1.1 g.) develops an orange colour and, on treatment with water, gives an orange powder, m. p. about 90°. After crystallisation from alcohol, this powder is obtained in fine red needles (1.0 g.); these, alone or mixed with an authentic specimen of the red oxidation product, melt at 89–90°.

By passing hydrogen chloride into a dry ethereal solution of the condensation product, its *monohydrochloride* is obtained as a white solid which, after being washed with ether and dried in a vacuum, melts at 62–64° and at 80° undergoes vigorous decomposition

(Found: HCl, 11.1.  $C_{18}H_{22}O_2N_2 \cdot HCl$  requires HCl, 10.9%). The solid is stable in a vacuum for some hours, but on exposure to air turns black. It is decomposed by water with regeneration of the original condensation product in an almost pure condition.

*Formation of  $\beta$ -p-Chloroanilino- $\beta$ -methylpentan-8-one from the Condensation Product.*—The freshly recrystallised and finely powdered condensation product (50 g.) is shaken for 2 hours with *N*-hydrochloric acid (400 c.c.). The pale yellow solution is filtered from undissolved material (4–8 g.) and extracted three times with ether to remove azoxybenzene, mesityl oxide and a small quantity of  $\beta$ -phenylhydroxylamine. The acid solution is rendered alkaline and the precipitated bases (35–40 g.), after extraction and drying, are distilled under 15 mm. pressure. Two main fractions are obtained, (i) up to  $150^\circ$ , (ii)  $150$ – $180^\circ$ . The first contains water (if the receiver has been cooled in ice), mesityl oxide, *p*-chloroaniline, and a proportion of the higher-boiling base. The second fraction, which weighs about three times as much as the first and contains the *chloro-base*, is dissolved in ether and the solution is washed with successive small quantities of dilute hydrochloric acid; thereafter a mixture (4.8 g.) of azobenzene and azoxybenzene (1:4) is obtained from it. The hydrochloric acid solution is rendered alkaline, the precipitated *chloro-base* (20 g.) is extracted with ether and twice redistilled, and a fraction collected at  $169$ – $172^\circ/11$  mm. or at  $133$ – $136^\circ$  under the pressure attained with a mercury vapour pump. It is a golden-yellow liquid which shows no tendency to solidify (Found: C, 63.5; H, 7.3; N, 6.3; Cl, 15.7.  $C_{12}H_{16}ONCl$  requires C, 63.8; H, 7.1; N, 6.2; Cl, 15.7%). The *nitrosoamine*, obtained by means of sodium nitrite and ice-cold, dilute hydrochloric acid, crystallises from ether-petrol in rosettes of pale yellow needles, m. p.  $75$ – $76^\circ$  after softening at  $70^\circ$  (Found: N, 11.2.  $C_{12}H_{15}O_2N_2Cl$  requires N, 11.0%).

The *chloro-base* readily yields a *semicarbazone*, which crystallises from alcohol in microscopic, flat prisms, m. p.  $125^\circ$  (Found: N, 20.2.  $C_{13}H_{19}ON_4Cl$  requires N, 19.8%).

*Action of Sodium and Alcohol on the Chloro-base.*—To a solution of the base (5 g.) in warm alcohol, sodium (3 g.) is added in small pieces; a precipitate of sodium chloride forms. By working up the product in the usual way, there is obtained a non-basic fraction (1.7 g.), b. p.  $128$ – $133^\circ$ , with a camphoraceous odour; this, after treatment with semicarbazide to remove a little unreduced mesityl oxide as its semicarbazide semicarbazone (m. p.  $220^\circ$ ), distils at  $130$ – $134^\circ$  and reacts with *p*-nitrobenzoyl chloride in pyridine solution to give a crystalline *p*-nitrobenzoic ester which melts at  $24$ – $26^\circ$  either alone or when mixed with methylisobutylcarbinyl

*p*-nitrobenzoate. The basic portion of the product consists of unchanged chloro-base (0.5 g.), *p*-chloroaniline (1.0 g.), and aniline (0.9 g.). The chlorine present as sodium chloride in the aqueous portion, estimated volumetrically, is 0.36 g., corresponding to 0.93 g. of aniline. The substance therefore contains one aniline residue for each atom of chlorine present in the molecule.

*Decomposition of  $\beta$ -p-Chloroanilino- $\beta$ -methylpentan- $\delta$ -one by Acetic Anhydride.*—The chloro-base (1.5 g.) is warmed for 15 minutes with an equal weight of acetic anhydride, and the cooled reaction mixture diluted with water (60 c.c.). The crystalline solid, after being washed and dried (0.96 g.), melts at 172–174°, alone or mixed with *p*-chloroacetanilide (Found: N, 8.2. Calc.: N, 8.1%). The filtrate contains a few globules of mesityl oxide (b. p. 126–130°).

*Synthesis of  $\beta$ -p-Chloroanilino- $\beta$ -methylpentan- $\delta$ -one.*—(a) A solution of  $\beta$ -phenylhydroxylamine (168 g.) and mesityl oxide (148 g.) in just sufficient dry ether is kept for a month and then shaken for 3 hours with *N*-hydrochloric acid (400 c.c.). The acid layer is separated, extracted three times with ether, and rendered alkaline with sodium hydroxide, and the precipitated base is extracted, dried, and distilled; the principal fraction, b. p. 160–175°/15 mm., gives, after four distillations, a fraction (40 g.), b. p. 172–175°/13 mm. (Found: N, 6.3; Cl, 15.7. Calc. for  $C_{12}H_{16}ONCl$ : N, 6.2; Cl, 15.7%). During distillation the base undergoes slight decomposition into mesityl oxide and *p*-chloroaniline.

The semicarbazone, prepared in the usual manner, crystallises from alcohol in microscopic, flat prisms, m. p. 124–125°.

(b) The gelatinous sodium derivative of  $\beta$ -phenylhydroxylamine obtained from sodium (1 equiv.) and phenylhydroxylamine (20 g.) in dry ethereal solution dissolves on addition of mesityl oxide (1 mol.), heat is developed, and a precipitate slowly separates. After 10 days, this is filtered off, quickly washed with dry ether, and dried (wt. 10 g.) (Found: Na, 11.5.  $C_{12}H_{16}O_2NNa$  requires Na, 10.0%). The compound evidently contains unchanged sodium derivative of  $\beta$ -phenylhydroxylamine (Na, 17.6%). It is very hygroscopic and decomposes on standing. It is decomposed by water, and the liberated compound is converted by cold dilute hydrochloric acid into  $\beta$ -*p*-chloroanilino- $\beta$ -methylpentan- $\delta$ -one. This synthetic chloro-base yields a semicarbazone which melts at 125° either alone or when mixed with the semicarbazone of the chloro-base obtained by the action of dilute hydrochloric acid on the original condensation compound. Acetic anhydride decomposes it into mesityl oxide and *p*-chloroacetanilide.

*Behaviour of the Condensation Product.*—(a) Towards hot hydro-

*chloric acid.* A current of steam is passed into a mixture of the condensation product (100 g.) and concentrated hydrochloric acid (100 c.c.); rapid decomposition takes place and mesityl oxide (20.5 g.) distils with the steam. From the non-volatile product, *p*-chloroaniline (33 g.), azoxybenzene (16 g.), and a non-basic material of high boiling point (2 g.) are obtained.

(b) *Towards steam.* A rapid current of steam is passed over the finely powdered compound (20 g.). An oil distils with the first 6 l. of water, leaving a black tar (5 g.). The oil sets, on cooling, to a crystalline mass of azoxybenzene (9.7 g.). Extraction of the aqueous distillate yields mesityl oxide (2.5 g.).

(c) *Towards an alcoholic solution of zinc chloride.* Zinc chloride (50 g.), the condensation product (50 g.), and ethyl alcohol (250 c.c.) are heated together under reflux for 30 minutes. After cooling, the crystalline material is filtered off and recrystallised from alcohol, glistening leaflets (9.2 g.), m. p. 237–239°, of *p*-phenetidine zincchloride being obtained [Found: Zn, 15.6; Cl, 17.4; C, 46.3; H, 5.7.  $(\text{EtO} \cdot \text{C}_6\text{H}_4 \cdot \text{NH}_2)_2 \cdot \text{ZnCl}_2$  requires Zn, 15.8; Cl, 17.2; C, 46.6; H, 5.3%]. From the mother-liquor, aniline (2 g.), *p*-chloroaniline (10 g.), azoxybenzene\* (11.5 g.), and mesityl oxide (3 g.) are isolated. Much of the last substance is undoubtedly lost owing to its low boiling point (40°) at the pressure employed.

The zincichloride yields phenacetin when it is heated with acetic anhydride, and *p*-phenetidine hydrochloride, m. p. 236–237°, when heated with hydrochloric acid.

*Preparation of the Red Oxidation Compound.*—A mixture of the finely powdered condensation product (59.6 g.), light petroleum, b. p. 40–60° (1500 c.c.), and an ammoniacal solution of silver oxide (from 36 g. of silver nitrate) is mechanically shaken for 48 hours; oxidation commences almost at once, the petroleum solution turning bright red and metallic silver being deposited. The petroleum layer is separated from the filtered liquid, washed with water, dried, and evaporated slowly in a bath of warm water (to avoid overheating), until crystallisation sets in. The solid on the filter is washed with water until free from ammonia, air-dried, and repeatedly extracted with dry ether; the extracts are evaporated to small bulk and diluted with light petroleum until crystallisation sets in. About one-third of the oxidation product is contained in the original petroleum solution, the remainder having crystallised

\* It is stated in the literature (Meyer and Jacobson, "Organische Chemie," II, 251; Beilstein, "Organische Chemie," IV, 1335) that azoxybenzene decomposes on heating. We have found that it distils quite readily at 191°/12 mm. with only slight decomposition. The pale yellow distillate sets completely to a mass of long, hair-like needles, m. p. 35°.

and become mixed with the metallic silver. The yield is 58.4 g. (98% of the theoretical).

This substance crystallises from petroleum in compact, hemispherical clusters of bright red, glistening prisms which melt and decompose at 88–90°, producing a black liquid which does not resolidify [Found: C, 72.7; H, 7.15; N, 9.4; *M*, cryoscopic in benzene, 276 (mean of four values).  $C_{18}H_{21}O_2N_2$  requires C, 72.7; H, 7.1; N, 9.4%; *M*, 297].

Determinations of the molecular weight of the oxidised compound in acetone by the ebullioscopic method gave values ranging from 285 to 325, but little reliance can be placed upon these, as some decomposition occurred in the hot solution. After evaporation of the acetone, the residue had a strong odour of nitrosobenzene and contained crystals of the original unoxidised condensation product of m. p. 135–136°.

*Reactions of the Red Oxidation Compound.*—(a) *Reduction.* The compound in ethereal solution is quantitatively reduced to the original condensation product by (a) zinc dust and dilute caustic soda solution, (b) aluminium amalgam, (c) phenylhydrazine. The product melts at 133–136° and 136° before and after crystallisation, respectively.

By the action of potassium iodide and dilute acetic acid on an ethereal solution of the oxidation compound the original condensation product is obtained in 77% yield, the remaining material being a dark, thick oil from which nothing crystalline can be isolated.

(b) *Action of heat.* A rapid current of steam is passed over the oxidation compound (10 g.). Fusion and decomposition take place at once and nitrosobenzene (1.2 g.) passes over with the steam. From the non-volatile portion there are isolated the original condensation product (2.2 g.), azoxybenzene (2 g.), and tar. A similar decomposition is brought about at lower temperatures when a solution of the oxidation compound in acetone is heated under reflux for several hours; the original condensation product is obtained in a yield of about 50%.

(c) *Action of acylating agents.* (i) A mixture of acetic anhydride (8 c.c.) and the finely powdered oxidation compound (6 g.) is maintained at 35° for several minutes, until solution is complete. After 30 minutes, crushed ice is added to the brownish-red solution and the precipitated paste is macerated with cold water until a sandy powder (3.8 g.) with the odour of nitrosobenzene is obtained. This crystallises in colourless needles, m. p. 105–106° (from dry benzene) or 99–100° (from aqueous alcohol). Yield 50%. Analysis and mixed melting-point determinations prove that it is the acetyl

derivative of the original condensation product of m. p.  $136^{\circ}$ ; and it yields this on hydrolysis. A 50% yield of the same acetyl derivative is obtained by the action of acetyl chloride on a solution of the oxidation compound in pyridine.

In marked contrast to the behaviour of the original condensation product, which in pyridine solution readily gives an acetyl derivative in quantitative yield by the action of acetic anhydride, the oxidation compound is unacted upon under similar conditions at the ordinary or at a slightly raised temperature. At higher temperatures, profound decomposition sets in and unworkable tars are produced. This result clearly indicates that some prior reaction is necessary before acetylation can take place.

In a similar manner, by the action of benzoyl chloride (3 g.) on a pyridine (40 c.c.) solution of the oxidation compound (6 g.), there is obtained the benzoyl derivative of the original condensation product in 50% yield; m. p. and "mixed" m. p.  $97-99^{\circ}$ .

(d) *Action of hydrogen chloride.* Dry hydrogen chloride is rapidly absorbed by a dry ethereal solution of the oxidation compound, and an orange precipitate separates; the solution becomes colourless, but slowly turns green. If the passage of hydrogen chloride is still continued, nitrosobenzene and mesityl oxide can be isolated from the solution; but if the current is stopped when the solution becomes colourless, and the orange precipitate rapidly filtered off, washed with dry ether, and dried in a vacuum desiccator, it has the empirical formula  $C_{18}H_{21}O_2N_2 \cdot 2HCl$ . This substance is not identical with the monohydrochloride of the original condensation product (*vide* p. 1622), but it yields this product in nearly 50% yield on treatment with water.

*Action of Phenylcarbimide on the Condensation Product.*—A solution of the condensation product (9 g.) and phenylcarbimide (3.3 g.; 1 mol.) in dry ether is gently warmed for 3 hours and the ether is then evaporated. The residue of colourless, cubic crystals, coated with red oil, is washed with small quantities of cold light petroleum and recrystallised from acetone, transparent, colourless cubes, m. p.  $128-129^{\circ}$  (decomp.), being thus obtained (Found: C, 71.8; H, 7.0; N, 9.7.  $C_{25}H_{27}O_3N_3$  requires C, 71.8; H, 6.5; N, 10.0%). This substance is almost insoluble in cold alcohol and decomposes slightly in hot alcohol. A mixture of it with the original condensation product (m. p.  $136^{\circ}$ ) melts at  $104-109^{\circ}$ .

*Preparation of the Liquid Reduction Product.*—To a solution of the condensation compound (60 g.) in boiling absolute ethyl alcohol (500 c.c.), sodium (23 g.) is added sufficiently quickly to keep the liquid boiling. When all the sodium has dissolved, water is added to the dark red reaction mixture and the solution is

extracted several times with ether. The ethereal solution is washed with water, extracted with dilute hydrochloric acid, and evaporated to dryness; the residue is pure azobenzene. The basic material in the acid extract is recovered and repeatedly fractionally distilled under diminished pressure, being thus separated into aniline and the new *base* (15 g.), a golden-yellow, somewhat viscous liquid, b. p.  $130-133^{\circ}/2-4$  mm. or  $160-163^{\circ}/15$  mm.,  $d_4^{25}$  1.0043 (Found: C, 74.8; H, 9.6; N, 7.3.  $C_{12}H_{10}ON$  requires C, 74.6; H, 9.8; N, 7.25%).

Modifications of the method of reduction were tried with the object of preventing the formation of azobenzene. These included the gradual addition of sufficient acetic acid to neutralise the sodium ethoxide as it was produced—this procedure, however, caused the production of phenylcarbylamine, which was very difficult to remove on distillation. The presence of water—even 1%—in the alcohol diminishes the amount of base produced and increases the proportion of azobenzene formed even to the exclusion of the base when the quantity of water is considerable. When the absolute alcohol is replaced by amyl alcohol, no base is formed, an almost quantitative yield of azobenzene \* being obtained together with a trace of aniline.

By doubling the amount of sodium used in the reduction, there was produced, in addition to the liquid base, hydrazobenzene (5 g.), which was isolated from the acid extract in the form of benzidine.

The pure base readily yields a *diacetyl* derivative, which crystallises from acetone in clusters of prismatic needles, m. p.  $104-106^{\circ}$  (Found: N, 4.9;  $2CH_3\cdot CO$ , 31.8;  $1CH_3\cdot CO$ , 19.0.  $C_{16}H_{23}O_3N$  requires N, 5.05;  $2CH_3\cdot CO$ , 31.1;  $1CH_3\cdot CO$ , 15.5%). When the hydrolysis is effected by aqueous potassium hydroxide, a value for the acetyl content of 19% is quickly obtained; this value increases at only a slow rate as the heating is continued—the maximum value of 31.1% was only obtained by heating with *alcoholic* potassium hydroxide during 24 hours. It is evident, therefore, that one acetyl group is much more firmly attached than the other.

The *chloroplatinate* of the base is obtained by the addition of chloroplatinic acid (1 mol.) in alcoholic solution. The precipitate crystallises from methyl alcohol containing a small amount of hydrochloric acid in clusters of orange prisms which, after drying at  $110^{\circ}$  for 4 hours, melt and decompose at  $197-198^{\circ}$  [Found: Pt, 24.9, 24.6.  $(C_{12}H_{10}ON)_2\cdot H_2PtCl_6$  requires Pt, 24.5%].

The *nitrosoamine*, prepared by the addition of sodium nitrite to

\* It is somewhat remarkable that azobenzene is reduced by sodium and boiling ethyl alcohol only with great difficulty.

a solution of the base in cold hydrochloric acid, crystallises from ether in fine, pale yellow needles, m. p. 44–48° (Found: N, 12.8.  $C_{12}H_{18}O_2N_2$  requires N, 12.6%).

One of the authors (F. H. B.) is indebted to the Advisory Council of the Department of Scientific and Industrial Research for a grant which enabled this work to be carried out. The authors wish to thank Mr. P. S. Arup, M.Sc., for assistance in the early stages of the investigation.

## CCXII.—*The Classification of the Sugars.*

By JOHN GWILLIAM MALTBY.

THE original classification of the normal forms of the sugars and their derivatives into the *d*- and *l*-series was that of Fischer (*Ber.*, 1894, 27, 3208) and depended on their chemical relationship to naturally occurring (*d*-)glucose. The classification usually adopted to-day is that of Rosanoff (*J. Amer. Chem. Soc.*, 1906, 28, 114) in which the configuration of the asymmetric group furthest removed from the aldehydic group is the deciding factor. A classification depending on the mean of the rotations of the  $\alpha$ - and  $\beta$ -forms was put forward in an earlier paper (*J.*, 1922, 121, 2608).

Most sugars and their derivatives are obtainable in  $\alpha$ - and  $\beta$ -forms, and the usually accepted distinctions between them are those given by the action of enzymes, the mode of preparation and the rate of hydrolysis of the glucosides. A different distinction has been given by Hudson (*J. Amer. Chem. Soc.*, 1909, 31, 66) based on their rotations and on Fischer's classification into the *d*- and *l*-series. According to this, the  $\alpha$ -form of a *d*-sugar has a more positive rotation than the  $\beta$ -form. In the case of arabinose, however, the two methods of distinction do not agree (Hudson, *J. Amer. Chem. Soc.*, 1924, 46, 2591), the same being the case if Rosanoff's classification is used. It seems possible that the cause of the discrepancy lies in the classification into the *d*- and *l*-series being wrong.

It is suggested that, for the normal forms of the aldoses, the configuration of the middle group of the oxide ring (group 3) is the deciding factor in the classification into the *d*- and *l*-series. Naturally occurring arabinose therefore now belongs to the *d*- instead of to the *l*-series, and the  $\alpha$ -forms of the *d*-sugars have more positive rotations than the  $\beta$ -forms for all known cases, as shown in the table below. In an earlier paper (*J.*, 1923, 123, 1404), it was suggested from a consideration of the rotations of the sugars,

that, in the  $\alpha$ -form of the aldoses, groups 1 and 3 have opposite configurations. It was also shown that the configuration of group 3 determines the relative proportions of the two products formed by the cyanohydrin synthesis. This follows, since the configuration of group 2 in the main product is always the opposite of that of group 4, the latter being group 3 in the original sugar. This is also shown in the table below, in which the configurations are represented by + and - signs as suggested by Fischer (*Ber.*, 1894, 27, 3189) and the *d*-sugars have been taken as those with a positive sign for group 3.

KENMARE, DERBY PARK,  
ROCK FERRY.

[Received, April 24th, 1926.]

### CCXIII.—The Unsaponifiable Matter from the Oils of *Elasmobranch Fish*. Part I. A Contribution to the Study of the Constitution of Squalene (Spinacene).

By ISIDOR MORRIS HEILBRON, EDWARD DAVID KAMM, and  
WILLIAM MORGAN OWENS.

THE first mention of the occurrence of squalene in fish-liver oils is due to Tsujimoto (*J. Chem. Ind. Tokio*, 1906, 9, 953), who subsequently described its physical characteristics and assigned to it the molecular formula  $C_{30}H_{50}$  (*J. Ind. Eng. Chem.*, 1916, 8, 889; 1920, 12, 63). The hydrocarbon was found to yield a well-defined crystalline hexahydrochloride, but of indefinite melting point, sintering at about 112° and finally melting to a clear liquid at about 125°. Meanwhile, in 1915, A. Chaston Chapman, working independently, isolated from fish-liver oils obtained from Portugal what would appear to be the same hydrocarbon, for which he proposed the name spinacene, and assigned to it the same molecular formula (*J.*, 1917, 111, 56). Later (*J.*, 1918, 113, 458), from the

results of other analyses of the hexahydrochloride and hexahydrobromide and of molecular-weight determinations, he concluded that its constitution was in better accord with the formula  $C_{29}H_{48}$ . This author also remarked on the indefinite nature of the melting point of the hydrochloride. He found that whereas the crude compound commenced to shrink at  $100^\circ$  and began to melt at  $110^\circ$  (Cl, 33.8%),\* after purification by means of benzene and alcohol, the final preparation became pasty at  $120^\circ$  and melted to a clear liquid at  $126^\circ$  (Cl, 34.5%). In a recent communication by André and Canal (*Compt. rend.*, 1925, 181, 612), an account is given of the hydrochlorides prepared from the unsaponifiable matter of the oils of *Cetorhinus maximus* (A) and *Scymnorhinus lichia* (B). Whilst the oils from both fish had previously been examined by Tsujimoto and found to contain squalene, that from the latter has been used by us and was also almost certainly employed by Chapman (*Analyst*, May, 1917). From A, André and Canal separated two hydrochlorides:  $A_1$ , m. p.  $107-108^\circ$  (Cl, 35.3%, corresponding with a hydrocarbon  $C_{28}H_{46}$ ); and  $A_2$ , m. p.  $144-145^\circ$  (Cl, 33.9%, indicating  $C_{30}H_{50}$ ). On the other hand, they obtained from B the hydrochlorides  $B_1$ , m. p.  $107-108^\circ$  (Cl, 33.9%), and  $B_2$ , m. p.  $143-145^\circ$  (Cl, 33.2%), the latter chlorine content corresponding to the hydrocarbon  $C_{31}H_{52}$ . A mixture of  $A_1$  and  $B_1$  is stated to show no depression of melting point, whilst  $A_2$  and  $B_2$  give a slight depression ( $139-140^\circ$ ). From these highly conflicting results, the authors claim that neither squalene nor spinacene is a definite chemical compound, but each is a mixture of various unsaturated hydrocarbons from which the  $C_{29}H_{48}$  homologue proposed by Chapman is apparently absent. We agree with André and Canal in so far that we have separated hydrochlorides of different melting points, but find for each the same values for carbon, hydrogen, and chlorine in strict agreement with a hydrocarbon formula  $C_{30}H_{50}$ .† It would appear that three isomeric hydrochlorides, m. p.  $107-108^\circ$ ,  $113-114^\circ$ , and  $144-145^\circ$ , exist, although it is somewhat doubtful whether the lowest-melting one is a pure compound (see experimental part). The hydrocarbon has been regenerated from each hydrochloride and reconverted into its hydrochloride, which, in every case, is again separable into low- and high-melting fractions.

	C %.	H %.	Cl %.
* $C_{28}H_{46}Cl_6$	55.9	8.7	35.4
$C_{29}H_{48}Cl_6$	56.7	8.8	34.6

\* Calculated for  $C_{30}H_{50}$ .

These results lead to the conclusion, which is also borne out by other evidence, that squalene and spinacene are one and the same hydrocarbon of the molecular formula  $C_{30}H_{50}$ . Taking into account the number of species of fish from which squalene has been isolated, we are of the opinion that no evidence has been adduced in favour of André and Canal's view (*loc. cit.*) that homologues of this hydrocarbon exist in marine animal oils. On the other hand, the isolation of the isomeric hydrochlorides would appear to indicate that squalene is itself a mixture of isomerides. In support of this view, it has repeatedly been found that the density and refractive index are not absolutely constant, although the calculated molecular refraction is almost exactly the same for different specimens. This value shows a marked exaltation ( $\Sigma[R_L]_D = 1.8-2.3$ ) over the theoretical value for  $C_{30}H_{50}$ . This exaltation is not due, however, to the presence, as André and Canal claim, of a  $C_{31}H_{52}$  homologue in squalene, for the hydrocarbon regenerated from the hexahydrochloride melting at 107—108°, which, according to these authors, corresponds to  $C_{30}H_{50}$  in the case of *Scymnorhinus lichia*, also shows exactly the same exaltation. The exaltation is apparently not due to the presence of conjugated double bonds, since we, confirming Majima and Kubota (*Jap. J. Chem.*, 1922, 1, 9), have found that squalene is inert towards sodium and boiling amyl alcohol.

#### Sources of Squalene.

Squalene is widely distributed among elasmobranchs. It occurs chiefly in the family *Squalidae*, but is not found in every member of it. Moreover, it is not peculiar to elasmobranchs, for Drummond, Channon, and Coward (*Biochem. J.*, 1925, 19, 1047) have

reported its presence in the unsaponifiable matter of cod-liver oil. The hydrocarbon, although occurring chiefly in the liver oil, has also been found in the egg oils of *Chlamedoselachus anguineus* and *Lepidorhinus kinbei* by Tsujimoto (*loc. cit.*), and of *Etmopterus spinax*, *L. squamosus*, and *Scymnorhinus lichia* by us. Moreover, the intestines of the last-mentioned fish always contain a large amount (up to 300 c.c.) of a dark oil, the greater part of which is squalene. This may be produced *post-mortem*—the specimens when treated have always been dead for several days—but the fact that it is invariably present seems to us to favour the view that it is a characteristic of the living animal. An examination was made in May, 1925, of 115 female *E. spinax*. From some of these, eggs in a comparatively undeveloped condition were dissected, all of which contained squalene. In others, almost completely developed embryo with yolk-sac were found. The sac did not contain the hydrocarbon, which must therefore have been absorbed during the growth of the embryo. A noteworthy fact regarding squalene-containing fish is the remarkable health of their bodies, in which internal parasites are very rare (private communication from Professor Johnstone).

#### *Decomposition of Squalene by Heat.*

This has been studied by Chapman (J., 1923, 123, 769) and Majima and Kubota (*loc. cit.*). The latter investigators subjected squalene to dry distillation and obtained fractions boiling at all temperatures from 36°/760 mm. to 235°/18 mm. They claim to have identified isoprene; the constants recorded, however, are very low ( $D_D^{18}$  0.6692,  $n_D^{18}$  1.39641; compare Harries, *Ber.*, 1914, 47, 1999). From the most abundant higher fraction, a liquid,  $C_{10}H_{18}$  (b. p. 62.5–66°/17 mm.), was obtained the physical constants of which resemble those of *cyclodihydromyrcene* or *cyclodihydrolinolo-olene*. Chapman's methods of decomposition were somewhat different, but gave apparently similar products. He concludes that the low-boiling fraction is a mixture of one or more amylenes with some isoprene or isomeric substance, whilst the main products are considered to be 1-methyl-4-propylenecyclohexane (I) and the closely related diolefinic hydrocarbon (II).

By the dry distillation of squalene and careful fractionation of the product, we obtained members not only of the hemiterpene and monoterpene groups, but also of the sesquiterpene, diterpene, and probably even higher divisions of the same family.

The lowest-boiling liquid member obtained by us has been

definitely proved to be an amylene, oxidation of which by potassium permanganate yielded acetone, from which it follows that its structure must be  $\text{CMe}_2\text{:CHMe}$  (III).

The fraction of next higher boiling point ( $62\text{--}100^\circ/20\text{ mm.}$ ), which appears to be a mixture of monoterpenes and dihydromonoterpenes, is under investigation.

The third fraction, boiling between  $120^\circ$  and  $170^\circ/20\text{ mm.}$ , consists of a complex mixture of monocyclic sesquiterpenes. By repeated distillation a constant-boiling fraction has been isolated the physical characteristics of which (Table II) are identical with those of bisabolene (Ruzicka, *Helv. Chim. Acta*, 1925, 8, 259). In addition, ring closure by means of formic acid has yielded a dicyclic isomeride the constants of which agree closely with those of the dicyclic sesquiterpenes isolated by Ruzicka from nerolidol and which, according to this author, could only have resulted through the intermediate formation of farnesene and bisabolene (Table II).

TABLE II.

	B. p./12 mm.	$d_{20}^{25}$ .	$d_4^{25}$ .	$n_D^{25}$ .	$[R_L]_D$ .
Hydrocarbon from squalene ...	129—135°	0.8734	0.8716	1.4915	67.72
Synthetic bisabolene .....	130—137	—	0.8717	1.4923	67.99
				(Calc., 67.87)	

In an attempt to obtain further evidence regarding the carbon skeleton of the entire sesquiterpene fraction, this was dehydrogenated with sulphur (compare Ruzicka, *Helv. Chim. Acta*, 1922, 5, 345), and the product distilled over sodium. In three different experiments, addition of alcoholic picric acid produced, in insufficient quantity for analysis, orange crystals of what appeared from the melting point to be cadalene picrate. The difficulty of obtaining cadalene in appreciable quantity is not peculiar to the sesquiterpene mixture handled by us, for Staudinger (*Helv. Chim. Acta*, 1922, 5, 785) failed to isolate any trace of this hydrocarbon on dehydrogenation of the sesquiterpene fraction from caoutchouc, which should most certainly have yielded it. Moreover, Ruzicka was unable to obtain cadalene from the compound (IV) (*Helv. Chim. Acta*, 1923, 6, 487), whereas it was readily obtained from cadinene (V), which is similarly constituted.

From the complex mixture of higher-boiling fractions dicyclic terpenes have been isolated, and these, on treatment with formic acid, pass into tricyclic isomerides, a reaction reminiscent of the

conversion of the monocyclic  $\alpha$ -camphorene into its tricyclic isomeride (Ruzicka, *Helv. Chim. Acta*, 1924, 7, 279). The residue, which probably consists of members of the next higher group ( $C_{25}H_{40}$ ), has not yet been examined.

### *Isomerisation of Squalene.*

In addition to the isomerism due to variation in position of one or more of the ethenoid linkings, there exists, as might have been anticipated, isomerism due to ring formation. Majima and Kubota (*loc. cit.*) were the first to prove that squalene can be so isomerised, but it is apparent from their results that they failed to obtain a pure isomeride. As shown in Table III, 95% formic acid is the best catalyst for effecting ring closure in the squalene molecule, which, we have found, cannot be cyclised beyond the stage at which two double bonds remain (Table III).

TABLE III.  
Molecular Refractions of Squalene Isomerides.

### *Constitution of Squalene.*

At this point we would again emphasise our conviction that squalene and spinacene are identical. In addition to the evidence of the hydrochloride formation, we are led to this conclusion by the following considerations :

(a) The physical properties of spinacene as recorded by Chapman agree closely with those recorded by all other workers in the same field (Table I).

(b) The calculated molecular refraction for  $C_{29}H_{48}|_6^-$  is 133.1, not 134.3 as stated by Chapman (J., 1918, 113, 458). The value of 134.5 determined by him is in no better agreement with this than the value worked out from the same data for  $C_{30}H_{50}|_6^-$  (139.3) is with the theoretical value 137.7.

(c) It does not appear to us that evidence based on cryoscopic measurements can be considered sufficiently trustworthy to distinguish between successive homologues ( $C_{29}H_{48}$ ,  $C_{30}H_{50}$ ) of such high molecular weight.

show that the administration of squalene results in the amount of cholesterol in the liver being more than doubled. This observation may support the view that squalene is a precursor in cholesterol synthesis in the animal body; on the other hand, the large cholesterol increase may be due to some factor yet to be determined. Further biochemical work is in progress to confirm or disprove the hypothesis.

## EXPERIMENTAL.

*Extraction of Oils.*—The fish were dissected immediately on arrival, and the livers removed and weighed. The stomach was in each case ligatured and the contents were examined for the presence of oil. Any eggs in the females were separated and examined. Table V gives the oil content of the various species. The livers were cut into small pieces and the oil was extracted by heating with a coil into which steam was admitted for about  $\frac{1}{2}$  hour. The liberated oil was separated from tissue matter by means of a centrifuge and was obtained as a clear mobile liquid, pale yellow to orange in colour.

*Extraction of the Hydrocarbon from the Liver Oil.*—(a) *Saponification.* Considerable difficulty was experienced in saponifying the oil and separating the unsaponifiable matter. After many experiments, including saponifications in alcohol, it was found that the most satisfactory method was to heat the oil (500 c.c.) in a nickel basin to 105—110° and add drop by drop an equal volume of 20% sodium hydroxide solution with continuous stirring. After saponification was complete (about 1 hour), sodium chloride (150 g.) was added together with 150 c.c. of hot water. The mixture when cool was filtered through cloth, and the oil was separated from the aqueous layer, dried over sodium sulphate, and distilled at 3 mm. pressure. The squalene so obtained had a refractive index of about 1.497 and contained a small quantity of oxygenated substance (compare Chapman, J., 1917, 111, 56).

(b) *Distillation Method*.—This method (compare Tsujimoto, *loc. cit.*) is more rapid than the preceding for the preparation of large quantities of the hydrocarbon. The oil (in portions of not more than 200 g.) was distilled under 3 mm. pressure; no distillate appeared below 235°, the major portion distilling regularly between 240° and 250°. Distillation was stopped as soon as the first signs of fuming were noticed, and an oil, containing as chief impurity a small quantity of free fatty acid, was thus obtained ( $n_D^{20}$  1.497—1.498). It was dissolved in ether, the solution, after being washed several times with dilute sodium hydroxide solution and finally with water, was dried over calcium chloride, the ether removed, and the residual oil distilled. The products ( $n_D^{20}$  1.498) thus obtained from different samples, as in the previous case, contained varying quantities of oxygen (C, 87.4, 87.2; H, 11.9, 12.0%). Pure squalene can, however, be obtained from them (a) through the hydrochloride, (b) by treatment with phthalic anhydride.

The crude hydrocarbon (160 g.) was heated for 5 hours with phthalic anhydride (18 g.) at 130—140°. After cooling and removal of unchanged anhydride, the oil in ethereal solution was shaken successively with dilute sodium carbonate and sodium hydroxide solution and washed with water. The ether was removed from the dried solution, and the residual oil distilled, the whole coming over at 260—262°/9 mm.;  $n_D^{18}$  1.4982,  $n_D^{20}$  1.4965,  $d_4^{25}$  0.8596;  $[R_L]_D$  139.6 (Found: C, 87.7, 87.7; H, 12.1, 12.0.  $C_{30}H_{50}$  requires C, 87.8; H, 12.2%).

The sodium carbonate washings contained no acid phthalate, and it must be concluded that the impurity present in the crude hydrocarbon is either a tertiary alcohol, which would seem to be closely related to the hydrocarbon, or an internal oxide similar in nature to cineole, which compound on treatment with dehydrating agents readily passes into dipentene. This point is being further examined.

Treatment of crude squalene with acetic anhydride and *d*-cam-

phorsulphonic acid also removes the impurity as a lower-boiling liquid of sharp odour. This method, however, cannot be used for the preparation of squalene, because isomerisation also occurs.

*Squalene Hexahydrochloride. General Method of Preparation.*—Dry acetone (15 g.) was saturated with dry hydrogen chloride at  $-5^{\circ}$  and squalene (5 g.) was added, the stream of gas being continued until the whole became solid; the colour of the solution changed through red to almost black. The resulting hydrochloride (6 g.) was washed free from coloured oily impurity with dry ether. By keeping the filtrate, again saturated with hydrogen chloride, in the ice-chest, a further small crop was obtained (approx. 3%). If the acetone is not presaturated with hydrogen chloride, the first crop obtained is very much smaller; the total yield, however, is only slightly diminished, as a large crop separates during the second treatment. This method is much slower and generally less satisfactory than the first. Ether also can be employed as solvent, but cannot be relied upon to give such consistent yields, being apparently sensitive to minute alteration of conditions. Analysis of the washed crude hydrochloride from any of the sources examined by us always gave similar analytical values (e.g., found: C, 57.1, 57.0; H, 9.0, 8.8%). The hydrochloride can be prepared equally readily from squalene-containing oils.

*Separation of the Isomerides. Isolation of the 107—108° Hydrochloride from Squalene obtained from Scymnorhinus lichia.*—The crude hydrochloride (14 g.), m. p. 109—112°, was digested with dry acetone (300 c.c.) for 10 minutes at  $50^{\circ}$ , boiled for one minute, and the residue (2.4 g.) filtered off. The filtrate on standing deposited hydrochloride (9.2 g.) which melted at 107—108° (Found: C, 57.2, 57.2; H, 8.8, 9.1; Cl, 33.6%). The yields of this compound, which was not always produced, varied widely even when the conditions were precisely similar. Although it appeared to be a definite isomeride, nevertheless, on digestion with hot acetone, a small residue (m. p. 111—122°) was invariably obtained.

*Isolation of the High-melting Isomeride.*—The residue (m. p. 126—130°) obtained above was combined with other sparingly soluble fractions which had been worked up in the same way. The total material (6 g.) was boiled with acetone (175 c.c.), which was then filtered quickly. The undissolved solid (2.3 g.), m. p. 140—142°, was again similarly treated with acetone (250 c.c.), and the residue (1.7 g.), now melting at about  $144^{\circ}$ , recrystallised from ethyl acetate. It formed characteristic rhombic plates, m. p. 144—145°, very similar in appearance to the 107—108° isomeride, and was practically insoluble in acetone or alcohol and moderately easily soluble in ethyl acetate (Found: C, 56.9, 56.8; H, 8.9, 8.8; Cl, 33.6, 33.8%). The intermediate portions obtained from the filtrates melted in

definitely between 111° and 120° and were separated into the high-melting hydrochloride and an isomeride, m. p. 113—114°.

The latter compound was readily prepared as follows: The washed crude hydrochloride (36 g.) was recrystallised from ethyl acetate (270 c.c.), and the separated solid (32 g., m. p. 111—120°) digested with boiling ethyl acetate. The insoluble residue (11 g., m. p. 117—130°) was now taken up in hot acetone and separated from 5 g. of undissolved material (m. p. 131—137°) by filtration. From the filtrate, crystals, m. p. 113—114°, were obtained. This compound showed no alteration in melting point on further crystallisation from acetone, in which it is moderately easily soluble, although less so than the 107—108° form (Found: C, 56.8; H, 8.9; Cl, 33.8, 33.9%).

*Regeneration of Squalene from the Hydrochlorides.*—(A) 113—114° *Isomeride*. The hydrochloride (17 g.) was boiled under reflux with pyridine (68 g.) for 4 hours in an atmosphere of carbon dioxide. The reaction mixture was poured into an excess of dilute sulphuric acid, and the hydrocarbon extracted with ether. The ethereal solution was well washed with water, dried, and, after removal of the solvent, the residual oil was distilled at 4 mm. The constant-boiling fraction was again redistilled at the same pressure, and the major portion, boiling at 240—242°, collected separately,  $n_D^{20}$  1.4990,  $d_{20}^{20}$  0.8592,  $[R_L]_D$  140.2,  $[R_L]_D$  calc. for  $C_{30}H_{50}$  137.7 (Found: C, 87.8, 87.5; H, 12.1, 12.2.  $C_{30}H_{50}$  requires C, 87.8; H, 12.2%). The regeneration can also be brought about with alcoholic sodium ethoxide, silver acetate, or quinoline. Even prolonged boiling with absolute alcohol is sufficient to effect complete decomposition of the hydrochloride.

(B) 107—108° *Isomeride*. This was similarly decomposed and the constants of the pure hydrocarbon were determined,  $n_D^{20}$  1.4955,  $d_{20}^{20}$  0.8563,  $[R_L]_D$  139.8 (Found: C, 87.6, 87.7; H, 12.3, 12.3%).

(C) 144—145° *Isomeride*. This proved slightly more difficult to decompose. The constants of the hydrocarbon after distillation over sodium were:  $n_D^{18}$  1.4990,  $d_{18}^{18}$  0.8612,  $[R_L]_D$  139.8 (Found: C, 87.4; H, 12.2%).

*Regeneration of the Hydrochlorides.*—Each of the regenerated hydrocarbons was converted into the hydrochlorides in the usual way and these, on treatment with acetone as previously described, were separated into high- and low-melting components.

*Treatment of the Oily Residues.*—After removal of the major portions of the hydrochloride, the acetone and ethyl acetate mother-liquors invariably yielded, on concentration, successive crops of lower-melting compounds (e.g., 95—96°, 84°, and 69°) and finally a sparingly soluble oil separated. That this consisted of partly decomposed hydrochloride was shown by again saturating it with

hydrogen chloride, when, on standing at  $0^{\circ}$ , the usual mixture of isomerides (m. p.  $110-116^{\circ}$ ) was again produced (Found: C, 57.0, 57.1; H, 8.9, 8.9%).

*Squalene Hexahydrobromide*.—Tsujimoto (*loc. cit.*) gives m. p.  $115-126^{\circ}$  for this compound, whilst Chapman states that, after three crystallisations from benzene, it softens at  $126^{\circ}$  and melts to a clear liquid at about  $132^{\circ}$ . Provided that the two compounds are identical, a similar discrepancy occurs in the analytical values, the results obtained by the former (C, 40.2; H, 6.4; Br, 53.0, 53.5%) being in good accord with  $C_{30}H_{50}$ , whilst Chapman's result (Br, 54.5%) agrees with  $C_{29}H_{48}$ . We have prepared this compound by the usual method (5 g. of squalene) and obtained it by recrystallisation from hot acetone in lustrous plates melting at  $118-120^{\circ}$  to a clear liquid. Although this compound has not been prepared in large quantity, a sufficient examination has been made to show that higher-melting isomerides can be obtained. The m. p. of a specimen that had been kept for 2 months in a desiccator over solid sodium hydroxide fell to  $110-113^{\circ}$ , doubtless owing to partial decomposition (Found: C, 40.1; H, 6.3; Br, 53.5, 53.7.  $C_{30}H_{50}Br_6$  requires C, 40.2; H, 6.3; Br, 53.5%).

*Isomerisation*.—(a) *Acetic anhydride containing sulphuric acid*. Squalene (150 g.) was boiled under reflux for  $2\frac{1}{2}$  hours with acetic anhydride (200 c.c.) containing 2 c.c. of sulphuric acid. The product was poured into water, neutralised with sodium carbonate, and extracted with ether. After removal of solvent from the dried solution, distillation of the residue yielded a pale yellow oil, b. p.  $253-256^{\circ}/4$  mm.,  $n_D^{20}$  1.5080,  $d_4^{20}$  0.8939,  $[R_L]_D$  136.7.

(b) *Alcoholic sulphuric acid*. Squalene (10 g.) was boiled under reflux with 50 c.c. of alcoholic sulphuric acid (15%  $H_2SO_4$ ) for 2 days. The product, after extraction as above, gave on distillation a main fraction, b. p.  $235-240^{\circ}/3$  mm.,  $n_D^{15}$  1.5049,  $d_{15}^{15}$  0.9073,  $[R_L]_D$  134.01.

(c) *Formic acid*. The hydrocarbon was boiled under reflux with twice its weight of formic acid (98%) for various periods. After cooling, the solution was diluted with water and treated as above. The products were:

*Reaction period,  $\frac{1}{2}$  hour*.—Mobile, pale yellow oil, b. p.  $215-225^{\circ}/2$  mm.,  $n_D^{15}$  1.5060,  $d_{15}^{15}$  0.8900,  $[R_L]_D$  136.8.

*Reaction period, 3 hours*.—Rather viscous, pale yellow oil, b. p.  $232-233^{\circ}/3$  mm.,  $n_D^{15}$  1.5150,  $d_{15}^{15}$  0.9207,  $[R_L]_D$  134.3, iodine value 179.9 ( $C_{30}H_{50}|_2$  requires iodine value 185.8,  $[R_L]_D$  132.6).

*Reaction period, 24 hours to 3 days*.—Very viscous, pale yellow oil, b. p.  $230-232^{\circ}/3$  mm.,  $n_D^{15}$  1.5211,  $d_{15}^{15}$  0.9359,  $[R_L]_D$  133.2, iodine value 117.4 ( $C_{30}H_{50}|_2$  requires iodine value 124.6,  $[R_L]_D$  130.9).

It will be seen that the isomerisation occurs in stages. On the assumption, which seems likely from the final results, that the

exaltation of the molecular refraction persists throughout, the product of  $\frac{1}{2}$  hour's treatment contains two rings, that of 3 hours' treatment, three rings, whilst the maximum ring closure (four) is reached after 3 days, when only two double bonds remain. For each ring formed, an increase in density and in viscosity occurs; the final product has the consistency of thick treacle, only pouring with difficulty from a test-tube at room temperature.

*Attempted Reduction of Squalene by Sodium and Amyl Alcohol.*—A mixture containing squalene (5 g.), sodium (10 g.), and amyl alcohol (20 g.) was heated to boiling, and to this, amyl alcohol was added drop by drop until all the sodium had dissolved. After treatment with water, and extraction with ether, the whole was distilled; unchanged squalene was then recovered ( $n_D^{20}$  1.5022,  $d_4^{20}$  0.8655,  $[R_L]_D$  139.85). The reaction was repeated with *n*-octyl alcohol, with the same result.

*Dry Distillation of Squalene.*—Squalene (700 g.) was distilled, in portions of not more than 150 c.c., from a 250 c.c. flask through an air condenser into another distillation flask, which served as a receiver for all high-boiling liquid. The side tube of this receiver was connected to a spiral of glass tube immersed in a freezing mixture of ice and salt, which effectively condensed the low-boiling products of the reaction. The outlet of this spiral was connected to an absorption bottle containing a 10% solution of bromine in chloroform.

During the distillation, no appreciable absorption took place, although a small quantity of a combustible gas passed through the bromine solution. The total distillate amounted to about 600 g., the residue being a polymerised resin.

The distillate was separated by fractionation into five main portions:

B. p.	Pressure.	Wt.	B. p.	Pressure.	Wt.
1. 30—45°	760 mm.	36 g.	4. 170—20°	115 mm.	110 g.
2. 60—100	20 "	224 "	5. 210—240	15 "	65 "
3. 120—170	20 "	137 "			

Fraction 1 was refractionated at atmospheric pressure, yielding (a) 28 g., b. p. 32—40°,  $n_D^{20}$  1.3940; (b) 2 g., b. p. 55—75°,  $n_D^{20}$  1.4290; (c) 4 g., b. p. above 75°,  $n_D^{20}$  1.4615.

20 G. of (a) (which was not further divisible by fractional distillation) were dissolved in cold dry carbon disulphide and treated with a 10% solution of bromine in the same solvent until the colour of the bromine just persisted after vigorous shaking and standing. After removal of carbon disulphide, the residue was distilled, and the fraction, b. p. 80—100°/20 mm., collected (yield, 35 g.). After several fractionations, a colourless liquid was obtained as the main portion, having b. p. 65—67°/13 mm.,  $n_D^{20}$  1.5140,  $d_4^{20}$  1.6773,  $[R_L]_D$  41.29 (Found: Br, by the Carius method, 72.1.  $C_5H_{10}Br_2$  requires Br, 69.6%;  $[R_L]_D$  40.84).

In order to satisfy ourselves that under precisely similar conditions isoprene yields the tetrabromo-derivative, we brominated this hydrocarbon. The product was a heavy, yellow oil, b. p. 152—156°/12 mm.,  $n_D^{20}$  1.5978, agreeing well with previously reported values for isoprene tetrabromide (Staudinger, *Helv. Chim. Acta*, 1922, 5, 765, gives b. p. 153—155°/12 mm.). Since in the case under consideration a dibromide only was formed, it is obvious that the low-boiling distillate was either a single amylene or a mixture of isomerides.

*Oxidation of the amylene.* 9 G. were shaken with a slight excess of 2½% potassium permanganate solution (23 g.  $\text{KMnO}_4$ ). After treatment with sodium bisulphite, the solution was filtered and fractionally distilled through a long column. The first 60 c.c. of the distillate were treated with *p*-nitrophenylhydrazine in hydrochloric acid and, after 12 hours, the precipitate produced was twice crystallised from dilute aqueous alcohol; yellow crystals of acetone-*p*-nitrophenylhydrazone (m. p. and "mixed" m. p. 146°) were thus obtained.

*Fraction 3* (b. p. 120—170°/20 mm.). This was distilled at 15 mm. and separated into the following fractions: (A) b. p. 110—122°, 16 g.; (B) b. p. 122—134°, 29 g.; (C) b. p. 134—144°, 40 g.; (D) b. p. 152—162°, 26 g.; (E) viscous residue.

(A) was apparently a mixture of mono- and sesqui-terpenes ( $n_D^{20}$  1.4782,  $d_4^{20}$  0.8459). Cyclisation by boiling with 98% formic acid (30 g.) for 3 hours yielded an oil which was distilled at 25 mm. into two main fractions: (1) 5 g., b. p. 86—100°,  $d_{20}^{20}$  0.8326,  $n_D^{20}$  1.4560,  $[R_L]_D$  45.17 (calc. for  $\text{C}_{10}\text{H}_{16}$ , 45.2). (2) 8 g., b. p. 130—140°,  $n_D^{20}$  1.4850.

(1) was a colourless mobile oil with an odour closely resembling that of pinene. (2) was added to sub-fraction B, which, however, further distillation indicated to be an inseparable mixture and was not further examined.

Sub-fraction C was distilled over sodium and yielded as major portion a faintly greenish-yellow oil, b. p. 129—135°/12 mm.,  $n_D^{20}$  1.4915,  $d_{20}^{20}$  0.8734,  $d_4^{20}$  0.8716,  $[R_L]_D$  67.7 (calc. for  $\text{C}_{15}\text{H}_{24}$ , 67.8). These constants are identical with those of bisabolene (Table III) (Found: C, 87.9, 87.6; H, 11.6, 11.8. Calc. for  $\text{C}_{15}\text{H}_{24}$ : C, 88.2; H, 11.8%).

20 G. of this substance were cyclised by boiling with 98% formic acid (40 g.) for 3 hours, and the product was distilled at 21 mm. and separated into: (1) 2 g., b. p. 132—135°,  $n_D^{20}$  1.4870; (2) 1 g., b. p. 137—145°,  $n_D^{20}$  1.4912; (3) 14 g., b. p. 140—145°,  $n_D^{20}$  1.4965,  $d_{20}^{20}$  0.8994,  $[R_L]_D$  66.28 (calc. for  $\text{C}_{15}\text{H}_{24}$ , 66.1).

The main fraction would appear to be very similar to one of the hydrocarbons obtained by Ruzicka (*loc. cit.*) by treating nerolidol with formic acid, the constants for which were b. p. 114—116°/12 mm.,  $d_4^{20}$  0.9069,  $n_D^{20}$  1.4964,  $[R_L]_D$  65.82.

The whole of (3) was heated with finely-powdered sulphur (5 g.) at 200—250° until no more hydrogen sulphide or mercaptan was evolved (16 hours). The volatile products of the reaction (4 g.) were distilled in a vacuum from the large amount of resinous matter produced, repeatedly distilled over sodium until colourless, and treated with a concentrated hot alcoholic solution of picric acid. After 12 hours, the deposited red oil was redissolved in alcohol. In the solution, after several weeks, there suddenly appeared yellow laminæ of picric acid mixed with long orange needles, which were mechanically separated. These commenced to shrink at 95° and melted to a clear red liquid at 108—111° (cadalene picrate has m. p. 114—115°). Similar treatment of somewhat less highly fractionated sesquiterpene products gave, on two occasions, the same orange crystals, but sufficient pure material has not yet been collected for mixed melting-point determinations with cadalene picrate.

Sub-fraction D was a somewhat more viscous and more deeply coloured oil. The constants  $n_D^{20}$  1.4990 and  $d_4^{20}$  0.8934 and the impossibility of obtaining constant-boiling fractions on redistillation indicate that it is a mixture containing a large proportion of the next fraction.

Fraction 4 (b. p. 170—210°/15 mm.). 20 G., on fractional distillation at 9 mm., gave: (A) 8 g., b. p. 180—190°,  $d_4^{20}$  0.9073,  $n_D^{20}$  1.5082,  $[R_L]_D$  89.39 (Found: C, 87.8; H, 11.6); (B) 6 g., b. p. 190—200°,  $d_4^{20}$  0.9157,  $n_D^{20}$  1.5130,  $[R_L]_D$  88.88 (Found: C, 88.0; H, 11.7; *M*, cryoscopic in benzene, 259. Calc. for  $C_{20}H_{32}$ : C, 88.2; H, 11.8%; *M*, 272.  $C_{20}H_{32}|3$  and  $C_{20}H_{32}|4$  require  $[R_L]_D$  88.76 and 90.46, respectively).

Both (A) and (B) were greenish-brown, rather viscous, and almost odourless oils. The latter seems to be identical with the compound of molecular weight 303, obtained by Staudinger (*loc. cit.*) by the distillation of caoutchouc, and assumed by him to be  $C_{25}H_{40}|4$  (see Table IV).

Treatment of (B) with boiling formic acid for 3 hours gave an isomeride, b. p. 190—200°/9 mm.,  $d_4^{20}$  0.9258,  $n_D^{20}$  1.5090,  $[R_L]_D$  87.72 (calc. for  $C_{20}H_{32}|2$ , 87.1).

Fraction 5 was a dark-coloured, viscous oil which awaits detailed examination.

In conclusion, we desire to thank the Council of the Department of Scientific and Industrial Research for grants which have enabled this work to be carried out. We are also indebted to Professor L. Ruzicka for a specimen of cadalene picrate, to Mr. H. Rogerson for help with certain portions of the experimental work, to Dr. R. Burns of the Royal Technical College, Glasgow, for confirmatory analyses of the hydrochlorides, and to Professor J. Johnstone and Mr. R. J. Daniel for obtaining and identifying the material upon which the research has been carried out.
